The most recent threat to *G. g. gorilla* is disease, especially the Ebola virus. Since the early 1990s, Ebola has caused several massive *G. g. gorilla* die-offs in the most remote parts of the species' range (Huijbregts *et al.* 2003). These include some of the most important sites for the conservation of *G. g. gorilla*; Lopé N. P., Minkébé N. P. and Mwagné forest block in Gabon, and Odzala N. P. in NW Congo. The Ebola epizootic wave is moving eastward at ca. 45 km/year. As such, Ebola is expected to reach most of the remaining range of *G. g. gorilla* within the next decade (Walsh *et al.* 2003, 2005, Lahm *et al.* 2006). Ebola causes ca. 95% mortality within populations of *G. g. gorilla* (Bermejo *et al.* 2006, Caillaud *et al.* 2006). A conservative estimate is that ca. 33% of the total protected area population of *G. g. gorilla* has been killed by Ebola over the past 13–14 years. In short, since the early 1980s, hunting for the commercial bushmeat trade and outbreaks of Ebola virus have largely eliminated *G. gorilla* from vast areas of intact forest and caused a rapid decline in numbers elsewhere.

While it is hoped that the sites mentioned above that have been affected by commercial hunting and Ebola will eventually recover (Ryan & Walsh 2011), there remain a few strongholds that have yet to be much affected by hunting and where Ebola has not as yet reached. Among these are the Sangha Trinational Complex of Central African Republic, Cameroon and Congo, the Lac Tété/Likouala complex in Congo, the Dja Conservation Complex and Boumba-Bek/Nki Complex in Cameroon, and the Loango/Moukalaba-Doudou/Gamba Complex in Gabon (Tutin *et al.* 2005). Tourism based on

gorilla-viewing is increasing within the range of *G. gorilla*, but this activity needs to be carefully implemented and closely monitored (Klailova *et al.* 2010, Macfie & Williamson 2010).

Since 2000, *G. g. diehli* has been ranked as one of the world's most threatened primates (Sunderland-Groves *et al.* 2007, Nicholas *et al.* 2009). Most of the surviving 250–300 *G. g. diehli* are in 11 small subpopulations occasionally linked by immigration (Bergl & Vigilant 2007), and most are outside of protected areas and engulfed by a dense human population. Thus, this subspecies is at risk from inbreeding, various human activities (e.g. hunting and habitat loss) and disease. In Nigeria, *G. g. diehli* occurs in the Okwangwo Division of Cross River N. P. and Afi Mountains Wildlife Sanctuary, but fragmentation, degradation and loss of habitat to agriculture continue at a rapid rate, even within the Cross River N. P. In Cameroon, *G. g. diehli* occurs in the Kagwene Gorilla Sanctuary and in the 'proposed' Takamanda N. P. All four of these sites, additional sites and connecting lowland sites, need to be protected and effectively managed if *G. g. diehli* is to survive over the long term (Oates *et al.* 2003, 2007, Sunderland-Groves *et al.* 2007, Nicholas *et al.* 2009, Bergl *et al.* 2011). (See also Thalman *et al.* 2012.)

Measurements

Gorilla gorilla

Standing ht (♂ ♂): 1670 (1380–1760) mm, n = 25

Girth (♂ ♂): 1430 (1320–1690) mm, n = 19

Arm span (♂ ♂): 234 (202–272) mm, n = 17

Arm length (♂ ♂): 1120 mm, n = 8*

Leg length (♂ ♂): 770 mm, n = 8*

Napier & Napier (1967), after Groves (1970)

*Range not given

HB (♂ ♂): (1030–1070) mm, n = 3

HB (♀ ♀): n.d.

T (both sexes): 0 mm

HF (♂ ♂): (289–312) mm, n = 3

HF (♀ ♀): n.d.

E (♂ ♂): (56–60) mm, n = 3

E (♀ ♀): n.d.

WT (♂ ♂): 168 (145–191) kg, n = 11

WT (♀ ♀): 63 (58–72) kg, n = 3

GLS (♂ ♂): 299 (259–340) mm, n = 264

GLS (♀ ♀): 232 (206–264) mm, n = 170

GWS (♂ ♂): 178 (155–201) mm, n = 259

GWS (♀ ♀): 147 (132–173) mm, n = 166

Measurements from various localities (C. P. Groves pers. comm.).

G. g. gorilla and *G. g. diehli*: for various long bone, hand bone, foot bone, vertebral, cranial, facial, and dental measurements and indices, see Sarmiento *et al.* (1996) and Sarmiento & Oates (2000).

Gorilla beringei EASTERN GORILLA

Fr. Gorille de l'Est; Ger. Östlicher Gorilla

Gorilla beringei Matschie, 1903. Sitzb. Ges. Naturf. Fr. Berlin, 257. Mt Sabinyo, Rwanda.

Mountain Gorilla *Gorilla beringei beringei* adult male.

Taxonomy Polytypic species. The history of gorilla taxonomy is a long and complicated one, and is covered in detail by Groves (1966). As early as 1961, Vogel resurrected *beringei* to full species status and put forth a taxonomy in which there are two species of gorilla (Western Gorilla *Gorilla gorilla* of western central Africa and the Eastern Gorilla *Gorilla beringei* of eastern central Africa), and two subspecies (Mountain Gorilla *G. b. beringei* and Grauer's [= Eastern Lowland] Gorilla *G. b. graueri*). None the less, until the mid-1990s, Vogel's (1961) taxonomy was largely ignored in favour of a one species, three subspecies taxonomy: *G. g. gorilla*, *G. g. beringei* and *G. g. graueri* (Groves 1966, 1970, 1986, Dandelot 1974, Jenkins 1990, Kingdon 1997). *Gorilla g. gorilla* is separated from *G. b. beringei* and *G. b. graueri* by ca. 900 km of lowland forest. Since the early 1990s, mitochondrial DNA sequence data (but not the nuclear DNA sequence data; Jensen-Seaman 2000) have emerged that indicate that genetic differences between gorillas living in these two regions are slightly greater than the differences between the Robust Chimpanzee *Pan troglodytes* and the Gracile Chimpanzee (= Bonobo) *Pan paniscus*, and that the difference approaches the level of genetic divergence exhibited between *Pan* and *Homo* (Morell 1994, Ruvolo *et al.* 1994, Garner & Ryder 1996, Uchida 1996, Ryder *et al.* 1999). The genetic distance, together with a number of newly identified ecological, behavioural and morphological differences (e.g. lower molar size

differences; Uchida 1998), suggest more diversity among gorillas than can be accommodated by a single species taxonomy; but, crucially, many of these differences appear to be fixed in the genetic sense, i.e. the two species are diagnosably different as required by the Phylogenetic Species Concept. As such, Vogel's (1961) taxonomy has been resurrected and is the currently accepted view (Ruvolo *et al.* 1994, Groves 1996, 2001, 2005c, Sarmiento & Butynski 1996, Ryder *et al.* 1999, Grubb *et al.* 2003). Molecular research suggests that *G. b. beringei* and *G. b. graueri* diverged ca. 400,000 years ago (Vigilant & Bradley 2004).

Gorillas of Bwindi Impenetrable N. P., SW Uganda, are often referred to as 'Mountain Gorillas', but their taxonomy remains uncertain (Groves 1966, 2001, Jenkins 1990, Sarmiento & Butynski 1996, Sarmiento *et al.* 1996, Kingdon 1997, Sarmiento 2000, Grubb *et al.* 2003, Ferriss *et al.* 2005). As such, in this profile, the gorillas of this population are referred to as 'Bwindi Gorillas' *G. beringei* ssp.?

Synonyms: *beringeri* (*lapsus*), *graueri*, *manyema* (*lapsus*), *mikenensis*, *rex-pygmaeorum*. Chromosome number: $2n = 48$ (Mai 1983).

Description Very large (adult ♂♂ >155 kg, adult ♀♀ >80 kg), small-eared, tailless, black, mostly terrestrial primate. Well-developed supraorbital ridges. Nostrils large. Nasal openings nearer to mouth than to orbits. Eyes small, flat, dark brown. Ears relatively small, black or brown. Bare skin of face, hands and feet black. Bare skin of chest, grey or black. Length, colour and distribution of hair variable. In general, individuals living at higher altitudes have longer hair than those living at lower altitudes. Pelage typically (dull or shiny) black, but sometimes with brown or reddish tint. Schaller (1963) describes one adult ♀ with a brown crown, one with a brown rump and one with brown hair between the breasts. Pelage becomes increasingly greyish-silver with age in both sexes, but especially in ♂♂. Pelage shortest on back and longest on arms, reaching 200 mm in some adult ♂♂ (Schaller 1963).

Adult: Adult ♂♂ older than 12 years are especially large, have well-developed sagittal crest and completely greyish-silver 'saddle' on the back (i.e. 'silverback'). Old ♂♂ completely greyish-silver except for the arms, which remain black (Schaller 1963). Adult ♀♀ about half the weight of adult ♂♂ and lack a well-developed sagittal crest.

Infant: Skin at birth pinkish-grey or medium-brown becoming dark brown or black by ca. 1.5 months. Newborns with soft, black, relatively sparse hair on head, dorsum and outside of arms and legs, while rest of the body essentially bare. Hair growth increases at ca. 2 months. Ventrums covered with hair at 3 months. Pelage of inside of forearms and inside of legs sparse until 6–7 months. Rump with white (pygal) tuft of hair at birth that persists until >4 years of age. Crown becomes brown at ca. 1.5–2.5 months and then black again by 8–9 months (Schaller 1963).

Geographic Variation

G. b. beringei Mountain Gorilla. Virunga Mts. Hair longer, tending towards jet black or bluish-black, rarely with brownish or reddish tones. Pelage on crown longer, shaggier. Face wider. Nostrils more ovate and angular, strongly outlined above and well defined. Upper lip (alae) weakly padded. Cranial height longer. Facial height and palate breadth of ♂ shorter. Hallux longer. Humerus

Mountain Gorilla *Gorilla beringei beringei* adult male skull.

shorter. Clavicle longer. Scapula with vertebral border pulled outward at root of scapular spine, sinuous (Groves 1966, 2001, Jenkins 1990). Although it is often stated that *G. b. beringei* is larger than *G. b. graueri*, the available data on body size do not support this.

G. b. graueri Grauer's Gorilla. West of the Western Rift Valley. Hair, shorter, black, often with brownish or reddish tones. Pelage on crown shorter, less shaggy. Face narrower. Nostrils rounded, not strongly outlined above. Upper lip (alae) strongly padded. Cranial height shorter. Facial height and palate breadth of ♂ longer. Hallux shorter. Humerus longer. Clavicle shorter. Scapula with vertebral border relatively straight, not sinuous (Groves 1966, 2001, Jenkins 1990).

G. b. ssp.? Bwindi Gorilla: known only from Bwindi Impenetrable N. P. with a few individuals entering Sarambwe Forest across the border in DR Congo (see below). See Sarmiento *et al.* (1996) for details of morphology.

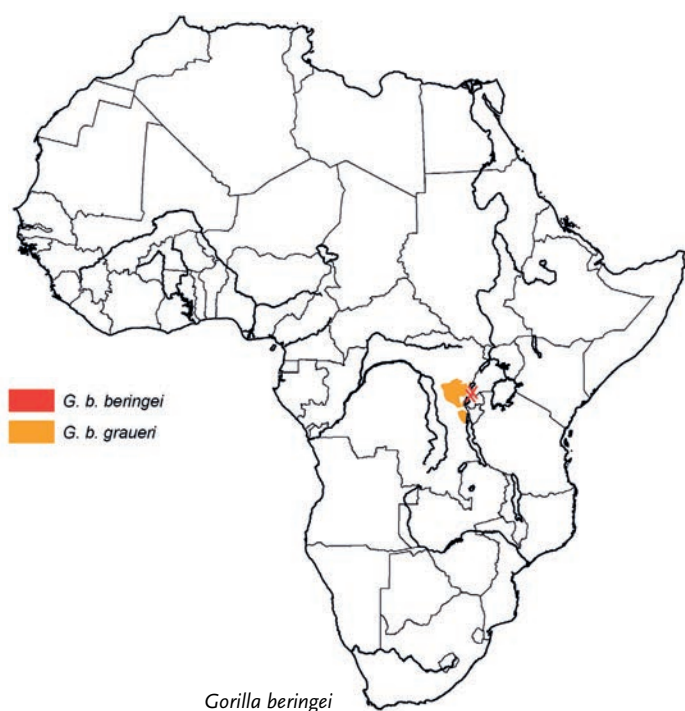

Similar Species

Pan troglodytes. Sympatric below ca. 2300 m. Smaller (adult ♂♂ <55 kg). Ears relatively large. Sagittal crest absent or weakly developed in adult ♂♂. Nasal openings nearer to mouth than to mouth.

Distribution Endemic to extreme NW Rwanda, extreme SW Uganda and E DR Congo; Rainforest and Afromontane–Afroalpine BZs. *Gorilla b. beringei* restricted to one population in the Virunga Mts, where the borders of Uganda, Rwanda and DR Congo meet (Sholley 1991). This subspecies/population occupies an area of 447 km² (Owiunji *et al.* 2005), previously given as 375 km², within an altitude range of 1850–4100 m, but typically <3800 m (Harcourt & Fossey 1981, Vedder & Weber 1990, Butynski 2001, Ferriss *et al.* 2005).

Bwindi Gorillas occupy an area of ca. 215 km² within the Bwindi Impenetrable N. P. and range in altitude from ca. 1400 to 2500 m (IGCP/M. Gray pers. comm.). A small number of Bwindi Gorillas cross the Uganda–DR Congo border to enter the Sarambwe Forest, but no Bwindi Gorillas are resident there. Bwindi Impenetrable N. P. is ca. 25 km to the north of the Virunga Mts, with the intervening area densely settled by people (>300 people/km²) and intensively cultivated.

Gorilla b. graueri has a discontinuous distribution in eastern DR Congo from the Lualaba R. eastward to the Western Rift. Its

northern limit is the headwaters of the Lindi (= Ulindi) R. and the Mitumba Mts (Mt Tshiaberimu) off the north-west corner of L. Edward. Its southern limit is the Itombwe Mts off the north-west corner of L. Tanganyika (Hall *et al.* 1998a, Butynski 2001). *Gorilla b. graueri* is endemic to DR Congo (unless the Bwindi Gorilla is of this subspecies). Subspecific status of some other gorilla populations generally referred to as *G. b. graueri* remains equivocal, such as the population on Mt Tshiaberimu to the north-east of L. Edward (Groves & Stott 1979, Sarmiento & Butynski 1996). *Gorilla b. graueri* ranges in altitude from 600 to 2900 m (Ferriss *et al.* 2005) and has a geographic range of roughly 112,000 km² (Butynski 2001). In 1963 the area occupied was ca. 21,000 km² but declined greatly over the subsequent 35 years to ca. 15,000 km² in the early 1990s (Hall *et al.* 1998a). For *G. b. graueri*, the area occupied is roughly 13% of the geographic range, reflecting the subspecies' current highly fragmented distribution.

In 1908 three gorilla skulls were obtained from local people at Bili (near Bondo) on the right bank of the Uele R. ca. 500 km north-north-west of the nearest present-day known distribution for *G. beringei*. It is not known whether these skulls originated from this locality or were carried there (Schaller 1963, Groves 1966) from distant populations to the west or east. Surveys in the Bondo region over the past decade have failed to locate any gorillas. Whether these skulls are those of *G. beringei* or of *G. gorilla* remains unclear at this time (Groves 1966, 2001).

Habitat Primary and secondary lowland, mid-altitude (= transition), montane and bamboo forests, as well as afromontane vegetation (Schaller 1963, Butynski 1984, Harcourt 1996, Sarmiento *et al.* 1996, Ferriss *et al.* 2005). Altitude limits ca. 600–4100 m. In the Virunga Mts, *G. b. beringei* makes frequent use of *Hagenia abyssinica* and *Hypericum revolutum* woodland where the canopy is open and there is a dense, tall, herbaceous ground layer in which *Galium* climber *Galium ruwenzoriense*, Wild Celery *Peucedanum linderi*, Thistle

Carduus nyassanus, Nettle *Laportea alatis*, Stinging Nettle *Urtica massaica*, *Rubus* spp., *Mikania chenopodiifolia* and *Mimulopsis excellens* are often abundant. Bamboo *Sinarundinaria alpina* covers large areas, either in monodominant stands or mixed with widely scattered trees, often *Podocarpus latifolius* and *H. abyssinica*. The montane forest is comprised largely of the trees *H. abyssinica*, *P. latifolius*, *Morella salicifolia*, *Prunus africana*, *Myrsine melanophloeos*, *Ilex mitis*, *Nuxia congesta*, *Agarista salicifolia*, *Pittosporum spathicalyx*, *Bersama abyssinica*, *Xymalos monospora*, *Dombeya torrida*, *Croton macrostachyus*, *Neoboutonia macrocalyx* and *Maesa lanceolata*.

In the Bwindi Impenetrable N. P., as well as over much of the range of *G. b. graueri* to the west of the Western Rift, some of the more common emergent (21–>37 m) tree species are *P. latifolius*, *Prunus africana*, *Parinari excelsa*, *Newtonia buchananii*, *Entandrophragma excelsum*, *Chrysophyllum gorungosanum* and *Symphonia globulifera*. The more common middle stratum (9–21 m) tree species include *C. macrostachyus*, *N. macrocalyx*, *Albizia gummifera*, *Carapa procera*, *Faurea saligna*, *Harungana madagascariensis*, *Macaranga capensis kilimandscharica*, *Olea capensis* ssp. *macrocarpa*, *Polyscias fulva*, *Strombosia scheffleri* and *Syzygium guineense*. The following are among the more common understorey (<9 m) trees: *Alchornea hirtella*, *Cyathea manniana*, *Myrianthus holstii*, *Tabernaemontana pachysiphon*, *Vepris nobilis*, *Galiniera saxifraga*, *Musanga leo-errerae*, *Xymalos monospora*, *Maesopsis eminii* and *Vernonia* spp. The more common species of vines, herbs, shrubs and ferns in the ground layer are often Bracken Fern *Pteridium aquilinum*, *Mimulopsis arborescens*, *Smilax anceps*, *Urera hypselodendron*, *Piper capense*, *Brillantaisia* spp., *Aframomum* spp., *Impatiens* spp., *Palisota* spp. and *Laportea* spp.

Mean annual rainfall over the range of *G. beringei* is ca. 1500–2500 mm, perhaps reaching 3000 mm at the highest altitude used by *G. beringei* on Mt Kahuzi. Temperatures range from ca. –4 °C to ca. 32 °C.

Abundance In 1989 there were ca. 324 *G. b. beringei* in the Virunga Mts (Sholley 1991). A 2000 census of this population led to an estimate of 359–395 individuals (Kalpers *et al.* 2003), while a 2003 census estimated 380 individuals (Gray *et al.* 2009). A census, conducted in 2010, yielded an estimate of 480 individuals (Gray *et al.* 2011).

Bwindi Gorillas numbered ca. 300 individuals during the early 1990s (Butynski & Kalina 1998, Butynski 2001) and in 1997 (McNeilage *et al.* 2001). A census in 2002 resulted in an estimate of 320 individuals (McNeilage *et al.* 2006), while a 2006 census found ca. 300 gorillas (Guschanski *et al.* 2009).

Surveys conducted from 1989 to 1995 indicate that there were about 16,900 *G. b. graueri* (8660–25,500) in at least 11 populations. Roughly 86% of these lived in the Kahuzi-Biega N. P. – Kasese region. Approximately two-thirds are within the Kahuzi-Biega N. P. and Maiko N. P. (Hall *et al.* 1998a, b). There is concern that there has been a substantial decline in the number of *G. b. graueri* as a result of poaching related to coltan ore mining and of the warfare that has engulfed the whole of the range of *G. b. graueri* from the late 1990s until the present (Ferriss *et al.* 2005).

The above surveys indicated that the total number of *G. beringei* is roughly 17,500 individuals. Of the ca. 17,500 *G. beringei*, roughly 96% are *G. b. graueri*, 2% are *G. b. beringei* and 2% are Bwindi Gorillas. *Gorilla beringei* is, by far, the rarest of Africa's four species of great ape (Butynski 2001, Caldecott & Miles 2005).

The density of *G. b. beringei* in the Virunga Mts was ca. 1.0 ind/km² in 2003 (Kalpers *et al.* 2003) and ca. 1.3 ind/km² in 2010 (Gray *et al.* 2011). The density of the Bwindi Gorilla in the Bwindi Impenetrable N. P. is ca. 1.4 ind/km² (Butynski 2001, McNeilage *et al.* 2001, 2006, Guschanski *et al.* 2009).

Adaptations Diurnal and semi-terrestrial. *Gorilla beringei* deposits large amounts of fibrous dung on leaving the nests to begin feeding soon after sunrise. Animals spend ca. 50% of daylight hours feeding and the remainder resting (Watts 1988). During heavy or persistent rain the gorillas stop eating and seek shelter in dense vegetation or under fallen tree trunks. The long, dense pelage effectively sheds rain. Predominant mode of adult locomotion is knuckle-walking quadrupedalism (Doran 1997b), for which the forearm and hand are modified (Tuttle & Watts 1985). *Gorilla b. beringei* has shorter arms and less divergent big toes than *G. g. gorilla*, but terrestriality is not obligate (Remis 1998); modified brachiators (Napier 1963) with broad scapulae and relatively short phalanges and metacarpals, but only 3% of daily activity of *G. b. beringei* takes place in trees (Tuttle & Watts 1985). Age-class differences are apparent in suspensory behaviour: adult ♂♂ spend 2% of time above ground, adult ♀♀ 7%, juveniles 13% (Doran 1997b).

Gorilla b. beringei is adapted to high altitude where temperatures drop below freezing at night: thick, black hair and large body retain heat; extremities (ears, hands, feet, penis) are small so heat loss is reduced. The wide nostrils allow the animal to breathe more easily at high altitude (Dixson 1981).

Gorillas have a generalized hominoid morphology (Shea 1983) and physiology (Chivers & Hladik 1984) but show craniodental and gastrointestinal specializations associated with an herbivorous diet. A highly developed sagittal crest in ♂♂ indicates a powerful jaw musculature for crushing. The high crested molar surfaces and narrow central incisors are adaptations for shearing leaves (Groves 1986, Uchida 1996). *Gorilla b. beringei* has a wide mandibular corpus and symphysis, a large area for masseter attachment, with incisor–molar and cusp area proportions adapted for feeding on fibrous vegetation (Taylor 1997, Uchida 1998). These features are more pronounced in *G. b. beringei* than in *G. b. graueri* (Uchida 1996).

The stomach is simple and non-fermenting. The relatively long small intestine and enlarged hindgut (Caton 1999) enable *G. beringei* to subsist on a bulky diet high in structural carbohydrates (Watts 1996). The caecum is small with a vermiform appendix and the colon is complex with specialized fermentation chambers. Together, the caecum and colon provide a large surface area for absorption of nutrients (Chivers & Hladik 1980). Large body size and long gut retention times also facilitate digestion of fibre (Remis 2000). *Gorilla beringei* tolerates high levels of fibre, total phenols and condensed tannins in food (Waterman *et al.* 1983).

Gorilla beringei does not use tools, relying on physical strength to tear apart food items. These gorillas do, however, learn complex techniques for gathering food with bimanual coordination of the hands. Many foods with stings (e.g. nettles) or spines are processed in a sequence of precision movements (Byrne & Byrne 1993).

Adult ♂♂ have laryngeal air sacs in the chest cavity that produce resonance when the chest is beaten with open palms of the hands (Schaller 1963, Dixson 1981).

Like all great apes, *G. beringei* builds a nest in which to sleep at night by bending or breaking vegetation (twigs and branches of

trees, and stems of herbs and grasses, including bamboo). Many different species of plants are used for nest construction. There have been numerous studies of nest-building: *G. b. beringei* almost always nests on the ground (Kabara, DR Congo 97% ground nests, n = 2488, Schaller 1963). *Gorilla b. graueri* in the highlands also nests mostly on the ground (88%, n = 3547), but in the lowlands, 40% of nests (n = 375) are found in trees (Yamagiwa 2001). Much of this difference in the use of trees as nest sites may have to do with the fact that tree density is many times higher in the lowlands than in the highlands. Lighter-bodied individuals nest at greater average heights: immatures 15 m above ground, adult ♀♀ 12 m, compared to adult ♂♂, 4 m (Yamagiwa 2001). Variation in nest structure correlates with habitat type, but there is no significant difference in the proportion of tree to ground nests between wet and dry seasons (Yamagiwa 2001). Day nests are resting places moulded between bouts of feeding. These are simpler and less flattened than night nests, since they are used for shorter periods (Schaller 1963). *Gorilla b. beringei* feeds for the first few hours of the morning, then takes leisurely rest periods in the middle of the day (Harcourt 1978, Fossey 1983).

Foraging and Food Herbivorous. Upon rising from their night nests, gorillas spread out to forage. Animals sit on their haunches, or eat while walking (travel-feed). *Gorilla b. beringei* is terrestrial for 96% of feeding time (Watts 1984). Adults climb for only 4% of feeding time, immatures feed in trees 18% of the time (Fossey & Harcourt 1977). Adult ♂♂ eat ca. 30 kg of vegetation per day. There is little competition between individuals, as food is generally abundant. *Gorilla b. beringei* is a selective eater, choosing specific plant parts and often foraging on rare species (Vedder 1984, Watts 1984). The diet is high in protein (3.5–25.38% dry weight) and low in acid detergent fibre and condensed tannins (Waterman *et al.* 1983).

There is considerable variation between and within the diets of the various populations of *G. beringei* (Yamagiwa *et al.* 2003, Ganas *et al.* 2004). Diets consist of young and mature leaves, stems, fruits, seeds, bark, pith, wood and insects (Yamagiwa *et al.* 1994, Stanford & Nkurunungi 2003, Ganas *et al.* 2004). *Gorilla b. beringei* is more folivorous than *G. b. graueri*. In the Virunga Mts, herbaceous foods are abundant and ubiquitous, predominantly leaves and stems (93% food intake). Here >75% of diet is comprised of three species: *G. ruwenzoriense*, *P. linderi* and *C. nyassanus* (Watts 1984). Bamboo shoots, a highland food (above ca. 2300 m), are a seasonal, highly preferred, food that is eaten when available, sometimes comprising as much as 90% of the diet (Casimir & Butenandt 1973, Vedder 1984). Highland populations of *G. b. graueri* also eat large quantities of the basal parts of the sedge *Cyperus latifolius* (Casimir 1975).

Diversity of the plant diet increases with decreasing altitude as the plant diversity of the habitat increases. Lowest number of species consumed was recorded for *G. b. beringei* in Rwanda (62 species; Watts 1996), and highest for Bwindi Gorillas at Buhoma (140 species; Ganas *et al.* 2004). *Gorilla b. graueri* is intermediate, with many more species eaten in the lowlands than in the highlands of Kahuzi-Biega N. P. (121 species vs. 79 species; Yamagiwa *et al.* 2003). Fruit availability is also inversely correlated with altitude and reflected in gorillas' degree of frugivory (Goldsmith 2003, Ganas *et al.* 2004). Fruit consumption by *G. b. beringei* is negligible due to lack of suitable fruit in the environment (Vedder 1984, Watts 1984,

McNeillage 2001). *Gorilla b. graueri* feeds on more species of fruit than sympatric *P. troglodytes* (Yamagiwa *et al.* 2003). Fruit remains are present in 89–96% of faecal samples. Fruit accounts for 25% of food species in highlands, 40% in lowlands (Yamagiwa 2004). Diet of Bwindi Gorillas is more similar to *G. b. graueri* than to *G. b. beringei*, due to greater overlap in food availability (Robbins *et al.* 2006). Fruit remains are found in 66–82% of faecal samples, forming ca. 26% of species in the diet (Ganas *et al.* 2004). By volume, fruit accounts for ca. 25% of diet; the most important species is *M. holstii* (seeds found in 20% of faecal samples; Stanford & Nkurunungi 2003). Fruit is eaten on 60–80% of days (Robbins & McNeillage 2003, Ganas *et al.* 2004).

Gorilla b. beringei diet changes little during the year (Watts 1998c). Only bamboo shoots are limited by season (Casimir & Butenandt 1973, Vedder 1984). Seasonality of diet increases as altitude declines (Yamagiwa *et al.* 1994, Nkurunungi *et al.* 2004, Robbins & McNeillage 2003). Fruit intake correlates with availability (Stanford & Nkurunungi 2003), and varies interannually (Robbins *et al.* 2006). *Gorilla b. graueri* and Bwindi Gorillas rely on fibrous items as fallback foods, which are always available, but eaten only when is fruit scarce (Ganas *et al.* 2004). All subspecies of *G. beringei* consume insects. *Gorilla b. beringei* does so rarely as ant availability decreases with increasing altitude (Watts 1989a). *Gorilla b. graueri* in the lowlands consumes ants and termites frequently (ants in 37% of faecal samples, $n = 171$; Yamagiwa *et al.* 1991). There are few sex or age differences in the diets of *G. beringei*, but in Bwindi Gorillas smaller individuals are more insectivorous (2% of faecal samples from adult ♂♂ contain ants, compared to 13% adult ♀♀, 11% juveniles, Ganas & Robbins 2004). Individuals in some groups ingest earth a few times a year (Mahaney *et al.* 1990). Geophagy coincides with feeding on plants containing high levels of toxins (Mahaney *et al.* 1995). *Gorilla b. beringei* also eats dung (Harcourt & Stewart 1978). The functions of coprophagy are unclear, but adult ♀♀ and juveniles sometimes compete for the dung of adult ♂♂ (E. A. Williamson pers. obs.).

Gorilla beringei subspecies move ca. 1 km each day, but differences are known. Daily travel distances are greater in lowland than in highland areas. *Gorilla b. beringei* is surrounded by food, so travels ca. 570 m/day (range 190–3000 m, $n = 116$; Watts 1991b). Mean day range for *G. b. graueri* in the highlands is ca. 851 m (range 239–3570 m, $n = 225$) but these gorillas travel farther in the lowlands in search of fruit (mean = 1531 m, range 142–3439 m, $n = 8$; Yamagiwa *et al.* 2003). Bwindi Gorilla groups travel ca. 716 m/day (range 242–2055 m, $n = 109$; Stanford & Nkurunungi 2003).

Gorilla beringei home-range size varies widely. *Gorilla b. beringei* range is smallest as herbaceous food densities are exceptionally high (annual home-range 3.1–33.8 km², $n = 11$ groups; McNeillage 1995, Watts 1998b, IGCP/M. Gray pers. comm.). *Gorilla b. graueri* in the lowlands requires a larger area than in the highland sector but size of home-range is unknown (Yamagiwa *et al.* 2003). Estimates for the highlands vary widely: 23–31 km² ($n = 1$ group; Casimir & Goodall cited in Yamagiwa 1999) to 13–17 km² ($n = 1$ group; mean = 14.1 km²; Yamagiwa *et al.* 2003). Total area used over eight years was 42.2 km². Bwindi Gorilla home-ranges are comparable to *G. b. graueri* and *G. g. gorilla*: annual home-range 16–28 km² (mean = 22 km², 45.5 km² for 6 years, $n = 1$ group; Robbins *et al.* 2006). *Gorilla b. beringei* group home-ranges overlap 24–72% ($n = 6$ groups;

Watts 1998b). Overlap is similarly ‘extensive’ for *G. b. graueri* and Bwindi Gorilla (Yamagiwa *et al.* 2003, Ganas & Robbins 2005). Availability of particular foods influences ranging even where food is abundant (Casimir & Butenandt 1973, Vedder 1984, Watts 1998b). *Gorilla b. beringei* shows no seasonal patterns of range use except for increased time spent in the bamboo zone when shoots are present (Vedder 1984, Watts 1998c). *Gorilla b. graueri* increases travel to access preferred fruits, and increases range during the dry season (Yamagiwa *et al.* 1996). The limited distribution of bamboo causes seasonal shifts in ranging (Casimir & Butenandt 1973). Ranging patterns are also influenced by social factors such as inter-group encounters, mate-searching and acquisition of group members. Mate competition has a strong short-term effect (Watts 1998c), at times concealing the influence of ecological factors. Home-ranges of solitary ♂♂ are larger than would be necessary to meet nutritional requirements as they follow groups in attempts to acquire ♀♀ (Yamagiwa 1986, Watts 1994). Groups also range farther after interactions with other social units, and aggressive encounters can cause abrupt shifts in range (Watts 1998c).

Social and Reproductive Behaviour *Gorilla beringei* is social and lives in stable, cohesive, polygynous groups composed of several ♀♀, their offspring and at least one adult ♂ (i.e. ‘silverback’). Groups are one-male, multimale or non-reproductive (containing no adult ♀♀). Multimale groups in the Virunga Mts, exceptionally, have up to eight adult ♂♂. Some adult ♂♂, but no ♀♀, become solitary.

Gorilla beringei group sizes range from 2 to >50 individuals with a mean of roughly 10 (*G. b. beringei*: mean 12.5, median 10.5, 2–47, $n = 36$ [Gray *et al.* 2011]; *G. b. graueri* highlands: mean 9.7, 2–36, $n = 25$ [Inogwabini *et al.* 2000]; *G. b. graueri* lowlands: mean 6.8, 2–31, $n = 41$ [calculated from Hall *et al.* 1998b]. See also Amsini *et al.* (2008) and Hart *et al.* (2007). Bwindi Gorilla: mean 11.3, 3–25, $n = 27$ [McNeillage *et al.* 2006]). In the Virungas, habituated groups are larger than unhabituated groups (14.5 vs. 8.4, Gray *et al.* 2011). One *G. b. graueri* group with >40 individuals (Yamagiwa 1983), one *G. b. beringei* group with >50 individuals (Gray *et al.* 2010) and one Bwindi Gorilla group with >32 individuals (T. Butynski pers. obs.). Polygynous *G. b. graueri* groups sometimes fission temporarily into subgroups and nest apart, each subgroup with at least one adult ♂ (Yamagiwa 2001). Subgrouping is most frequent during fruiting seasons (Yamagiwa *et al.* 2003).

Typical *G. b. beringei* group composition is one adult ♂, five adult ♀♀, and their offspring (Harcourt & Stewart 2007b). Multimale groups form when maturing ♂♂ remain in their natal group. Both *G. b. beringei* and Bwindi Gorillas have a significant proportion of multimale groups (*G. b. beringei* 36% [Gray *et al.* 2010]; Bwindi Gorillas 44% in 2002 [McNeillage *et al.* 2006] compared to *G. b. graueri* ca. 10% [Yamagiwa *et al.* 2003, 2009, 2012]). One adult ♂ dominates the ♂ hierarchy. Adult ♀♀ are ‘dispersal-egalitarian’, forming neither hierarchies nor coalitions (Sterck *et al.* 1997). Affiliative behaviour between adult ♂♂ is rare. Competition among adult ♂♂ is intense and aggression between ♂♂ is likely when ♀♀ are in oestrus (Harcourt *et al.* 1980). Most intra-group aggression is between adult ♀♀, and is usually limited to aggressive vocalizations. Rarely does aggression between adult ♀♀ escalate beyond screaming as adult ♂♂ intervene to end disputes. Interactions between adult ♂♂ and

Bwindi Gorillas *Gorilla beringei* ssp. resting.

adult ♀♀ are limited to interventions, exchanges of vocalizations, aggressive displays by ♂♂ towards ♀♀, and appeasement behaviour by subordinates. Most affiliative behaviour is between related ♀♀, who maintain close proximity and groom each other.

Grooming is a common intra-group behaviour in Mountain Gorillas. Most grooming is between mothers and offspring, but is also extended, in reducing frequency, to maternal relatives, paternal relatives and unrelated individuals. Juveniles groom each other and also groom the dominant ♂; adult ♀♀ are known to groom dominant ♂♂, and adolescent ♂♂ sometimes groom adult ♀♀ (Schaller 1963, Harcourt 1979a, b, Fossey 1983, Watts & Pusey 1993, Fletcher 1994). Grooming almost certainly serves a social purpose in terms of reinforcing such bonds as exist between individuals, but is ultimately related to the removal of ectoparasites, dry skin flakes and vegetation.

Gorilla beringei ♂♂ and ♀♀ are both philopatric, but most emigrate from their natal group (Robbins 1995, Watts 2000a). Some ♀♀ are known to reproduce within their natal group (31%, $n = 29$) and many reproduce in more than one group (56%, $n = 27$; Watts 1996). Half of *G. b. beringei* and most *G. b. graueri* ♂♂ emigrate from their natal group by age 15 years (range 9.6–14.4, $n = 6$; Robbins 1995, Yamagiwa & Kahekwa 2001). Maturing ♂♂ who emigrate either spend time in an all-male group, or remain solitary and attempt to attract ♀♀. Solitaries, however, are rarely successful at establishing groups (Robbins 1995, Watts 2000a, E. A. Williamson pers. obs.). Adult ♂♂ in multimale groups are often related, and subordinate ♂♂ in these groups sire a small proportion of offspring (Bradley *et al.* 2005, Yamagiwa *et al.* 2012).

Adult social bonds are strongest between ♀♀ and ♂♂. Most ♀♀ are unrelated and do not associate regularly with each other (Watts 1996). Adult ♀♀ associate with adult ♂♂ as a means to avoid infanticide by extra-group ♂♂ (Watts 1989b, Yamagiwa *et al.* 2009, 2012). Most infanticides occur when a mother is not

accompanied by an adult ♂ (Watts 1989b). Infanticide shortens the time for mothers to become fertile again and accounts for 26% of infant deaths ($n = 19$; Robbins & Robbins 2004). Multimale groups are more stable; if the dominant ♂ in a multimale group dies, a subordinate takes over and the group remains intact (Robbins 1995). Habituated groups of *G. b. beringei* are almost all multimale (Kalpers *et al.* 2003).

Copulation is initiated by both sexes. Females initiate 63% by approaching, staring and reaching towards the ♂. Males initiate through approach, display and 'train-grunt' vocalization (Watts 1991a). Copulations are brief (median = 80 sec, range 30–310 sec, $n = 251$; Watts 1991a). Dominant ♂♂ perform most copulations. Subordinate ♂♂ also mate but are often harassed by a dominant adult ♂. Newborns cling to the mother's hair, suckle and are carried ventrally. Infants are highly dependent on their mothers at birth and unlikely to survive if orphaned before three years of age. During the first few months, infants have a white tail tuft and travel in a ventro-ventral position. Travel on the mother's back (dorsal ride) starts at 1–2 months and climbing at 6–12 months (Fossey 1979). From ca. six months infants spend increasing amounts of time away from the mother (Fletcher 2001). Play begins when the infant is ca. nine months old, peaks during juvenility and decreases during adolescence (Fletcher 1994). Infants manipulate vegetation at eight months, build clumsy nests by 18 months, but sleep in the mother's nest until age three years (Fossey 1979). They become independent at 3.5–4 years, eating solid food and building their own nests. By four years their locomotion is roughly adult (Tuttle & Watts 1985).

The dominant ♂ has a protective role, defending ♀♀ and offspring from other adult ♂♂ and predators with intimidating displays (Schaller 1963). Immatures are attracted to the dominant ♂ as the group's focal point during both feeding and resting periods (Stewart 2001). As time spent near the mother decreases in late infancy, time spent in proximity to the dominant ♂ increases. Adult ♂ frequently intervenes during aggressive conflicts between immatures, which serves to protect immatures from high levels of aggression (Watts 1997, Stewart 2001).

More than 16 *G. b. beringei* vocalizations have been identified. The vocal repertoire and sound production within groups is dominated by adult ♂♂ (92% of all vocalizations; Marler & Tenaza 1977). When encountering another group, adult ♂♂ convey alarm or threat by barks, roars and screams, usually accompanied by displays (Schaller 1963, Fossey 1972). Over half of within-group vocalizations are exchanges with neighbours (Harcourt & Stewart 2001). When *G. b. beringei* feeds, individuals disperse and often cannot see each other in the dense vegetation. At such times they emit belch vocalizations to maintain contact within the group, and 'close calls' are thought to be important for spacing. Close calls seem to coordinate group movement by signalling intent (Harcourt & Stewart 1996). Other vocalizations include threat barks during aggressive displays, question barks, a mildly aggressive cough-grunt, infant whimpers, breathy chuckles during play, staccato whimpers during copulation, 'humming', 'singing' and hoots (Schaller 1963, Fossey 1972, Harcourt & Stewart 1996, Sicotte 2001).

Chest-beats are provoked by excitement and used in many contexts from play to intimidation within groups, to communication between groups (Schaller 1963, Dixson 1981). All age classes charge, but only adult ♂♂ produce the full displays incorporating charges,

chest-beats, strutting, screams or barks, hoot-series (vocalizations), ground-thumping and vegetation throwing. The 'stiff-legged strut' is described as 'showing off' (Schaller 1963). Adult ♂♂ emit a musky odour from axillary glands in the armpit in situations of excitement or fear (Schaller 1963), and all age classes produce diarrhoeic dung when stressed or afraid. Inter-group encounters, where adult ♂♂ exchange chest-beats and vocalizations, are aggressive contests for adult ♀♀, not for food (Sicotte 1993). Groups usually try to avoid each other, but when inter-group encounters occur over two-thirds of them induce aggressive interactions between adult ♂♂ (Harcourt 1981, Sicotte 1993). When these escalate to physical contact, the fights are intense (Harcourt 1981, Watts 1989b) and sometimes fatal (E. A. Williamson pers. obs.). Adult ♂♂ in multimale groups cooperate by herding to prevent ♀♀ from emigrating (Sicotte 1993).

Gorilla beringei is sympatric with *P. troglodytes* over all but the highest altitudes of their geographic range. The diets of *G. beringei* and *P. troglodytes* overlap but they show different foraging strategies when fruit is scarce, and there is little evidence of inter-specific feeding competition (Yamagiwa *et al.* 1996, Stanford & Nkurunungi 2003). *Gorilla b. beringei* shows curiosity and is gentle on the rare occasions that they interact with other animals (E. A. Williamson pers. obs.), unless they encounter potential dangers (e.g. poachers, Cape Buffalo *Syncerus caffer*), at which times adult ♂♂ actively defend other group members.

Reproduction and Population Structure The median length of the menstrual cycle in *G. b. beringei* ♀♀ is 28 days (mean = 28.8, range 20–39, $n = 25$; Watts 1991a). Females are proceptive for 1–4 days (Watts 1991a). Ovulation is at the mid-cycle, and mating occurs near peak oestrogen concentrations (Czekala & Sicotte 2000). *Gorilla b. graueri* ♀♀ menstrual cycles are slightly longer at 33.2 days (Yamagiwa & Kahekwa 2001). Nulliparous ♀♀ have small sexual swellings but parous ♀♀ show no external signs of oestrus (Czekala & Sicotte 2000).

Gestation lasts ca. 255 days (Watts 1991a, Czekala & Sicotte 2000, Yamagiwa & Kahekwa 2001). There is no evidence of seasonality in births for *G. b. beringei* ($n = 206$; Gerald 1995, Watts 1998c), but there appears to be a May–Jul birth peak for *G. b. graueri* ($n = 47$; Yamagiwa *et al.* 2012). *Gorilla beringei* typically give birth to a single infant. Twins are rare, but have been born into the Virunga and Kahuzi-Biega populations; however, there is only one known case of both twins surviving (Meder 2004). Birth weight ca. 2 kg. Sex ratio at birth is 1 : 1 ($n = 214$; Robbins *et al.* 2007). Birth rate is 0.22–0.28 births per adult ♀ per year, or about one birth per adult ♀ every 4.4 years ($n = 101$; Gerald 1995, Steklis & Gerald-Steklis 2001). Females surviving to adulthood (60%) have an average reproductive lifespan of 14 years and produce a mean of 4.6 offspring that survive to beyond infancy (Gerald 1995).

Females are not fertile whilst suckling young and lactational anoestrus lasts ca. three years. *Gorilla b. beringei* mean inter-birth interval is close to four years when the previous sibling survives (median 3.9 years, S.D. = 0.7 years, $n = 62$). If an infant dies before weaning, another is born two years later (S.D. = 1.1 years, $n = 39$; Gerald 1995). *Gorilla b. graueri* has a slightly longer interval of 4.6 years (range 3.4–6.6, $n = 9$) between surviving offspring, or 2.2 years when an infant dies (range 1.4–2.7, $n = 3$; Yamagiwa

& Kahekwa 2001). Infants are weaned at 3–4 years (median = 43 months, range 22–62 months, $n = 5$; Stewart 1988, Fletcher 2001).

Gorilla b. beringei grows faster than *G. g. gorilla* (Taylor 1997). Age at fertility in ♂♂ is unknown, but ♂♂ do not copulate until age 9–10 years (Watts 1991a). *Gorilla b. beringei* ♂♂ show a growth spurt and develop secondary sexual characteristics from ten years of age, but are not fully grown until 15 years (Watts 1991b, Watts & Pusey 1993). *Gorilla b. beringei* ♀♀ reach sexual maturity and first copulate at 7.0–7.5 years (Groves & Meder 2001), but experience ca. two years of adolescent sterility before first conception (Watts 1991a). *Gorilla b. graueri* has a similar sterile subadult period (Yamagiwa & Kahekwa 2001, Yamagiwa *et al.* 2003). Mean age at first parturition is 10.2 years in *G. b. beringei* (range 8–13, $n = 42$; Gerald 1995), and 10.6 years in *G. b. graueri* (range 9.1–12.1, $n = 6$; Yamagiwa & Kahekwa 2001). In *G. b. beringei* the ♂ : ♀ ratio is 1 : 1.7 and of immatures : adults is 1 : 1.2 in a population of 255 individuals (based on Kalpers *et al.* 2003).

Mortality rates are highest for infants and older adults (Gerald 1995). *Gorilla b. beringei* infant mortality is greatest in the first six months (18%, $n = 151$; Gerald 1995) and 34% in first three years ($n = 65$, Watts 1991a). Rates are similar in *G. b. graueri* (20% in first year, 26% in first three years, $n = 46$; Yamagiwa & Kahekwa 2001). Mortality is highest in the wet season due to increase of respiratory infections (200% higher than predicted; Watts 1998c). About 60% of *G. b. beringei* survive to age eight years (Gerald 1995). Survivorship is constant from the young adult age-class (8–12 years) through the mature adult age class (12–20 years) and drops thereafter. Adult ♂♂ die relatively young, perhaps because of competition among them (Groves & Meder 2001). About 32% of ♂♂ die at 24–30 years, compared to only 8% for ♀♀ (Gerald 1995). The oldest known *G. b. beringei* individual died at 45 years of age (Robbins & Robbins 2004).

Predators, Parasites and Diseases Due to its large size, *G. beringei* probably has only two predators of any significance. Humans are, by far, the primary predator of *G. beringei*, killing them for their meat, body parts and in retaliation for damage to crops (Plumptre *et al.* 2003a). Several cases of *G. beringei* predation by Leopards *Panthera pardus* are described by Schaller (1963).

Gorilla beringei is susceptible to numerous diseases and parasites, including: common cold, pneumonia, whooping cough, influenza, hepatitis A and B, Epstein–Barr virus, chicken pox, smallpox, bacterial meningitis, tuberculosis, diphtheria, measles, rubella, mumps, yellow fever, yaws, paralytic poliomyelitis, encephalomyocarditis, schistosomiasis, giardiasis, filariasis, strongyloidiasis, cryptosporidiosis, shigellosis, salmonellosis, *Capillaria hepatica*, *Entamoeba coli*, *E. histolytica*, *Endolimax nana*, *Ancylostoma* sp., *Oesophagostomum* sp., *Acanthocephala* sp., *Cyclospora* sp., *Chilomastix* sp., *Iodamoeba buetschlii* and *Sarcoptes scabiei* (Ashford *et al.* 1990, 1996, Durette-Desset *et al.* 1992, Butynski & Kalina 1998, Homsy 1999, Butynski 2001, Woodford *et al.* 2002, Ryan & Walsh 2011). See also Conservation.

Conservation IUCN Category (2012): *G. beringei* Endangered; *G. b. beringei* Critically Endangered; *G. b. graueri* Endangered. CITES (2012): Appendix I as *G. gorilla*. Listed as an 'Endangered Species' under the US Endangered Species Act of 1973.

Threats to *G. beringei* all relate to the high human population density within the geographic range and human requirements for natural resources, especially land for agriculture, timber and bushmeat. Populations of *G. beringei* are being increasingly fragmented, isolated and destroyed directly through unsustainable hunting (i.e. poaching), and indirectly through habitat degradation, loss and fragmentation (Lee *et al.* 1988, Kemf & Wilson 1997, Bowen-Jones 1998, Hall *et al.* 1998a, Butynski 2001, Plumptre *et al.* 2003a, Rose *et al.* 2003, Ferriss *et al.* 2005, Yamagiwa *et al.* 2012). Such fragmented populations are susceptible to extinction not only from further habitat loss and over-exploitation, but also from random (stochastic) genetic and demographic changes, and from environmental catastrophes such as disease.

While much has been written about the impact of habitat loss and hunting on populations of *G. beringei*, less has been said about the known and potential impacts of disease on this species. Disease, including parasites, is another major concern as transmission from humans to *G. beringei* occurs and has the potential to be catastrophic. Because *G. beringei* is phylogenetically close to humans, this species is highly susceptible to numerous human diseases (see Predators, Parasites and Diseases, and Homsy 1999, Butynski 2001, Woodford *et al.* 2002, Ferriss *et al.* 2005, Palacios *et al.* 2011). Many of the diseases to which *G. beringei* is susceptible are fatal or cause morbidity, with severe consequences for normal behaviour and reproduction. Of particular concern at this time is the fact that, each year, thousands of tourists from hundreds of localities around the world, step out of crowded, poorly ventilated airplanes and airports and within 1–2 days are close to, and sometimes touching, habituated *G. beringei* (Butynski & Kalina 1998, Sandbrook & Semple 2006, Macfie & Williamson 2010, Ryan & Walsh 2011). These visitors can carry exotic strains of pathogens while not yet showing clinical signs of disease. The risk is that humans will transfer a disease to an immunologically naïve population of *G. beringei*, triggering an epidemic. Both of the *G. beringei* populations that are now the focus of intensive tourist viewing are already small and highly threatened: the Virunga Mts populations with ca. 480 individuals, and the Bwindi Impenetrable N. P. population with ca. 300 individuals. Each day, ca. 75% of the individuals in the Virunga population are visited by people (tourists, researchers, guides, porters, rangers and military escorts).

The risks and consequences of disease transmission between humans and *G. beringei* are predicted to become increasingly serious if once-stable ecosystems and large (genetically diverse) populations of *G. beringei* are fragmented, reduced and stressed by humans. Small populations are likely to have diminished genetic variation, one result of which is increased vulnerability to infectious diseases. In the case of *G. beringei* the stress involved with the habituation process and frequent visits by people may further challenge their well-being, compromising their ability to respond normally to disease. The introduction of a human-borne infection into small, stressed, genetically depressed populations of *G. beringei* could lead not only to the extinction of the population but also (where the subspecies is represented by but one population) to the extinction of the subspecies (Butynski & Kalina 1998, Butynski 2001).

Identifying and implementing actions to minimize and reduce the major threats to *G. beringei* have been the focus of many workshops, articles and books (e.g. Schaller 1963, Dixon 1981, Lee *et al.* 1988, Butynski 2001, Caldecott & Miles 2005, Ferriss *et al.* 2005, Pain

2009) and will not be reviewed here. The major protected areas whose effective management is critical to the long-term survival of *G. beringei* are Kahuzi-Biega N. P., Maiko N. P., Itombwe Nature Reserve and Virunga N. P. in DR Congo, Bwindi Impenetrable N. P. and Mgahinga Gorilla N. P. in Uganda, and Volcanoes N. P. in Rwanda.

Research priorities for *G. beringei* at this time are: (1) new surveys to determine the present distribution and numbers of *G. b. graueri*; (2) more research on the impacts of tourism on the ecology and behaviour of *G. b. beringei* and the Bwindi Gorilla; and (3) a detailed assessment of the taxonomic status of the gorillas of Mt Tshiaberimu and Bwindi Impenetrable N. P.

Measurements

Gorilla beringei

WT (♂ ♂): 165 (?–?) kg, n = 5

WT (♀ ♀): 90 (?–?) kg, n = 3

G. b. beringei and *G. b. graueri* from various sites combined (Sarmiento *et al.* 1996)

G. b. beringei

Standing ht (♂ ♂): 1700 (1610–1710) mm, n = 5

Girth (♂ ♂): 1490 (1380–1630) mm, n = 8

Arm span (♂ ♂): 2310 (2000–2760) mm, n = 8

Arm length (♂ ♂): 1050 (970–1110) mm, n = 5

Leg length (♂ ♂): 660 (610–710) mm, n = 2

HB (♂ ♂): 1105 (1010–1200) mm, n = 2

T (both sexes): 0 mm

HF (♂ ♂): 305 (286–320) mm, n = 10

E (♂ ♂): 58 (50–65) mm, n = 6

WT (♂ ♂): 152 (120–191) kg, n = 7

WT (♀ ♀): 84 (70–98) kg, n = 2

GLS (♂ ♂): 311 (287–342) mm, n = 19

GLS (♀ ♀): 247 (237–260) mm, n = 11

GWS (♂ ♂): 183 (179–197) mm, n = 19

GWS (♀ ♀): 148 (140–154) mm, n = 10

Virunga Mts. Compiled primarily by C. P. Groves (1966, pers. comm.) from numerous sources. Includes one adult ♂ collected by E. Heller in 1925. Details taken from E. Heller's notes, which are on deposit at FMNH (J. Kerbis pers. comm.). One ♀ WT from C. A. Whittier (pers. comm.).

G. b. graueri

Standing ht (♂ ♂): 1820 (1690–1960) mm, n = 6

Girth (♂ ♂): 1540 (1420–1600) mm, n = 4

Arm span (♂ ♂): 2510 (2340–2700) mm, n = 3

Arm length (♂ ♂): 990 (860–1100) mm, n = 3

Leg length (♂ ♂): 795 (790–800) mm, n = 2

HB (♂ ♂): 1090 (1040–1140) mm, n = 4

T (both sexes): 0 mm

HF (♂ ♂): 297 (287–312) mm, n = 4

E (♂ ♂): 52 (50–54) mm, n = 4

Tribe PANINI

Chimpanzees

Panini Delson, 1977. *Journal of Human Evolution* 6: 450.

As outlined in the tribal designation of Gorillini, the need for a tribe that is effectively synonymous with the genus is dictated by a generally accepted need to separate bipedal and quadrupedal apes

(Groves 1986). The tribe Panini consists of a single genus; hence its definition and characterization is the same as that for *Pan* (below).

Colin P. Groves

GENUS *Pan*

Chimpanzees

Pan Oken, 1816. *Lehrbuch der Naturgeschichte*, ser. 3 (2): 11.

(a) Western Chimpanzee *Pan troglodytes verus*. (b) Eastern Chimpanzee *Pan troglodytes schweinfurthii*. (c) Central Chimpanzee *Pan troglodytes troglodytes*. (d) Gracile Chimpanzee (Bonobo) *Pan paniscus*.

Polytypic genus endemic to the forests of tropical Africa. There are two species in this genus: the Robust or Common Chimpanzee *Pan troglodytes* and the Gracile Chimpanzee, also known as the Bonobo or Pygmy Chimpanzee, *Pan paniscus*. The latter was described as a subspecies of chimpanzee by Schwarz (1929), and elevated to the

rank of species by Coolidge (1933). The last shared ancestor was ca. 1.8 mya (Gondet *et al.* 2011). A suggestion that the West African *P. troglodytes verus* might also be ranked as a distinct species (Morin *et al.* 1994) has not been widely adopted.

The differences between the two species of chimpanzees relate primarily to body build: *P. paniscus* is much more slender (i.e. 'gracile'), with an especially small round head and heavy, pillar-like legs. As such, the intermembral index (ratio of arm length to leg length) for *P. paniscus* is about equal to 100, whereas the intermembral index is >100 in *P. troglodytes*. Infant *P. troglodytes* have pink faces that gradually darken with age, often developing conspicuous freckles and large tan spots, becoming black at or after maturity; infant *P. paniscus* already have black faces, except around the mouth, and this does not essentially change with age. Both species go bald on the scalp with age, ♀♀ earlier and usually more extensively than ♂♂.

Compared to *Gorilla*, *Pan* differs as follows. Size is much smaller (large chimpanzee ♂♂ weigh about as much as small gorilla ♀♀), and sexual dimorphism is not so marked, chimpanzee ♂♂ being (in most populations) little larger than ♀♀. The ears are conspicuously larger, and in adults generally remain bronze rather than black. The nose is both shorter and narrower, though an approach to the 'squashed tomato' nostrils of many gorillas may be made. The arms are relatively shorter (intermembral index, even in *P. troglodytes*, is lower), the hand is much longer and narrower, the thorax is narrower, the vertebral border of the scapula is much shorter, the iliac crests lack the expansion, the calcaneum is shorter, the feet are narrower, the toes are longer, and the hallux (great toe) is more slender and more divergent. The pelage is almost invariably jet black; adult ♂♂ lack a 'silverback' saddle, although with extreme age both sexes become grey, first on the lower back and thighs, the greyiness later

spreading to other parts of the body. Like gorillas, infant chimpanzees have a whitish tuft above the anus.

The skull can be distinguished from that of gorillas, first, by the smaller size (the greatest length of the skull is rarely above 220 mm, whereas even in ♀ gorillas it is rarely below 250 mm), and, secondly, by the flattening of the upper face. The supraorbital tori, though often dorsoventrally expanded, are more or less flattened on their anterior surface (as well as being separated in the midline by a depression at glabella), and the lateral orbital pillars are also wide and flat; in particular, the interorbital space is very wide and flat, and there is no median nasal ridge.

In the dentition, the enamel is thin. The maxillary incisors are distinctive: broad, thick at the base and with a strong lingual tubercle, deeply incised around the base. Lateral incisors are similar to the central ones. The canines of ♂♂ are not as elongated as in ♂ gorillas, and canine dimorphism is less. Cheekteeth are bunodont, with the cusps low but fairly well defined, without the sharp crests of *Gorilla*, so that, for example, the central basins of the maxillary molars are not strongly interrupted by the crista obliqua.

It is safe to suppose that the ancestral *Pan* ranged over a larger geographic area and was less restricted in its choice of habitats than the two species are today. Furthermore, on the basis of recent historical evidence, Kortlandt & Van Zon (1969) concluded that *P. troglodytes* also occupied a broader spectrum of habitats, and they envisaged earlier populations occupying semi-open habitats. These authors emphasized the part played by humans and proto-humans in constraining and progressively diminishing the chimpanzee's ecological niche.

If this is correct, the geographic and ecological range of *Pan* evidently contracted greatly as the apes relinquished more open habitats to hominins, and such a history has important implications for understanding the behaviour and even the morphology of contemporary populations. For example, their ability to climb tall rainforest trees with apparent ease may be a skill that has been superimposed during the last 5 million years or so over an older, less specialized semi-arborealism. Recent discovery of a half-million-year-old fossil chimpanzee in Kenya (McBrearty & Jablonski 2005), in the Kapthurin Formation, where early human fossils are also found, may take the prediction of such evolutionary changes out of the realm of speculation and into scientific documentation.

The exploitation by *Pan* of fruit or seeds in tall emergent trees within the forest has provoked debate on how making use of this particularly demanding resource might have had a precedent in earlier *Pan* habitats, such as open woodlands. For a majority of primates, the canopy of the rainforest is the main resource: a second 'floor' above the relatively barren, deeply shaded ground below. Competition for all types of food is intense here but the spaced-out emergents above this crowded floor are less accessible to smaller primates for two reasons. One is the physical challenge of climbing thick trunks, the other, more decisive inhibitor, is exposure to predators. Even if, as Kortlandt & Kooij (1963) and others have suggested, *Pan* was originally less of a true forest animal, its exploitation of spaced out large woodland trees (something that still occurs) would have 'pre-adapted' these large-bodied, powerfully muscled apes to make use of forest emergents (Kingdon 2003). Such an interpretation is consistent with the exceptional development of the forelimbs and strength of the chimpanzee's long, curved fingers. In relation to their putative hominin competitors, these traits would have closed off

Central Chimpanzee *Pan troglodytes troglodytes* adult male.

Gracile Chimpanzee (Bonobo) *Pan paniscus* adult male.

any possibility of chimpanzees becoming bipedal. For that outcome an opposite trend – reduction, not amplification – of the forelimb would have been necessary.

All *P. troglodytes* populations so far studied have turned out to be partially carnivorous, hunting monkeys (predominantly red colobus *Procolobus* spp.) in particular, also occasionally small ungulates such as duikers *Cephalophus* spp. and *Philantomba* spp., Bushbucks *Tragelaphus scriptus* and young Bushpigs *Potamochoerus larvatus*. Hunting is often a cooperative affair and, like many other aspects of chimpanzee behaviour, differs in its cultural norms from place to place. This, as well as the fission–fusion community social organization, patterns of tool-use and tool-making, and so on, speaks of a behavioural heritage that in many respects parallels that of humans – or were these features already characteristic of the common ancestor, as parsimony would suggest?

The first identified chimpanzee fossil (consisting of teeth only) was, as described above, found in the Baringo region of Kenya, in deposits only slightly less than 545,000 years old (McBrearty & Jablonski 2005). Schwartz & Tattersall (2003) suggested that some isolated teeth from the Plio-Pleistocene (ca. 1.8 mya) of Koobi Fora, east of L. Turkana, Kenya, a well-known site of early hominins, may also actually be proto-chimpanzee, including one of the teeth (1590F) usually ascribed to a specimen of *Homo rudolfensis*. If this is so, it implies that we should also look for other representatives of the Panini in early hominin deposits.

Pan troglodytes ROBUST CHIMPANZEE (COMMON CHIMPANZEE)

Pan troglodytes (Blumenbach, 1775). De generis humani varietate nativa, p. 37. Mayoumba, Gabon.

Brachiating adult male Central Chimpanzee
Pan troglodytes troglodytes.

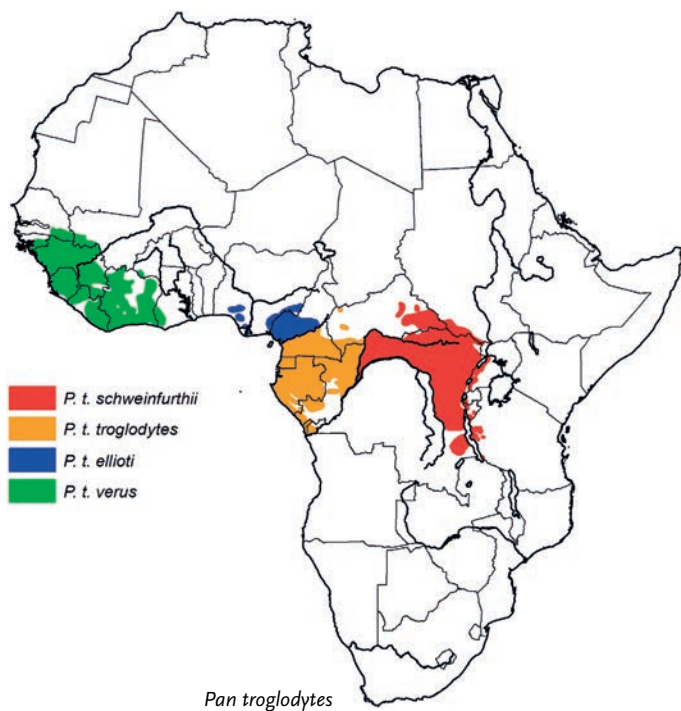

Taxonomy Polytypic species. There is a complicated history of generic, specific and subspecific classification, resulting from both broad anatomical similarities among African and Asiatic ape taxa, and from considerable inter-individual variation in colouring and facial features within *Pan*. Most common former classifications substituted the generic names *Anthropopithecus*, *Troglodytes* or *Simia* and/or the species name *satyrus* (Hill 1969, Jenkins 1990, Groves 2001). The type specimen, no longer in existence and given the name *Simia troglodytes*, was likely *P. t. troglodytes* (Hill 1969). Current designation as a single species can be traced to Schwarz (1934, using the species name *satyrus*) and Allen (1939), who both included the Gracile Chimpanzee (or Bonobo) *Pan paniscus* within *Pan troglodytes*. Coolidge's (1933) classification of the Gracile Chimpanzee into a separate species is widely accepted today. One genetic study suggests that the Western Chimpanzee has diverged sufficiently to be designated as a full species, *Pan verus* (Morin *et al.* 1994). Modern taxonomic usage is fairly

consistent, though genetic similarities prompted some researchers to suggest that *Pan* could be regarded as a subgenus of *Homo* (Wildman *et al.* 2003). Genetic studies put the divergence of the *Homo*–*Pan* clade in the late Miocene (ca. 8–6 mya) (Caccone & Powell 1989, Ruvolo 1997, Perelman *et al.* 2011, Roos *et al.* 2011). No confirmed cases of hybridization between *P. troglodytes* and any other ape taxon.

Synonyms: *adolphi-friederici*, *africanus*, *angustimanus*, *aubryi*, *calvescens*, *calvus*, *castanomale*, *chimpanse*, *cottoni*, *elliotti*, *fuliginosus*, *fuscus*, *graueri*, *heckii*, *ituricus*, *ituriensis*, *jocko*, *koolookamba*, *lagaros*, *leucoprymnus*, *livingstonii*, *mafuca*, *marungensis*, *nahani*, *niger*, *ochroleucus*, *oertzeni*, *pan*, *papio*, *pfeifferi*, *pongo*, *purschei*, *pusillus*, *rarihilosus*, *reuteri*, *satyrus*, *schneideri*, *schubotzi*, *schweinfurthii*, *steindachneri*, *tschego*, *vellerosus*, *verus*, *yambuyae*. The complete genome has been sequenced (Chimpanzee Sequencing and Analysis Consortium 2005). Chromosome number: $2n = 48$ (Young *et al.* 1960).

Description Moderately large, robustly built, knuckle-walking ape. Sexes alike in colour but adult ♀♀ have smaller canines, narrower shoulders, and are about 80% as heavy as adult ♂♂. Face, ears, hands and feet of infants pink, generally darkening to brown or black in adults; often with a dark 'mask' in juveniles. Head prognathic with pronounced brow ridges. Face and centre of forehead primarily bare and framed by hair. Iris orange-brown to dark brown. Sclera brown (rarely, white). Ears completely or partially bare, human-like in general shape but relatively large, and can face forward or lay flat against the side of the head. Upper and lower lips highly flexible and strong. Hands long and slender with short, opposable thumb. Metacarpals and phalanges curved. Fingers and palms hairless. Grasping feet with broad soles and short toes. Sole and toes hairless. Forelimbs slightly longer than hindlimbs. Tail absent. Pelage long, coarse, dark brown to black. Many older adults with light brown or grey hair on the lower back, legs and/or chin. Immatures with tuft of white hair above the anus.

Geographic Variation Three subspecies widely recognized (Groves 2001, Becquet *et al.* 2007). Genetic (Gonder *et al.* 1997, 2006, 2011, Stone *et al.* 2010, Bowden *et al.* 2012) and molar morphometric (Pillbrow 2006) data strongly support the designation of a fourth subspecies, *P. t. elliotti* (formerly *vellerosus*; Oates *et al.* 2009, Morgan *et al.* 2011, Oates 2011), and point to weak divergence between *P. t. troglodytes* and *P. t. schweinfurthii* (Gonder *et al.* 2011). Hill (1969) described a fifth subspecies, *P. t. koolokamba*, the Gorilla-like Chimpanzee; this designation has no current credence, as both historical (Schwarz 1939) and modern (Groves 2001) experts define these specimens within *P. t. troglodytes*. Based on a recent craniometric study, Groves (2005b) argues for two subspecies within what is presently *P. t. schweinfurthii*; a north-eastern subspecies (*P. t. schweinfurthii*) and a south-eastern subspecies (*P. t. marungensis*). This is, however, not supported by the genetic evidence (Gonder *et al.* 2011). Others argue that subspecies designations are not warranted (Fischer *et al.* 2006). Resolution of these issues awaits

greater understanding of gene flow among populations and studies at the known and probable geographic limits or contact zones for each taxon (Jolly *et al.* 1995, Won & Hey 2005).

Here, four subspecies are recognized, following the current IUCN classification (Grubb *et al.* 2003). All subspecies are best diagnosed based on the locality of collection or sighting; we provide some general phenotypic characteristics of each subspecies, though individual phenotypic variation is extensive enough to preclude diagnostic field criteria to distinguish the taxa.

P. t. verus Western Chimpanzee or Upper Guinea Chimpanzee. South-eastern Senegal and S Mali south-east to either the Dahomey Gap (Bénin) or Niger R. Tend towards profuse white 'beards'. Darkly pigmented circumocular and/or nasal 'mask' develops rapidly. Face often maintains some pink colouration into adulthood. Face typically broad across forehead with ears large, prominent and pale. Hair of scalp parting along midline. Palms and soles pale with irregular patches of darker pigment on digits.

P. t. ellioti Elliot's or Gulf of Guinea or Nigerian-Cameroon Chimpanzee. Southern Nigeria and W Cameroon, probably from the Dahomey Gap (Bénin) or Niger R. south to the lower Sanaga R. (Morgan *et al.* 2011, Oates 2011). Recognized based on mtDNA (Gonder *et al.* 1997, 2011) and molar morphometric (Pilbrow 2006) evidence. Relative to *P. t. verus*, ears small and lie close to head; top of head rounder; brow ridge straighter, more gracile build; face, hands and feet uniform black in adults (Oates 2011).

P. t. troglodytes Central Chimpanzee or Lower Guinea Chimpanzee. Sanaga R. south-east to Ubangi R. and south to Congo R. Skin, including face, ears, palms and soles, tends to be uniformly dark brown or black in adulthood. Ears small to medium. Tends to quickly develop prominent bald patches on the forehead.

P. t. schweinfurthii Eastern Chimpanzee or Long-haired Chimpanzee. Ubangi R. east across DR Congo, north of Congo R. and east of

Eastern Chimpanzee *Pan troglodytes schweinfurthii* juvenile.

Lualaba R. to SW Tanzania. Slightly smaller in body size than other subspecies. Hair long, particularly around the face and shoulders. Facial pigmentation ranges from pale brownish-pink to brown or greyish-black in adulthood, with traces of pink evident primarily near the lips in some individuals. Face typically longer than *P. t. verus*. Palms and soles usually brick red to bronze.

Similar Species

Pan paniscus. Parapatric. Limited to central Congo Basin, DR Congo, south of the Congo R. More gracile, ca. 15% lighter. Head small and round. Mouth region contrastingly pink. Face black at birth. Upper molar rows not parallel.

Gorilla gorilla and *Gorilla beringei*. Sympatric. Larger (adult ♂ >130 kg). Ears relatively small and black. Sagittal crest well developed in adult ♂♂. Nasal openings nearer to mouth than to orbits.

Distribution

Historical Distribution The historical geographic range of *P. troglodytes* is roughly 2.3 million km² (Butynski 2003), comprising 25 countries. Probably extirpated from Bénin, Burkina Faso and Togo, but confirmation needed. On the verge of extirpation from Senegal and Ghana. Extirpated from large areas within most countries.

Current Distribution Endemic to equatorial Africa. Rainforest BZ. Occurs in 22 or 23 countries from Senegal east to SW Tanzania, from ca. 13°N to 7°S (Butynski 2001, 2003).

Habitat Most habitats are mosaics, particularly of moist evergreen or semi-deciduous forest, swamp forest, gallery forest, woodlands, colonizing forest and grassland. Preferred habitats are mature forests, though colonizing forests are frequently used. Altitudes range from sea level to at least 2949 m (Nyungwe Forest, Rwanda; Gross-Camp *et al.* 2009). Mean annual rainfall is typically

over 1400 mm (summarized in: Kortlandt 1983, Butynski 2001). A few populations, including those at Fongoli and Mt Assirik, Senegal (*P. t. verus*), and Ugalla (Tongwe), Tanzania (*P. t. schweinfurthii*), utilize drier, open grassland and woodland habitats (Itani 1979, McGrew *et al.* 1981, Pruetz 2007). Associated and important plant species cannot be generalized across sites, though the density of Robust Chimpanzees seems to vary positively with the density of large trees bearing fleshy fruit (Balcomb *et al.* 2000).

Abundance Estimates of abundance are rough given that only a small portion of the species' range has ever been surveyed, and that most of the survey data were collected well over a decade ago. Abundance data for many areas may now be overestimates due to recent catastrophic disease outbreaks, heavy hunting and habitat loss (see Conservation). These figures may also be misleading due to highly fragmented habitats; e.g. Uganda contains 4000–5700 Robust Chimpanzees, but many of these are in small populations (<500 individuals) that may have low long-term viability (Plumptre *et al.* 2003b). Densities are <1 ind/km² in most areas, with 2–8 ind/km² in some protected areas (Kormos *et al.* 2003, Plumptre *et al.* 2003b, Oates 2011). The following figures represent the most recent population estimates (Butynski 2003, Plumptre *et al.* 2010, Morgan *et al.* 2011):

- P. t. verus* 21,300–55,600. Largest populations are in Côte d'Ivoire, Guinea, Sierra Leon and Liberia. Senegal, Ghana and Guinea-Bissau each hold fewer than 1000 individuals.
- P. t. ellioti* 3500–9000. Largest population is probably in Cameroon.
- P. t. troglodytes* 70,000–116,500. Largest populations are in Congo (10,000), Cameroon (31,000–39,000) and Gabon (27,000–64,000). Angola, Central African Republic and DR Congo each hold fewer than 1000 individuals
- P. t. schweinfurthii* 76,4000–119,600. Largest populations are in Uganda (4000–5700) and DR Congo (70,000–110,000). Sudan, Burundi and Rwanda each hold fewer than 500 individuals.

Adaptations Diurnal and semi-terrestrial. Active 10–13 h per day (Wrangham 1977, Lodwick *et al.* 2005). Although Robust Chimpanzees feed mostly in trees, they travel all but the shortest distances on the ground, where they also do most of their resting and grooming. Arboreal locomotion is primarily via vertical climbing, palmar walking on the tops of tree limbs, quadrumanous clambering and, rarely, brachiation; terrestrial locomotion is by quadrupedal knuckle-walking (forelimb bears weight through the dorsal surface of knuckles and medial phalanges rather than palm). Skeletal features, including mobile shoulder joint, narrow scapula and triangular rib cage are adaptations for efficiency in arboreal foraging via vertical climbing, grasping support and arm-hanging. Terrestrial bipedal walking is rare, e.g. during play and aggressive displays, or when carrying food (Hunt 1994, Videan & McGrew 2002, Carvalho *et al.* 2012).

Relatively large incisors (Shea 1983), with elongated cutting surfaces relative to molar teeth (Pickford 2004), are likely adaptive for tearing into large, fleshy fruits. Male canines ca. 25–40% greater in height than in ♀♀, functioning in intrasexual competition (Leutenegger & Shell 1987, Plavcan & van Schaik 1992).

All populations use tools that provide access to important foods such as termites ('fished' for with modified twigs and grass stems; McGrew 1994, Sanz *et al.* 2004, Fowler & Sommer 2007, Abwe &

Lateral, palatal and dorsal views of the skull of Eastern Chimpanzee *Pan troglodytes schweinfurthii* adult male.

Morgan 2008), hard-shelled nuts (smashed open with stones, logs or sticks; Boesch & Boesch 1983, Sakura & Matsuzawa 1991) and honey (McGrew 1994, McLennan 2011). Some tools are widely distributed, such as sponges made by chewing leaves or moss to absorb drinking water (Sugiyama 1995, Lanjouw 2002). However, most are restricted to a few populations or even individuals, such as those involved in aggression (e.g. sticks used to club others; Wrangham & Peterson 1996). Variation in tool use may be explained by a combination of ecological, genetic and cultural factors (Whiten *et al.* 1999, Gruber *et al.* 2009, Langergraber *et al.* 2011).

Self-medication is evidenced by two distinct behaviours. Swallowing of whole, often folded, hispid leaves is practised by many populations, and likely expels intestinal parasites through physical action (Wrangham 1995, Huffman 1997). Chewing of bitter pith is well known in one site (Mahale, Tanzania), and is suspected to control gut pathogens via ingestion of steroid glucosides (Huffman & Seifu 1989; Jisaka *et al.* 1992).

Adults sleep in nests that they construct or refine each evening, or rest in by day (Goodall 1962). Tree nesting is most common, though some communities also utilize ground nests (e.g. Maughan & Stanford 2001). Mean nest heights of 10–20 m are reported from most sites (Fruth & Hohman 1994, 1996), though nest height can vary substantially within populations (e.g. Budongo, Uganda: 2.5–32.5 m, n = 601, Brownlow *et al.* 2001). Males tend to nest at lower heights than ♀♀ (Brownlow *et al.* 2001), perhaps due to their

weight. Robust Chimpanzees are selective in tree species and habitat types utilized for nesting; they prefer areas of high, dense vegetation and different tree species from those they feed from, though the particular species used varies by site (Fruth & Hohman 1994). Nests are frequently constructed at sites adjacent to recent feeding sites (Goodall 1986). High temperatures can lead individuals to seek refuge in less open portions of the habitat. Caves are sometimes used in the warmer, more open habitats in Fongoli, Senegal (Pruetz 2007).

Robust Chimpanzees spend the majority of their waking hours in the pursuit of food. An average of ca. 55% of the day is spent foraging (Gombe, Tanzania: 46–60% in four seasons, Wrangham 1977, Budongo: 49%, Newton-Fisher 1999b). Resting (ca. 25%), travelling (ca. 14%) and allogrooming (ca. 6%) are the next most frequent activities (Wrangham 1977).

Foraging and Food Omnivorous. Ripe fruit specialists. Ripe fruit pulp is both an important and preferred food, comprising ca. 60% of the diet in most populations, whether measured as a proportion of feeding time, items used, or gross weight. Diet in any given month consists of 0–90% fruit (e.g. Hladik 1977, Nishida & Uehara 1983, Emery Thompson & Wrangham 2008a, Watts *et al.* 2012a, b). Leaves or piths are major supplemental foods, particularly during months of low ripe fruit availability. Small amounts of unripe fruit, seeds, flowers, bark, wood, shoots, sap, honey, insects, eggs and vertebrate prey are also consumed. Red colobus monkeys *Procolobus* spp. are the most frequent mammalian prey reported (Struhsaker 2010, Lwanga *et al.* 2011); Robust Chimpanzees in the wild also consume Guerezas *Colobus guereza*, Blue Monkeys *Cercopithecus mitis stuhlmanni*, Red-tailed Monkeys *Cercopithecus ascanius*, Olive Baboons *Papio anubis*, Yellow Baboons *Papio cynocephalus*, Vervets *Chlorocebus pygerythrus*, Uganda Grey-cheeked Mangabeys *Lophocebus ugandae*, lesser galagos *Galago* spp., dwarf galagos *Galagoides* spp., Bushbucks *Tragelaphus scriptus*, Bushpigs *Potamochoerus larvatus*, Sunis *Nesotagus moschatus*, duikers *Cephalophus* spp. and *Philantomba* spp., White-tailed Mongooses *Ichneumia albicauda*, Bush Hyraxes *Heterohyrax brucei*, and a variety of rodents, birds, and tadpoles (Goodall 1986, Newton-Fisher *et al.* 2002, Watts & Mitani 2002, O'Malley 2010). Partial and complete cannibalization of chimpanzee infants has also been observed (Arcadi & Wrangham 1999). Hunting is performed almost exclusively by adult ♂♂, though ♀♀ and adolescents sometimes follow a hunt closely and kill incapacitated animals. Though individuals come across potential prey items frequently, the probability of attempting a hunt (and of succeeding) varies with seasonal food availability, the number of adult ♂♂ travelling together, and the presence of low or broken canopy that thwarts prey escape (Watts & Mitani 2002, Gilby 2004, Gilby & Wrangham 2007). Participation of highly skilled hunters promotes investment of other ♂♂ in hunting (Gilby *et al.* 2008).

Feeding typically begins shortly after dawn, declines at midday and resumes in the late afternoon before nesting. Fruits tend to be eaten earlier in the day than lower quality resources like leaves (Hladik 1977, Wrangham 1977).

Robust Chimpanzees in the wild do not often share food or provide direct provisioning to offspring, though young offspring can take bites from the mother's mouth or hand. Meat is the major shared food item, though portions are not shared by all group members, or even by all of the hunting party. Though it has been argued that meat may be used as a currency for social bonding (Nishida *et al.*

1992) or sexual access (Stanford *et al.* 1994), studies suggest that sharing is mainly a response to costs imposed by intensive begging or harassment (Wrangham 1975, Stevens & Gilby 2004).

Mean day ranges vary from 1.9 km/day (mothers at Kibale Forest, Uganda, Pontzer & Wrangham 2004) to 4.6 km/day (adult ♂♂ at Gombe, Wrangham 1977). In addition to community-level variation (e.g. at Taï, Côte d'Ivoire: 2.1 km/day in Middle Community, 4.2 km/day in South Community, Herbinger *et al.* 2001), ♂♂ range farther than ♀♀ within communities (e.g. at Kibale, 2.0 km/day for adult ♀♀ without clinging infants, 2.4 km/day for adult ♂♂, Pontzer & Wrangham 2004). Day range is expected to vary with the location and abundance of food resources, as well as with age and physical condition (Wrangham 1977, Herbinger *et al.* 2001, Pontzer & Wrangham 2004). On rare occasions, an individual may travel more than 10 km in a single day (Wrangham 1975), while sick, injured, or heavily pregnant individuals sometimes do not move at all in a day.

Home-ranges typically vary from 6–32 km² (e.g. Wilson 2001, Williams *et al.* 2002b). In low-density populations, community ranges can be >200 km². Ranges of individual ♂♂ are large and broadly overlapping, whereas ♀♀ often limit ranging to smaller core areas or 'neighbourhoods' within the community range (Hasegawa 1990, Wilson 2001, Emery Thompson *et al.* 2007a). Males are highly territorial; encounters near borders can result in killing of extra-community ♂♂, ♀♀ or infants (reviewed in: Arcadi & Wrangham 1999, Wilson & Wrangham 2003). Males modify vocal and grouping behaviour in accordance with this risk (Wilson *et al.* 2007); small parties, and particularly ♀♀ with dependent infants, avoid borders (Chapman & Wrangham 1993, Williams *et al.* 2002b). Groups of ♂♂ actively patrol border areas (Watts & Mitani 2001) and respond with agonistic approach to vocalizations of strangers (Wilson *et al.* 2001). Given the significant risk involved, encounters with neighbouring ♂♂ are only initiated when the aggressors have a clear numerical advantage (Wilson *et al.* 2001). Home-range size at Gombe is positively associated with ♀ reproductive rates, suggesting that ♂♂ defend territories to increase resources available to reproductive ♀♀ (Williams *et al.* 2004).

Social and Reproductive Behaviour Robust Chimpanzees are social, with a fission–fusion social organization in which the members of an expanded social network ('community') form smaller temporary associations ('parties') (Nishida 1968, Sugiyama 1968). Party size can vary as a function of food patch size and availability, presence and number of cycling ♀♀ with sexual swellings, and social affinities of community members (e.g. Wrangham *et al.* 1996, Doran 1997a, Matsumoto-Oda 1999b, Pepper *et al.* 1999). Most communities contain 20–60 individuals, including multiple breeding ♂♂ and ♀♀ and their offspring. However, communities can number >140 individuals or, in particularly disturbed habitats, <20 individuals (Reynolds 2005, Watts 2007).

Males are philopatric. Some ♀♀ remain in their natal community, though most transfer during adolescence (Pusey 1980). Females rarely transfer after their first birth, though cases have been noted in three communities (Nishida *et al.* 1990, Williams *et al.* 2002b, Emery Thompson *et al.* 2006a). Sexually attractive swellings of the anogenital region (see Reproduction and Population Structure) likely facilitate transfer into a new community (Nishida 1979, Boesch & Boesch-Achermann 2000).

Overt aggression among ♀♀ is rare, with daily feeding competition reduced by foraging in smaller parties and maintaining more differentiated core areas than those of ♂♂ (Wrangham 2000b, Williams *et al.* 2002a). Female–female aggression intensifies when foraging areas are challenged, such as upon new immigrations, and can include severe attacks on other ♀♀ and infanticide attempts on their infants (Townsend *et al.* 2007, Kahlenberg *et al.* 2008, Pusey *et al.* 2008). Though subtly expressed, ♀♀ form linear dominance relationships that are correlated positively with age (Pusey *et al.* 1997, Wittig & Boesch 2003b, Kahlenberg *et al.* 2008). Males form linear dominance hierarchies; high-ranking ♂♂ are more aggressive than low-ranking ♂♂ and have higher testosterone and cortisol levels (Muller 2002, Muller & Wrangham 2004a, b). Male status competition frequently involves strategic alliances between two or more ♂♂ who affiliate preferentially and cooperate in aggressive contests (Goodall 1986, Newton-Fisher 1999a, Mitani *et al.* 2000a). Male aggression occurs most often in the contexts of sexual competition, reunion after ♂♂ have been travelling separately and unresolved dominance relationships (Goodall 1986, Muller 2002). Males also direct both mild and severe aggression at ♀♀, particularly during oestrous periods (Matsumoto-Oda & Oda 1998, Muller *et al.* 2007). The majority of aggressive interactions involve charging or stationary displays directed at specific individuals or as a generalized demonstration of strength and size. Display hallmarks are piloerection and erratic or exaggerated behaviours that emphasize size or strength, such as bipedal charges, pant-hoot vocalizations, tree-limb dragging, ground-stamping, ‘drumming’ on tree buttresses, flinging rocks, slapping at individuals in passing and shaking vegetation or hitting others with it. Despite these animals’ potential to inflict serious damage, severe aggression within groups is rare (Goodall 1986). However, within-community lethal attacks on mature ♂♂ have been observed at three field sites (Kitopeni *et al.* 1995, Fawcett & Muhumuza 2000, Watts 2004), and within-community infanticides by ♂♂ have been reported from five sites (Wrangham *et al.* 2006).

Males are more gregarious than ♀♀ (Doran 1997a, Pepper *et al.* 1999, Wrangham 2000b, Emery Thompson & Wrangham 2006), though this sex difference varies by community; while ♀♀ in East Africa generally travel in small parties (Wrangham 2000b), larger parties among ♀♀ in Tai are attributed to protection from Leopard *Panthera pardus* predation (Lehmann & Boesch 2005). Affiliation rates among adult ♂♂ are higher than among adult ♀♀ (Watts 2000c, Arnold & Whiten 2003). While ♂♂ maintain a larger number of social relationships, ♀♀ may form a small number of strong relationships with other kin or non-kin ♀♀ while rarely associating with others (Lehmann & Boesch 2008, Wakefield 2008).

Grooming is the principal affiliative behaviour and is commonly mutual, with partners grooming simultaneously or in succession. Rank has some effects on grooming distribution, particularly across age–sex classes, but reciprocity is high, especially among adult ♂♂. Males have more grooming partners than ♀♀ but tend to concentrate most grooming on a few major partners, often those near them in the hierarchy (Boesch & Boesch-Achermann 2000, Watts 2000b, c). Among ♂♂ grooming can be exchanged for support in agonistic interactions (Watts 2002). Grooming can be used to reconcile conflicts, ease tension, or console others, as can conciliatory behaviours such as embracing, social mounting, reaching out a hand or the back of the wrist, touching another’s genitals, or

placing an open mouth on the partner in a mock bite (De Waal & Van Roosmalen 1979, Goodall 1986). Reconciliation occurs in only about 15% of conflicts among wild groups (Arnold & Whiten 2001, Kutsukake & Castles 2004), and individuals with stronger social relationships reconcile more often (Wittig & Boesch 2003a).

Sexual behaviour is concentrated during morning hours, peaking just after individuals emerge from nests and at mid-day after feeding has slowed (Tutin 1979, Wallis 2002). Mating is promiscuous; ♀♀ copulate hundreds of times for each birth, usually with all ♂♂ in the community (Wrangham 2002). Female copulation rates while in oestrus vary from approx. 0.4–5/h, dependent on ♀ fecundity and the number of potential ♂ partners (Emery Thompson 2005, Watts 2007). During the periovulatory period, ♀♀ behave proceptively to fewer ♂♂ and resist more (Matsumoto-Oda 1999a, Stumpf & Boesch 2005), which appears to be a response to ♂ coercive aggression rather than explicit ♀ choice (Muller *et al.* 2007, 2011). Males most frequently initiate copulations, particularly when ♀ conception risk is high (Goodall 1986, Emery Thompson & Wrangham 2008b); this can involve direct approach and chasing or solicitation of ♀ approach by displaying an erect penis and swaggering, stamping his feet, flicking his penis, shaking or bending branches, nodding his head, waving his arms, or clipping bunches of leaves with his teeth. Females initiate copulations or respond to solicitations by presenting their swollen genital areas, often while crouching down and backing towards the ♂. Copulations are brief (mean = 7 seconds, range 2–13 seconds, *n* = 132; Nishida 1997). Most are dorsoventral, with the ♂ holding the ♀ with one hand or leaning back for balance while thrusting his pelvis forward. Females often scream near the end of copulation and/or dart away before or after ejaculation.

Most mating is opportunistic in bisexual parties, but high-ranking ♂♂, alone or in pairs, often mate-guard, preventing other ♂♂ from gaining access to the ♀ (Tutin 1980, Tutin & McGinnis 1981, Watts 1998a). Male relationship strength impacts mating tolerance (Duffy *et al.* 2007). A third ♂ strategy is to form a consortship with a ♀, leading her away from the rest of the community for days or weeks (Tutin & McGinnis 1981). Long-term data from Gombe suggested that fewer than one-quarter of conceptions could have occurred in consortships, though this is presumably an effective strategy for particular ♂♂ (Wallis 1997).

Play occurs in individuals of all ages, peaking between two and four years (Goodall 1968, Clark 1977). Before infants are able to move independently, mothers tickle them or apply soft bites. Gradually, individuals play with other juveniles, as well as with adult ♂♂ and related adult ♀♀. Play often consists of tickling, wrestling and chasing, as well as mock-biting, somersaulting, swinging and slapping at one another, and flinging objects. Sticks are sometimes carried and treated as ‘dolls’, particularly by juvenile ♀♀ (Kahlenberg & Wrangham 2010). Related or unrelated nulliparous ♀♀ provide occasional alloparental care in short bouts (typically 4–10 minutes). Mothers rarely interact with unrelated offspring, but can be aggressive to them (Nishida 1983). Adults, usually male–male or male–female dyads, also play together, often beginning with ‘finger-wrestling’ behaviour with outstretched arms that can escalate into more intense tickling, gentle wrestling, or slow circular chasing (Goodall 1986).

In populations that use tools to fish for termites or crack nuts, juvenile development includes learning of tool use. Juveniles begin

Eastern Chimpanzees *Pan troglodytes schweinfurthii*.

these extractive techniques at ca. 2–4 years, taking several years to achieve proficiency. Females spend more time observing their mothers use tools and practise more often, reaching proficiency sooner than ♂♂ who spend more time in social play (Boesch & Boesch-Achermann 2000, Lonsdorf *et al.* 2004).

Robust Chimpanzees have a broad vocal repertoire, with many graded or hybridized calls (Goodall 1986). A major species-typical vocalization is the ‘pant-hoot’, incorporating a build-up of low booming sounds followed by series of high-pitched whoops, usually in chorus with others. Pant-hoots are given in many situations of excitement, such as when joining a group and during displays; pant-hoots carry over long distances (ca. 1 km for a single caller; J. Mitani pers. comm.), and parties often respond to each other’s calls. Acoustic structure of calls varies across populations (Mitani *et al.* 1999). Males of adjacent communities produce acoustically different calls, independent of genetic relatedness, suggesting the role of vocal learning (Crockford *et al.* 2004). Within communities, pant-hoot structure varies among individuals, and individual calls are often stereotyped enough for experienced human observers to identify the caller (Marler & Hobbett 1975, Mitani *et al.* 1996). During pant-hoot displays, ♂♂ often drum on tree buttresses with hands and feet, providing a secondary acoustic signal that carries at least as far as the vocal signal. The temporal patterning of drumming, like the pant-hoot itself, varies both inter-individually and across populations (Arcadi *et al.* 1998). The ‘pant-grunt’ is given at close range as a signal of deference when a higher-ranking individual approaches or threatens aggression; it is often accompanied by other signs of submission. High-pitched screaming is common in the context of aggression or other threat. Acoustic characteristics of screams differ between aggressor and victim, and vary with severity of attack, though this can be exaggerated in eliciting support from high-ranking individuals (Slocombe & Zuberbühler 2005, 2007). ‘Hoo’ vocalizations signify curiosity or mild distress, while shrill ‘wraah’ barks indicate alarm (e.g. sighting of a snake or strange individual) and short ‘barks’ are given as threats. Juveniles make a variety of whimpers and loud, protesting cries, in addition to panting ‘laughs’ given during play. Soft grunts are given in many contexts; good food sources elicit excited grunts. Exaggerated lip smacking and tooth clapping often occurs during grooming.

Facial expressions are equally diverse and graded (Goodall 1986, Parr *et al.* 2005). A ‘play face’ is indicated by an open mouth with lower teeth exposed and upper teeth usually covered. During displays and agonism, lips are pressed tightly together so that the mouth bulges out. Slight fear or submission can be indicated with a ‘fear grin’ in which lips are drawn back and teeth exposed. More intense fear is shown with an open mouth, lips retracted and both upper and lower lips exposed, with or without screaming. Begging and infant protests are often accompanied by a ‘pout-face’, extension and flattening of the upper lip while the lower lip is drawn back slightly. In older individuals both lips are extended and spread open during excitement or mild distress, with or without accompanying pant-hoot or hoo vocalizations.

Outside of hunting, individuals rarely interact with other species, though interspecific grooming and play have been observed with other primate species (*P. cynocephalus*, Goodall 1986; *C. ascanius*, Tinka & Reynolds 1997). Despite their dominant body size, Robust Chimpanzees are occasionally attacked by monkeys (*P. cynocephalus*, Eastern Red Colobus *Procolobus rufomitratus*, Goodall 1986; *C. guereza*, Newton-Fisher *et al.* 2002).

Eastern Chimpanzee *Pan troglodytes schweinfurthii* adult male.

Reproduction and Population Structure Cycling ♀♀ display exaggerated swelling of the anogenital tissue for approximately 10–12 days of a cycle that averages 35 days in length (Tutin 1980, Wallis 1997, Matsumoto-Oda 1999b, Emery Thompson 2005). Fully tumescent swelling size varies from 60 to 450 cm² in the dorsal area (Emery & Whitten 2003, Deschner *et al.* 2004); larger swellings are associated with higher fecundity and greater ♂ sexual interest (Emery & Whitten 2003, Deschner *et al.* 2004). Copulations are almost entirely confined to the period of maximal sexual swelling. Ovulation is most likely during the last six days of swelling; copulation rates with adult ♂♂ and possessive mating by dominant ♂♂ increase during this period (Hasegawa & Hiraiwa-Hasegawa 1990, Matsumoto-Oda 1999a, Deschner *et al.* 2003, Emery Thompson 2005). Sexual swellings sometimes also occur during pregnancy (Wallis & Goodall 1993).

Males have a long filiform penis (length when erect: mean = 14.4 cm, range 10–18 cm, n = 11, captivity, Dixson & Mundy 1994). Testes are also large (combined weight, captive specimens, mean = 119 g, n = 3; Schultz 1938; mean = 158 g, n = 10; Dixson & Mundy 1994) and capable of producing large quantities of highly motile sperm. A portion of ejaculate coagulates to form a sperm plug in the ♀ reproductive tract that can prevent another male’s sperm from entering (Dixson & Anderson 2002).

Breeding is not strictly seasonal in that births can occur in all months of the year. However, long-term reproductive patterns reveal seasonal variation in births and the number of oestrous ♀♀; timing of these peaks varies by population and cannot be strictly attributed to climatic features such as rainfall (Nishida *et al.* 1990, Wallis 2002). For example, at Gombe, higher copulation rates and two-thirds of conceptions occur in the drier half of the year (May–Oct); at Budongo, conceptions peak (50%) in the three driest months of the year (Dec–Feb), but reach their nadir (11%) in the second, milder dry season (Jun–Aug) (Wallis 2002). Conception timing and the number of oestrous ♀♀ is closely related to utilization of high-quality food resources, many of which are themselves seasonally unpredictable (Emery Thompson & Wrangham 2008a).

Mean gestation length is ca. 230 days both in captivity (range 202–261 days, $n = 56$; Yerkes 1943, Martin *et al.* 1978, Shimizu *et al.* 2003) and in the wild (range 207–259, $n = 42$; Wallis 1997, M. Emery Thompson pers. obs.). Females near term are often increasingly solitary and lethargic, and may withdraw from social contact in the peripartum period (Pusey *et al.* 2008). Obvious labour lasts between 40 minutes and 8 h and typically takes place in an arboreal nest (Keeling & Roberts 1972, Pusey *et al.* 2005a). In captivity, infants weigh ca. 1.7 kg (range 0.9–2.4 kg, $n = 57$) at birth (Leigh 1996, Hamada & Udono 2002). Most births are singletons, though twins do occur; survival of both twins is rare in the wild.

The average inter-birth interval following surviving offspring is ca. 5–6 years (range 23–132 months, $n = 288$ intervals; Emery Thompson *et al.* 2007b). The majority of the birth interval is spent in lactational amenorrhoea (Gombe: mean = 46 months, range 29–68 months, $n = 28$, Wallis 1997; Mahale: mean = 55 months, range = 33–74 months, $n = 38$, Nishida *et al.* 2003; Tai: mean = 23 months, range = 2–60, $n = 26$, Deschner & Boesch 2007).

Growth in captive ♀♀ continues until ca. 12 years and continues about 1 year longer in ♂♂, who grow faster and with a more apparent growth spurt in late adolescence (Gavan & Swindler 1966, Leigh & Shea 1995). Dental and postcranial analyses both illustrate that wild individuals grow markedly slower and mature later than captive individuals (Kimura & Hamada 1996, Zihlman *et al.* 2007).

Adolescence in both sexes entails changes in association, as individuals begin to travel in separate parties from their mothers. Females begin experiencing minor, irregular swellings at ca. eight years, with larger, cyclic swellings emerging at ca. 10–11 years (Wallis 1997, Goodall 1986, Nishida *et al.* 2003). During puberty, ♀♀ begin to associate more frequently with unrelated ♂♂, and transfer usually follows the first full swelling (Pusey 1979, 1980, Stumpf *et al.* 2009). First births occur at ca. 14 years (range = 9–23 years, Wallis 1997, Boesch & Boesch-Achermann 2000, Nishida *et al.* 2003, Sugiyama 2004). Puberty in ♂♂, beginning at approximately eight years, entails substantial growth in muscle mass and testicular volume, along with increases in aggressive behaviour and affiliation with adult ♂♂. By the end of adolescence, around 15 years, ♂♂ are dominant to all ♀♀ and juveniles.

Paternity studies suggest that high-ranking ♂♂ father the majority of offspring (Constable *et al.* 2001, Vigilant *et al.* 2001, Boesch *et al.* 2006, Newton-Fisher *et al.* 2010). This is likely due mostly to intensified competition and increased mate-guarding by dominant ♂♂ in the periovulatory period (Emery Thompson & Wrangham 2008b). Females also have considerable variance in reproductive success. Dominant ♀♀ at Gombe have higher birth and infant survival rates, and faster-maturing daughters, than do subordinate ♀♀ (Pusey *et al.* 1997). The location of a female's core area can also influence her reproductive rate as a result of uneven access to resources within heterogeneous habitats (Williams *et al.* 2002b, Emery Thompson *et al.* 2007a).

Life expectancy at birth is less than 15 years, with about 20% mortality in the first year; life expectancy at maturity (age 15 years) is another 15 years (Hill *et al.* 2001). Males have significantly higher mortality rates as infants and as adults (Hill *et al.* 2001).

Maximum life-span is probably >60 years in the wild (R. Wrangham pers. obs.), and some captive individuals (including 'Cheeta' of *Tarzan* fame) are thought to have reached their 70s. Births

to ♀♀ aged 40 years or over are noted from five wild populations with the eldest mother aged mid-50s (Emery Thompson *et al.* 2007b, Jones *et al.* 2010); the maximum age of birth exceeds 60 years in captivity (A. Halloran pers. comm.). Senescence and accumulating health deficits lead to declining birth rates in the fourth decade (Emery Thompson *et al.* 2007b), and advancing age is associated with longer cycles, shorter oestrus periods, and changes in pituitary hormone production (Graham 1979, Nishida *et al.* 2003, Videan *et al.* 2006). However, recent studies of birth rates and ovarian follicle depletion suggest that few Robust Chimpanzees reach menopause (Emery Thompson *et al.* 2007b, Jones *et al.* 2007). This may help explain why ♂ chimpanzees prefer older ♀♀ as mates (Muller *et al.* 2006).

Sex ratios at birth tend to be slightly female-biased (e.g. 1 : 1.27 at Tai, Boesch & Boesch-Achermann 2000; 1 : 1.14 at Mahale, Nishida *et al.* 1990; 1 : 1.04 at Gombe, Goodall 1983). Mature ♀♀ typically outnumber mature ♂♂, though this varies markedly between populations (e.g. 1 : 3 at Tai, Boesch & Boesch-Achermann 2000; 1 : 1.3 at Ngogo, Pepper *et al.* 1999) and within populations over time (between ca. 1 : 1 and 1 : 3 within 15 years at Gombe, Goodall 1983; and Budongo, Townsend *et al.* 2007). Adult:immature ratios show no consistent trends across populations (e.g. 1 : 1.3 during stable period at Tai, Boesch & Boesch-Achermann 2000; 1.3 : 1 at Ngogo, Pepper *et al.* 1999), a result of the variable proportion of mature ♂♂; ratios of adult ♀♀ to immatures range between 1 : 1 and 1 : 2 (Goodall 1983, Pepper *et al.* 1999, Boesch & Boesch-Achermann 2000).

Predators, Parasites and Diseases Most common causes of 'natural' mortality are respiratory diseases, diarrhoeal or wasting diseases, within-species aggression and, in some locations, predation (see next section, Goodall 1986, Hill *et al.* 2001, Nishida *et al.* 2003, Williams *et al.* 2008). Robust Chimpanzee skeletons exhibit high incidence of trauma, suggesting that falls from the canopy contribute significantly to morbidity and mortality (Jurmain 1997, Carter *et al.* 2008). In many locations, human activities, including hunting and accidental snaring, are major sources of mortality (see Conservation).

Many populations appear to be untroubled by natural predators, but Leopard attacks can be a major source of mortality in the Tai Forest, accounting for 39% of deaths during one 3-year time span (Boesch 1991). See also Henschel *et al.* (2005, 2011). A transient pride of Lions *Panthera leo* preyed upon at least six chimpanzees at Mahale (Tsukahara 1993). In a population of free-ranging, rehabilitant chimpanzees, predation by Nile Crocodiles *Crocodylus niloticus* is strongly suspected in at least two deaths (Brewer-Marsden *et al.* 2006).

Because Robust Chimpanzees are phylogenetically close to humans, they are highly susceptible to many human infectious diseases, including parasites and, especially, viruses. Many of these diseases are fatal or cause morbidity, with severe consequences for normal behaviour and reproduction (Wallis & Lee 1999, Butynski 2001, Köndgen *et al.* 2008).

Robust Chimpanzees are particularly susceptible to frequently deadly respiratory illnesses, especially pneumonia, influenza and tuberculosis (Goodall 1986, Wallis & Lee 1999, Nishida *et al.* 2003, Reynolds 2005, Köndgen *et al.* 2008). Various forms of diarrhoeal disease or wasting illnesses are commonly reported (Goodall 1986,

Nishida *et al.* 2003); severe peritonitis has been diagnosed in some of these individuals (D. Koehler in Goodall 1986, W. Boardman *et al.* in Reynolds 2005). Lethal outbreaks of scabies (A. Pusey in Wallis & Lee 1999), poliomyelitis (Goodall 1986), anthrax (Leendertz *et al.* 2004) and Ebola haemorrhagic fever (Formenty *et al.* 1999, Leroy *et al.* 2004) also occur. Ebola outbreaks have been particularly devastating (Ryan & Walsh 2011). A single outbreak in Tai Forest in 1994 killed 25% of the community under study (Formenty *et al.* 1999); an outbreak in the Congo probably killed the majority of chimpanzees in Lossi Sanctuary (Leroy *et al.* 2004, Bermejo *et al.* 2006). While transmission to humans can occur while handling dead chimpanzees, the rapid, high mortality of infected apes suggests they are not a reservoir of the virus (Formenty *et al.* 1999).

Pan t. troglodytes and *P. t. schweinfurthii* each harbours a distinct strain of the simian immunodeficiency virus (SIV) (Santiago *et al.* 2002, Nerrienet *et al.* 2005); viral phylogenetic analyses point to *P. t. troglodytes* as the reservoir for HIV-1 in humans with at least three independent transmission events (Gao *et al.* 1999, Keele *et al.* 2006). The handling and consumption of Robust Chimpanzees as bushmeat is the likely source of transmission and remains a continuing threat for transmission of rapidly evolving viruses (Hahn *et al.* 2000).

The wide range of intestinal parasites found in faecal samples of free-ranging individuals include hookworms (*Necator*), pinworms (*Probstmayria*, *Enterobius*), whipworms (*Trichuris*), other nematodes (esp. *Oesophagostomum*, *Strongyloides*, *Physaloptera*), amoeba (*Entamoeba*, *Iodamoeba*), thorny-headed worms (*Prosthenorchis*), tapeworms (*Bertiella*) and flagellates (esp. *Chilomastix*) (e.g. File *et al.* 1976, McGrew *et al.* 1989a, Ashford *et al.* 2000, Krief *et al.* 2005). *Giardia* infections also occur and are suspected to have arisen from contact with human faeces (Ashford *et al.* 2000). Ciliates (esp. *Troglodytella*) are routinely present and may be digestive symbionts (Collet *et al.* 1984). Malarial infection also occurs; the endemic *Plasmodium reichenowi* is a close relative of the *P. falciparum* parasite common in humans (Escalante & Ayala 1994).

Conservation IUCN Category (2012): Endangered. All subspecies Endangered. CITES (2012): Appendix 1.

Though Robust Chimpanzees are, in theory, protected from international trade by CITES regulation and from hunting by national laws in most or all range countries, unsustainable hunting for 'bushmeat' is widespread, particularly in West Africa and central Africa, and represents a primary threat to species survival. Commercial logging intensifies hunting pressure by providing roads that allow hunters to penetrate deep into the forest and extract meat for urban markets (Butynski 2001, Kormos *et al.* 2003, Walsh *et al.* 2003, Morgan *et al.* 2011). While eating of primates is taboo in much of East Africa, chimpanzees are killed while crop-raiding and by immigrant hunters and traders (Wrangham 2001). They are also incidental victims of snares and steel-jaw traps intended to capture other species. One-third of mature chimpanzees in the Budongo study community (Reynolds 2005) and 27% in Kanyawara (Wrangham 2000a) exhibit snare injuries ranging from missing finger segments to severely deformed or missing hands and feet; lethal infections also occur (Wrangham & Goldberg 1997, Reynolds 2005). Given that these field sites maintain active snare removal programmes, it is likely that animals at other unmonitored sites within reach of human hunters suffer even more snare-related injuries and deaths.

Habitat destruction and degradation due to agricultural expansion, timber extraction and mining threatens the long-term survival of Robust Chimpanzees and other forest-dependent species. Chimpanzees suffer these effects disproportionately due to large home-range requirements, strict territoriality and slow reproductive rate. Gallery forests are a key habitat in savanna areas as they serve as ecological corridors among otherwise fragmented populations (Fleury-Brugière & Brugière 2010).

When habitat loss puts apes in close proximity and frequent contact with human populations, outbreaks of tuberculosis, Ebola and other anthropogenic illnesses are serious threats (Wallis & Lee 1999, Butynski 2001).

Capture and trade of infant Robust Chimpanzees for use as pets, research and entertainment results in a large number of deaths due to trauma and malnourishment of captured infants and killing of associated chimpanzees during capture (Kormos *et al.* 2003). Efforts to confiscate and rehabilitate orphaned chimpanzees have quickly filled existing sanctuaries. While rehabilitated chimpanzees have shown prospects for survival in natural environments under limited monitoring (Goossens *et al.* 2005, Brewer-Marsden *et al.* 2006), reintroduction efforts are limited by funds as well as by the availability of appropriate habitat not already inhabited by chimpanzees or under threat by humans.

The combined pressures from human interference result in an inverse relationship between Robust Chimpanzee densities and proximity to major cities (Walsh *et al.* 2003). Habitat loss and fragmentation, and ever-increasing human populations, all bring more chimpanzees into close contact with humans (Wrangham 2001), one result of which can be extremely quick and severe decline of chimpanzee populations (Campbell *et al.* 2008a).

Measurements

Pan troglodytes schweinfurthii

HB (♂ ♂): 834 (770–925) mm, n = 7

Fr. Bonobo; Ger. Bonobo

Pan paniscus Schwarz, 1929. Rev. Zool. Bot. Afr. 16: 4. South of the upper Maringa R., 30 km south of Befale, DR Congo.Gracile Chimpanzee (Bonobo) *Pan paniscus* infant (left) and adult female (right).

Taxonomy Monotypic species. In 1929, Schwarz designated the Gracile Chimpanzee as a subspecies (*Pan satyrus paniscus*) of the Robust (or Common) Chimpanzee *Pan troglodytes*. Thompson (1997) suggested that the first description of the Gracile Chimpanzee occurred in 1887 (*Troglodytes niger* var. *marungensis* Noack 1887) from a specimen collected in the Marungu Mts, west of L. Tanganyika. DNA analyses have, however, identified the specimen as *Pan troglodytes schweinfurthii* (J. Eriksson pers. comm.). Coolidge (1933) raised the Gracile Chimpanzee to a species, *Pan paniscus*. The original common name was 'Pygmy Chimpanzee', but the term 'Bonobo' came into regular use after Heck (1939) reported what he mistakenly thought to be an indigenous term. Some primatologists now prefer the name 'Gracile Chimpanzee' as this is the most descriptive common name for *P. paniscus*. Debate continues over which of the several common names is most appropriate (Gijzen 1974, White 1996, Kortlandt 1997, Kano & Nishida 1999, Butynski 2001).

Studies on nuclear DNA (Reinartz 1997) and mitochondrial DNA (Eriksson *et al.* 2004) from wild-born specimens show varying levels of genetic structuring among the eastern, northern and west-central populations of *P. paniscus*. Likely barriers to gene flow are the large rivers that transverse the species' range, especially the Lomami R. in the east (Eriksson *et al.* 2004). In captivity, a *P. paniscus* ♂ and *P. troglodytes* ♀ have produced offspring but it is not yet known whether these are fertile (Vervaecke & Van Elsacker 1992). Synonyms: none. Chromosome number: 2n = 48 (Chiarelli 1962a) exhibiting species distinctive karyotypic patterns (Gijzen 1974, Bogart & Benirschke 1977).

Description A black, forest-dwelling great ape that resembles *P. troglodytes* but is more gracile (Jenkins 1990). Sexes alike in colour. In the

Lateral, palatal and dorsal views of skull of Gracile Chimpanzee (Bonobo)
Pan paniscus adult male.

wild, adult ♀ ♀ about 73% as heavy as adult ♂ ♂. Females in captivity average 82% of males' weight. This is comparable to body weight dimorphism in the Eastern Chimpanzee *P. t. schweinfurthii* and humans (Parrish 1996). Despite its common name 'Pygmy Chimpanzee', *P. paniscus* is not a diminutive form of chimpanzee; the range in body size and weight overlaps (up to 85%) that of *P. t. schweinfurthii*. Head rounded with small brow. Face black, even in infants. Lips light to pink, contrasting with face. Ears small, close to sides of the head. Head hair flattened with long horizontal tufts of hair surrounding the face. Body covered by long silky black hair (except for face, hands, feet and genitalia). Anal tuft white. Upper molar rows curved. Features such as smaller head, less prominent canine teeth, white tail tuft and low degree of sexual dimorphism are considered by some primatologists to be juvenile characteristics indicating paedomorphic evolution (Gijzen 1974, Kuroda 1979, 1980, Kano 1992).

Geographic Variation None recorded.

Similar Species None within the known geographic range of *P. paniscus*.

Pan troglodytes. Parapatric with *P. paniscus*. More robust, ca.15% heavier. Head large, vault flattened, face prognathic, brow ridge well developed. Skull length greater (♂ ♂: mean = 198 mm, range = 182–213 mm, n = 23; ♀ ♀: mean = 186 mm, range

Pan paniscus

= 172–198 mm, n = 19) (Jenkins 1990). Mouth region not contrastingly pink. Chin beard noticeably white in adults. Anal tuft black in subadults and adults. Face pink at birth turning black by maturity. Upper molar rows parallel.

Distribution Endemic to central Congo Basin, DR Congo. Rainforest BZ. Distribution delimited by two large river systems: Congo-Lualaba River System on west, north-west, north and east, and Kwa-Kasai-Sankuru River System on south-west and south. Limits of distribution uncertain south-east of Sankuru and Lomami headwaters. Current distribution poorly known as surveys not conducted over most of the species' range and most records >20 years old. Today *P. paniscus* has a patchy, highly fragmented distribution (Butynski 2001). Rare or absent where human population density is high (Kano 1984, 1992, Reinartz *et al.* 2006). Surveys in the central portion of the range confirm presence at: North and South Sectors of Salonga N. P. (Reinartz 2003, Blake 2005, Reinartz *et al.* 2006, 2008, Grossman *et al.* 2008), Lui Kotal on the western edge of Salonga N. P. (Hohmann & Fruth 2003c, Mohneke & Fruth 2008), Wamba (Furuichi & Mwanza 2003, Idani *et al.* 2008), Lomako (Dupain *et al.* 2003), Lukuru (Thompson & Tshina-tshina 2003), Kokolopori north-east of Wamba (Thompson *et al.* 2003), and south of Lokoro (J. Eriksson pers. comm.). In the eastern extent of the range, *P. Paniscus* occurs between the Lomami R. and Congo-Lualaba R. (Hohmann & Eriksson 2000, Vosper *et al.* 2007). Five remnant populations have been confirmed at the extreme western end of the range: three between Lac Tumba and Lac Mai Ndombe (Mwanza *et al.* 2003, Inogwabini *et al.* 2007, 2008), and two between the Congo R. and Kwa-Kasai R. (Inogwabini *et al.* 2007).

Habitat Mosaic of low, dry, semi-deciduous forest punctuated by monotypic stands of primary evergreen forest, swamp forest and secondary forest (Evrard 1968, Boubli *et al.* 2004). In the drier and higher elevations of the southern portion of the range, the forest is

increasingly interposed by grasslands. Optimal habitat is dense, humid, mixed mature, semi-deciduous lowland forest on *terra firma* soils with herbaceous understorey (Marantaceae, Zingiberaceae) (Kano 1983, Kano & Mulavwa 1984, Kortlandt 1995, Reinartz *et al.* 2006). *Pan paniscus* can, however, utilize a wide variety of habitat types, including young and old secondary forest, grassland, marsh grasslands, seasonally inundated and swamp forests, and agriculture (Sabater Pi & Vea 1990, Thompson-Handler *et al.* 1995, Hashimoto *et al.* 1997). Altitudinal range: 300–565 m. Annual temperature range: 19–30°C. Annual rainfall range: 1670–2210 mm (Kano 1992, Thompson 1997).

Abundance The majority of the survey data for *P. paniscus* are two decades old and vast areas of the potential range, estimated at 343,000 km² (Butynski 2001), have never been surveyed (Thompson-Handler *et al.* 1995, Dupain & Van Elsacker 2001b). Population estimates are based on density estimates ranging from 0.25 ind/km² (Thompson 1997) to 0.40 ind/km² (Kano 1984) and extrapolated to the probable occupied area. Because of widespread hunting by humans and loss of habitat, the area occupied by *P. paniscus* at present is believed to be far less than the potential historical range. The most recent estimates are that there are between 20,000 and 50,000 individuals (Butynski 2001, Dupain & Van Elsacker 2001b).

Adaptations Semi-terrestrial and diurnal. *Pan paniscus* is considered more of a true forest ape than *P. troglodytes* and, as such, many of the morphological characters that separate *P. paniscus* from *P. troglodytes* are described as adaptations to differences in the habitats they occupy (Susman 1984a). Compared to *P. troglodytes*, *P. paniscus* has narrower shoulders, chest and hips, longer legs, nearly equal leg and arm lengths, a greater proportion of leg to body mass resulting in a lower centre of gravity, and a higher propensity to walk bipedally (Zihlman 1980, 1996, Susman 1984a, Thompson 2002). However, recent studies that extend the range of *P. paniscus* into drier forest/savanna mosaic habitats challenge this assumption (Thompson 2002).

When arboreal, *P. paniscus* engages in more leaping and diving types of movements than does *P. troglodytes* (Doran 1996). Whether or not *P. paniscus* is more arboreal than *P. troglodytes*, as once believed, is open to question. *Pan paniscus* is said to engage in bipedal behaviour more often than *P. troglodytes*, especially when carrying objects, entering water, to peer over tall grasses and during friendly social behaviour (whereas *P. troglodytes* is more likely to engage in bipedalism during aggressive interactions). Webbing that sometimes occurs between the toes of *P. paniscus* may be related to their willingness to enter water to forage. Molars of *P. paniscus* are more flattened than those of *P. troglodytes*, providing a greater grinding surface area. This may allow higher consumption rates of terrestrial herbaceous vegetation by *P. paniscus*, which may be associated with decreased individual feeding competition and larger social groups (Malenky & Stiles 1991). However, measurements of mandibular traits do not indicate that *P. paniscus* is necessarily adapted to a coarser and more fibrous diet than *P. troglodytes* (Taylor 2002).

Tool-using behaviour of *P. paniscus* differs from that of *P. troglodytes* (Hohmann & Fruth 2003a). The ability of *P. paniscus* to make and use tools is clear from observations of the extensive use of tools by captive individuals (Takeshita & Walraven 1996), as well as the complexity of their manipulation of objects in the wild during nest-building and arboreal bridging (Fruth & Hohmann 1993, Ingmanson

1996). *Pan paniscus* rarely use tools for food acquisition. However, they do incorporate tools into social communication, such as branch-dragging by adults (see Social and Reproductive Behaviour), or by infants during social play (Ingmanson 1988, 1996). In addition, *P. paniscus* occasionally makes and uses napkins, fly swatters, tooth picks and other items, and drapes vegetation over the head and shoulders to provide protection during heavy rains (Kano 1982, Fruth & Hohmann 1993, Ingmanson 1996).

Foraging and Food Omnivorous. *Pan paniscus* spend up to 40% of their time foraging/feeding. Most foraging occurs within groups while in trees (White 1989). At Lomako and Wamba, group size is positively correlated with food patch size and food abundance (White 1989, Kano 1992, Mulavwa *et al.* 2008, Furuichi *et al.* 2008), but studies in Salonga do not reveal any correlation (Hohmann *et al.* 2006).

Fruits, located most often in the canopy, constitute 54–83% of the diet. Fruits of Apocynaceae vines, *Pancovia*, *Dialium*, *Polyalthia* and *Annonidium*, are particularly common in the diet. Leaves comprise 15–21% (Caesalpinaceae, Papilionaceae) of the diet, and seeds, piths, shoots and animals constitute the remainder (Badrian & Malenky 1984, Kano & Mulavwa 1984, White 1992, Idani *et al.* 1994). Diet is high in protein, low in tannins and, compared to *P. troglodytes*, is relatively low in sugar and crude fat (Hohmann *et al.* 2006). Terrestrial herbaceous vegetation (predominantly Marantaceae) is an important source of protein (Malenky & Stiles 1991). When foraging on herbs, *P. paniscus* quietly splinter off into subgroups in search of shoots and petioles of *Haumania liebrechtsiana*, *Megaphrynium macrostachyum* and *Aframomum* spp. Fruit consumption (and species consumed) varies according to availability (Kano & Mulavwa 1984), whereas Marantaceae herbs are utilized at approximately the same levels throughout the year (Malenky & Stiles 1991). *Pan paniscus* occasionally eat marshland herbs and grasses (Uehara 1990), and sub-aquatic algae and vegetation (Thompson 2002). Coprophagy is practiced but is rare (Sakamaki 2010).

Although ‘cooperative hunting’ has never been observed, duikers (*Cephalophus* spp. and *Philantomba monticola*), anomalures *Anomalurus* spp., shrews, snakes and many invertebrate species are eaten (Ihobe 1992, Kano 1992, Hohmann & Fruth 1993). Patterns of meat eating, meat sharing and prey search image appear to vary among populations (Hohmann & Fruth 2003a). *Pan paniscus* travel 0.4–6.0 km per day while foraging in forest habitat (Kano 1992). Once a food patch is located, group feeding is often preceded by vocalizations and animated movements as food is collected and consumed (Kuroda 1980, Kano 1992). Food begging and sharing are frequent (Fruth & Hohmann 2002). Adults may reach out a hand slowly toward the possessor’s food, and may touch and grin. The possessor responds either by ignoring or by giving the beggar a portion of the food. Copulations between ♂♂ and ♀♀, as well as homosexual encounters, are frequent during feeding times (e.g. ♀♀ engage in intensive genito-genital rubbing).

Social and Reproductive Behaviour Social. As for *P. troglodytes*, the community or unit-group is the largest mixed-sex social unit, whose members maintain a closed social network. Community’s members share a discrete, large home-range (22–60 km²), but extensive overlap between communities (40–66%) may exist and there may be seasonal and yearly variations in home-ranges (Van Elsacker *et al.* 1995). Communities contain 10–22 individuals

Distinctive proportions of Gracile Chimpanzee (Bonobo) *Pan paniscus*; longer limbs and more slender than Robust Chimpanzee *Pan troglodytes* (gouache from photographs).

in Lomako and 30–120 individuals in Wamba (Kano & Mulavwa 1984). There are almost equal numbers of adult ♂♂ and adult ♀♀ in Wamba (Kano 1992), whereas in at least one Lomako community, the adult sex ratio is strongly female-biased (Fruth 1995, Hohmann *et al.* 1999). Entire communities come together less often at Lomako than at Wamba (Kano 1992, F. J. White 1992, Fruth 1995). Through fission and fusion, membership of parties changes in varying degrees within days, hours or even minutes. By contrast, membership of communities changes only with the birth or death of members, or permanent inter-group transfer.

Smallest functional unit of *P. paniscus* daily life is the party, defined as individuals remaining in sustained proximity to one another, or

within earshot of each other (Hashimoto *et al.* 2003), or travelling and foraging together (Van Elsacker *et al.* 1995). Larger, more stable parties are seen in Wamba, with on average 13 individuals (Kano 1992), than in Lomako, with about five individuals on average (1–16) (Hohmann & Fruth 2002). Parties usually contain mature individuals of both sexes, with more ♀♀ than ♂♂ (Kano 1982, F. J. White 1988, Fruth 1995, Hohmann & Fruth 2002).

Pan paniscus lives in fission–fusion communities or unit-groups (Kano 1992). Unit-groups have recognizable members, with ♀ transfer out of, and ♂ residency in, the natal group. A possible case of fusion of unit-groups was observed at Wamba following population disruption related to human activities (Hashimoto *et al.*

2008). In comparison to *P. troglodytes* in East Africa, *P. paniscus* unit groups tend to be more cohesive and larger. Strong social bonds exist among ♀♀ and ♂♂, and among ♀♀ (Furuichi 1997, Furuichi *et al.* 1998, Hohmann *et al.* 1999, Hohmann & Fruth 2002, Stevens *et al.* 2006). Relative to *P. troglodytes*, *P. paniscus* has low levels of aggression, both between and within unit groups. However, violent acts do sometimes occur during encounters of different unit groups (Hohmann & Fruth 2002). Males and ♀♀ both form dominance hierarchies within the group (Furuichi 1997, Vervaecke *et al.* 2000a, Stevens *et al.* 2007). Unrelated ♀♀ form social bonds with each other and support each other against aggression by ♂♂ (Kano 1992, Parrish 1996, Vervaecke *et al.* 2000b). The bond between mothers and their adult sons is very strong, long lasting and may play a role in the dominance hierarchy. In one unit-group at Wamba, ♂♂ rarely became alpha-male until their mother achieved alpha status (Kano 1992, Furuichi 1997).

Sexual behaviour occurs in almost all age–sex categories, including infants (Hashimoto 1997), and plays an important role in the non-reproductive social cohesion of a group, i.e. maintaining male–female coexistence (Kano 1992). Compared with *P. troglodytes*, *P. paniscus* ♀♀ exhibit sexual swellings that extend beyond the ovulatory period (Thompson-Handler 1990, Heistermann *et al.* 1996, Vervaecke 1999, Furuichi & Hashimoto 2002). Adult copulations are not limited to time of ovulation, but the majority of copulations occur at maximum swelling, a period that is loosely linked to the fertile phase (Furuichi 1987, Kano 1989, Vervaecke 1999, Reichert *et al.* 2002). Takahata *et al.* (1996) showed that adult *P. paniscus* ♂♂ at Wamba do not copulate more than adult *P. troglodytes* ♂♂ at Mahale (*P. paniscus*: 0.10–0.21/h; *P. troglodytes*: 0.20–0.29/h), that adolescent *P. paniscus* ♂♂ copulate less frequent than adolescent *P. troglodytes* ♂♂, and that adult *P. paniscus* ♀♀ copulate at an equal rate to adult *P. troglodytes* ♀♀. Only adolescent *P. paniscus* ♀♀ copulate more frequently than adolescent *P. troglodytes* ♀♀. Copulations also occur between adult ♀♀ and juvenile ♂♂, though rarely between mothers and sons (Kano 1992). Adult ♂♂ mount and thrust, and occasionally penetrate juvenile ♀♀, but the frequency of penetration increases as ♀♀ reach adolescence and begin exhibiting sexual swellings. Adult ♂♂ also use genital stimulation toward infants as an apparent means of soothing them (Hashimoto 1997). Sexual contact between adult ♂♂ takes the form of mounting, often reciprocally, rump–rump touching and, on rare occasions, penile fencing.

Sexual activities between adult ♀♀ have been much studied (Hohmann & Fruth 2002, 2003b, Fruth & Hohmann 2006). Genito-genital (G-G) rubbing occurs when two ♀♀ embrace ventrally and move their hips laterally, rubbing the labia and clitoris together (Kano 1992). Females engage in G-G rubbing during periods of excitement, such as greeting and feeding. This behaviour may serve as a mechanism for social bonding between the ♀♀, allowing them to cooperate and share feeding spaces without aggression. Young ♀♀ who first enter a group quickly seek out the dominant ♀♀ and engage in G-G rubbing (Idani 1991).

Kuroda (1984) describes the use of a rocking gesture by free-living *P. paniscus* to request closer proximity to one another. Ingmanson (1996) describes the use of branch-dragging to convey complex information related to coordinating group movement, such as direction and timing of movement.

Reproduction and Population Structure Most of the demographic data for *P. paniscus* come from Wamba, where free-living *P. paniscus* have been food provisioned and studied for 20 years (Kano 1992, Furuichi *et al.* 1998). In both species of *Pan*, mature ♀♀ have continuous cyclic ovarian activity accompanied by overt swelling of the anus and labia, reaching maximal volume and turgidity in the period around ovulation. In wild *P. paniscus*, swelling cycles and menarche first occur at 9–12 years of age (Kano 1992); in captivity, they occur, on average, at 8.2 years (range = 6.0–11.2 years, *n* = 9; Thompson-Handler 1990). Onset of menarche is generally followed by 2–3 years of adolescent sterility (Van Elsacker *et al.* 1997). In *P. paniscus*, the period of swelling is longer than the window of fertility, and the end of the period of maximal swelling and the timing of ovulation are weakly associated (Heistermann *et al.* 1996, Reichert *et al.* 2002). Wild adult ♀♀ at Wamba showed maximal swelling during 48% of the cycle (Kano 1992), while wild adolescent ♀♀ showed maximal swelling most of the time (Kano 1984). Swelling in *P. paniscus* may conceal rather than signal ovulation (Kano 1992, Reichert *et al.* 2002) leading to longer periods of ♀ sexual receptivity in *P. paniscus* than in *P. troglodytes* (Thompson-Handler *et al.* 1984, Furuichi & Hashimoto 2002).

In wild ♀♀, the mean interval between two successive maximal swellings is 42 days (range = 37–49, *n* = 3; Furuichi 1987). In captivity, the mean length of the menstrual cycle is 34 days (range = 31–51 days, *n* = 6; Heistermann *et al.* 1996). If conception does not occur, there are 1–3 days with slight vaginal bleeding (Vervaecke 1999, Vervaecke *et al.* 1999). In contrast to *P. troglodytes*, where the labia are entirely flat during non-fertile phases of a normal cycle, the labia are flat only in some captive adults during the latter half of pregnancy and/or early lactation (Vervaecke 1999). Captive ♂♂ reach sexual maturity at an average age of ca. seven years (Thompson-Handler 1990). However, DNA analyses confirm the paternity of captive ♂♂ as young as five years of age (Leus *et al.* 2003, Reinartz *et al.* 2003). In captivity, gestation averages 234 days (range = 229–238, *n* = 3) from hormonally detected ovulation, or 246 days (range = 227–277, *n* = 11) from last menses (Harvey 1997). Single young are most frequent; twins are exceptional. Newborns weigh ca. 1.5 kg (range = 1.2–1.8, *n* = 13; Mills *et al.* 1997).

Age of ♀♀ at first birth ca. 12–13 years in the wild (Kano 1992), and 14.2 years (*n* = 6) (Kuroda 1989) and 10.5 years in captivity (8–15 years, *n* = 20; De Lathouwers & Van Elsacker 2003, 2005, Reinartz *et al.* 2003). At Wamba, mean birth interval is 4.8 years (*n* = 28; Furuichi *et al.* 1998). At Lomako, however, the median birth interval may be as long as nine years (B. Fruth pers. comm. in Knott 2001). Mean birth interval in captivity is 4.93 years (range = 1.88–7.60, *n* = 34; De Lathouwers & Van Elsacker 2003, 2005). The infant is generally weaned at the birth of the next sibling. In the wild, births occur throughout the year with a peak (57%) in Mar–May (*n* = 15) and a low period (43%) from Oct–Feb (Furuichi *et al.* 1998). Furuichi *et al.* (1998) reported a 4.5% first-year mortality for infants at Wamba (*n* = 22 infants); however, this rate is the lowest reported for any great ape and may be a sampling artefact. In captivity, 16% of *P. paniscus* infants are stillborn (De Lathouwers & Van Elsacker 2003). Of live born infants, 21% die during the first year (*n* = 155 infants) (Reinartz *et al.* 2003) and 84% of live-born offspring survive until five years of age (*n* = 51) (De Lathouwers & Van Elsacker 2003, 2005, Reinartz *et al.* 2003).

Sex ratios:

♂ : ♀ ratio: 1 : 1.1 (n = 70; Kitamura 1983). 1 : 1.3 (n = 69; Kuroda 1979). 1 : 2.1 (n = 22) for Group 1; 1 : 1.6 (n = 23) for Group 2; 1 : 1.1 (n = 9) for Group 3 (White 1988).

Adult ♂ : adult ♀ ratio: 1 : 1.1 (n = 31; Kano 1982). 1.1 : 1 (n = 32) for Group 1; 1 : 0.9 (n = 39) for Group 2 (Kano 1987).

Adolescent ♂ : adolescent ♀ ratio: 1 : 1.6 (n = 13; Kano 1982). 1 : 1.6 (n = 18) for Group 2 (Kano 1987). In captivity, no sex ratio bias at birth (64 : 73 : 4 = ♂ : ♀ : unknown; n = 141; De Lathouwers 2004).

Females in the wild typically emigrate from their natal group at ca. 7–8 years. Males remain in their natal group and retain a lifelong bond with their mother (Kano 1992). Maximal life-span is unknown for wild *P. paniscus*, and is >50 years in captivity (Leus *et al.* 2003, Reinartz *et al.* 2003).

Predators, Parasites and Diseases Except where local taboos against hunting still exist, humans are the main predator of *P. paniscus* throughout the range, and present rates of off-take are unsustainable (Thompson-Handler *et al.* 1995, Butynski 2001, Dupain & Van Elsacker 2001a, Reinartz *et al.* 2006, Hart *et al.* 2008, Idani *et al.* 2008). Natural predators probably include Leopards, African Crowned Eagles *Stephanoaetus coronatus* (Horn 1980, Kano 1983), Nile Crocodiles *Crocodylus niloticus* and Central African Rock Pythons *Python sebae*.

Because of its close genetic relationship to humans and frequent close contact with humans, *P. paniscus* is highly susceptible to numerous human diseases, including the following (reviewed Butynski 2001, Woodford *et al.* 2002): colds, pneumonia, influenza, tuberculosis, measles, mumps, hepatitis A and B, bacterial meningitis, diphtheria, yellow fever, whooping cough, poliomyelitis, encephalomyocarditis, and haemorrhagic fevers such as Ebola. Thus, the species is vulnerable to the diseases/epidemics manifested in surrounding human populations. Near Wamba *P. paniscus* has displayed leprosy- and herpes-like lesions, and a high incidence of limb abnormalities (Kano 1992). Internal parasites in wild *P. paniscus* include *Troglodytella* sp., *Capillaria* sp., *Trichuris* sp., *Strongyloides* sp., dicrocoeliid eggs and strongylid eggs resembling hookworm eggs (Hasegawa *et al.* 1983). Illnesses in newly orphaned *P. paniscus* commonly include severe diarrhoea (attributed to or exacerbated by parasites), infections (gram-negative bacteria), gum disease, severe psychological stress, immune suppression and life-threatening malnutrition (Messinger & Bi-Shamamba 1997, D. Messinger pers. comm.). Their parasites include *Ancylostoma* spp., *Trichomonas intestinalis*, *Strongyloides* spp., *Entamoeba histolytica*, whipworms, tapeworms, mites and lice (Messinger & Bi-Shamamba 1997, Butynski 2001). Captives are sensitive to respiratory infections and laryngeal air sacculitis (Rietschel & Kleeschulte 1989).

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix I.

Population decline is primarily the result of unsustainable hunting due to the combination of several key factors, including a growing

bushmeat trade (Butynski 2001, Dupain & Van Elsacker 2001a, Rose *et al.* 2003), the disappearance of traditional taboos against eating *P. paniscus* (Furuichi & Mwanza 2003), the uncontrolled infusion of firearms into the region combined with the occupation of once-remote areas by soldiers and displaced people during civil wars (Draulans & Van Krunkelsven 2002, Amman *et al.* 2003) and the lack of law enforcement. Formerly dense populations of *P. paniscus* (e.g. Lomako) may have suffered a decline of up to 75% as a consequence of the civil war and concomitant increases in hunting (Amman *et al.* 2003, Dupain *et al.* 2003). Trade in orphans for pets is a continuing problem (C. André pers. comm.) Massive habitat destruction stems from logging and agriculture. While logging in DR Congo has not yet reached the levels of other central African countries (Wolfire *et al.* 1998), where logging occurs it has caused habitat destruction, population fragmentation and a dramatic increase in bushmeat hunting (Butynski 2001, Dupain & Van Elsacker 2001a, Rose *et al.* 2003).

There is only one national park designated for *P. paniscus* protection, the Salonga N. P. It is not yet clear whether this Park harbours a viable population (Reinartz *et al.* 2006). Conservation priorities are: (1) to assess the distribution/abundance of *P. paniscus* in order to identify major populations; (2) to determine the degree of population fragmentation and the ecological factors affecting distribution; and (3) to direct resources toward law enforcement, support for protected areas and creation of additional protected areas.

In captivity, *P. paniscus* has the smallest population of all the great ape species: 168 individuals worldwide (excluding African sanctuaries). With intensive genetic and demographic management, the captive population can be self-sustaining for up to five generations (Reinartz *et al.* 2003).

Tribe HOMININI

Hominins

Hominini Gray, 1825. *Annals of Philosophy* 10: 338.

An international scramble to find human and proto-human fossils, especially in Africa, has begun to flesh out the concrete, physical evidence for human evolution. Tracing the past fortunes of the Hominini, therefore, promises to become one of the best documented, and certainly the single most arresting, example of the process that has given rise not only to us but to all the astonishing diversity of life on Earth. It is this that makes the Hominini one of the most fascinating taxa among African mammals.

By the same token, this is a fast-moving field of enquiry and the wide scatter and fragmentary nature of most fossil hominins creates difficulties when it comes to listing and describing the substantial number of fossil forms belonging to this tribe.

The following genera are commonly recognized in the Hominini: *Sahelanthropus* Brunet *et al.*, 2002 ('Toumai'). Late Miocene (7–6 mya). Resemblances with gorillas *Gorilla* spp., chimpanzees *Pan* spp. and hominins suggest it might predate hominin emergence. While

possibly not Hominini, *Sahelanthropus* is listed here because it is a highly significant fossil for our understanding of hominin emergence.

Orrorin Senut *et al.*, 2001 (Millennium Human Ancestor). Late Miocene (ca. 6 mya).

Ardipithecus White *et al.*, 1995 (Ground Apes). Late Miocene to early Pliocene (5.8–4.4 mya). Also see White *et al.* (1994, 2009).

Praeanthropus Weinert, 1950 ('Lucies'). Early to mid-Pliocene (4.2–3.0 mya).

Australopithecus Dart, 1925 (Southern Ape and South Africa Man-ape). Mid- to late Pliocene (4.2–2.0 mya).

Kenyanthropus Leakey *et al.*, 1995 (Kenya Flat-face Man). Mid-Pliocene (ca. 3.5 mya).

Paranthropus Broom, 1938 ('Nutcracker Man'). Mid-Pliocene to early Pleistocene (2.6–1.4 mya).

Homo Linnaeus, 1758 (Early to Modern Humans). Mid-Pliocene (2.4 mya) to present day.

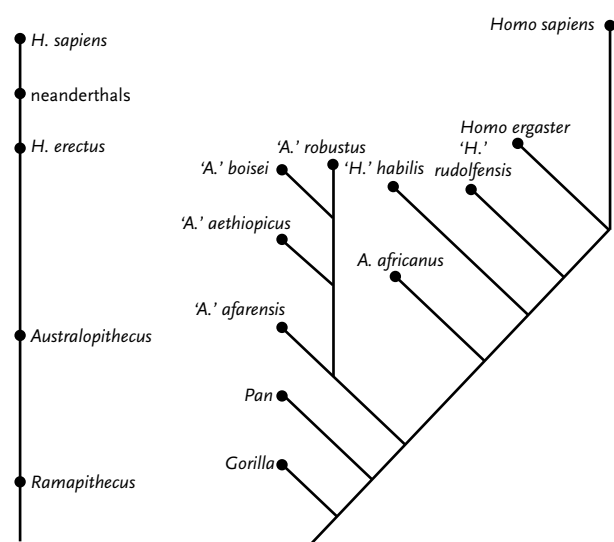

The certainty of ancestors – the uncertainty of ancestry (from Kingdon 2003).

Changing perceptions of Human ancestry. Left: Loring Brace (1971). Centre: Olson (1981)/Falk (1988). Right: Hominin genealogy according to the 'Evolution by Basin Model' (modified after Kingdon 2003).

This classification includes at least three paraphyletic genera, that are presumed to incorporate successive lineal ancestors of *Homo*. There has, however, been much reshuffling of species from one genus to another, especially as some authorities do not recognize *Paranthropus* as separate from *Australopithecus*, and yet others think that a further genus, *Praeanthropus*, may be distinct from *Australopithecus* (Strait *et al.* 1997, Kingdon 2003). Recently, it has been proposed that all the described species in the Hominini should be incorporated into a single genus, *Homo*, which of course would lead to the tribe itself being redundant except that it does serve to separate bipedal humans from quadrupedal apes.

One must avoid the mistake of assuming that human evolution was unilineal, one species succeeding another in unbroken advance. This assumption, in as far as it still survives, is a legacy of the historical origins of the subject itself – among (mainly medically trained) anatomists, not among evolutionary biologists. It is only since the 1970s that it has become clearer that, just like most other mammals whose fossil record is at all well-known, multiple species of hominins arose, coexisted for a while and mostly became extinct without issue: a bush not a ladder.

The characteristics of the Hominini include highly manipulative hands, specializations for habitual upright posture, bipedal locomotion, and extreme reduction of the canine teeth (involving a particular shortening of the pointed tip, but also raising of the mesial and distal 'shoulders', to render the canine almost incisiform in both jaws). An intermediate stage of the development of the postural/locomotor specializations appears to be illustrated by *Ororin*; in which canine reduction (including reduction of sexual dimorphism) can be seen in the stepwise sequence *Ardipithecus kadabba* – *Ardipithecus ramidus* – *Australopithecus* (*Praeanthropus*) *anamensis* – *Australopithecus* (*Praeanthropus*) *afarensis* (using 'traditional' generic designations). While intense interest in the origins of our own species has led to extraordinary squabbles, taxonomic instability, and disagreements on phylogeny based on anatomical salami-slicing, there is no doubt that it has led to the

human fossil record being one of the best represented (and, despite all the controversies, best understood) of any mammal lineage. Dated phylogenetic trees serve to illustrate both the growth in the number of taxa thought to be distinct, and significant conceptual progress from the 'ladder' model of evolution (Loring Brace 1971) to the much more complex and bushy trees of contemporary thinking. Given that the fossil record is always incomplete, all trees are essentially provisional and tentative, and can be seen as steps in a series of successive approximations.

Beyond the number of genera, note the geographical range of fossils and presumed habitats of this family. Prior to some 2.5–2.0 mya (after the emergence of the genus *Homo*), all representatives of the Hominini appear to have been African. With few exceptions, these Pliocene hominins are known from just two regions: the Rift Valley of eastern and north-eastern Africa, and the caves of the Transvaal highveldt. Throughout their evolutionary history, Hominini have been typical of south-eastern Africa. Partly the reflection of a paucity of fossil sites, this bias shows up in numerous other organisms and supports the supposition that the primary split between proto-hominins and quadrupedal apes had a geographic and ecological base (Kingdon 1993, 2003).

What caused only one of the lineages of hominins listed above (i.e. *Homo*) to persist and survive? Part of the answer must extend back to an exploration of how the earliest ancestors of humans might have responded to some of the challenges posed by the environment of their region/ecology of origin. Among the influential modifications made in response to specific local ecologies and climates, we can infer adjustments in behaviours such as social organization and modes of communication. Eventually, certain acquired characteristics allowed *Homo* to spread and out-compete other hominins. Tracing the regional specifics of adaptation, therefore, remains a central strand in the study of hominin and human prehistory. As such, discovering exactly where the human lineage emerged within the vastness of Africa is a quest

of the greatest importance and gives a special value to conserving the full spectrum of African habitats and species.

Implied habitats favoured by early hominins are generally wooded and close to water, although some sites represent more closed forest, later ones were adjacent to more open plains. Diets (known as far as the early stages are concerned from stable isotope analysis) were, perhaps, largely vegetarian, including both fruits and underground parts. The latter is clearly consistent with the terrestriality of hominins but also implies the means to excavate. The unearthing or capture of small but numerous food items is implied by hominins having highly manipulative hands (possibly assisted on occasion by crude digging tools). Termite feeding has been convincingly proposed and it can be argued that sustained use of the hands for collecting terrestrial and sub-terrestrial mini-foods was the initial driving factor in the emergence of hominins (Kingdon 2003). Because apes, as well as other primates, prefer a seated position while foraging over prolonged periods for small items on or under the ground, it is reasonable to suppose that this 'squat-foraging' posture (as in Geladas *Theropithecus gelada*) became the norm for the earliest (probably south-eastern African) ground apes. The habitual adoption of such a foraging posture has substantial long term implications inasmuch as natural selection is likely to favour a number of anatomical changes. A stable squatting position on the ground favours flatter, broader feet that can provide a firmer platform for long-armed, mobile forequarters. The latter would have been inhibited because the rib cage of a typical, top-heavy, ape is closely tied to the broad, high blades of the pelvis and the lumbar region is exceptionally weak and inflexible. The fossil record confirms that the development of a functional articulation between the thorax and the pelvis was one of the earliest innovations of hominins. The rib cage became narrower, shorter and flatter (from front to back) while the iliac blades of the pelvis retracted to form a more compact structure that was no longer integrated into a single body mass. Elongation

and strengthening of the lumbar region (including an increase in the number and robustness of lumbar vertebrae) allowed a 'waist' to develop. The most plausible rationale for this change is that a seated ape needs to twist and flex its body during squat-foraging. Another implication for this behaviour becoming habitual is that selection would favour the head becoming more vertically positioned above, rather than oblique to the spinal column. All these changes in early hominins are commonly correlated with bipedalism but can be even more strongly argued as evolutionary adaptations to squat-foraging.

If an intensification of terrestrial foraging *with the hands* was the motor of Hominin evolution then a seated position for this activity is demonstrably necessary. Previous difficulties for a quadruped attempting to rear up on two legs became negligible once the entire body had become rebalanced (more or less vertically) above a ground-based pelvic basin. Corroboration for a squat-foraging phase in hominin evolution can be inferred from the pelvis, spinal column, skull and feet of the earliest known and best-documented hominin, *Ardipithecus ramidus*. This species retained long ape-like arms but had a basin-like pelvis, a strong lumbar column with an increased number of larger vertebrae, a typically hominin foramen magnum and, surprisingly, the long legs of a slow but habitual walker (Lovejoy *et al.* 2009). Emerging from the inner aspect of their broad, splayed feet were rigid, strut-like 'big toes'. While such feet were crudely functional for both tree-climbing and walking their obviously platform-like structure was somewhat anomalous for both activities. Such a structure not only suggested a squatting ancestry but implied that squatting (on both flat ground and on branches) was still a functional activity for this long-armed, big handed terrestrial biped. It can now be argued that the combination of

features displayed by *A. ramidus* renders previous models involving any sort of direct leap from quadrupedalism to bipedalism obsolete.

Among later hominins, legs became longer still (and, eventually, arms shortened) and some species moved out into more open habitats. Large mammals began to be hunted by some hominins, having first, perhaps, been scavenged. As early hominins adapted to various and wider ranges of habitat, necessary changes in behaviour induced strong selection for appropriate incremental changes in physiology and morphology. At least three major lineages can be identified and as many as six or more hominin species might have existed in and out of Africa at any one time (though not in the same locality). One branch (including the famous 'Lucy' *Australopithecus* [or *Praeanthropus*] *afarensis*) culminated in the *Paranthropus* or 'nutcracker humans'. This

lineage dominated the scene 4–2 mya but was eventually replaced by the *Homo* lineage that were relative late-comers.

It now seems likely that, among a diverse scatter of hominins, the southern-most, more temperate-adapted species, *Australopithecus* (*Praeanthropus*) *africanus* and *Australopithecus sediba*, gave rise to the *Homo* lineage. It has been argued that strong seasonality in the hilly or mountainous habitats of *A. africanus* demanded exceptionally versatile social and strategic responses (Kingdon 2003). Global fluctuations in climate eventually permitted the descendants of these hominins (originally exclusive to South Africa) to spread northwards and eventually to enter Eurasia, where they proliferated still further. Because such studies are hostage to the availability of rare fossils, reconstructing progressive changes in a wide scatter of hominins through space and time, especially those of the *Homo* lineage, poses one of the most difficult but fascinating challenges in contemporary science.

GENUS *Homo*

Humans

Homo Linnaeus, 1758. *Systema Naturae*, 10th edn, 1: 20.

<i>Homo sapiens</i> Modern Human	<i>Homo floresiensis</i> 'Hobbit'
<i>Homo heidelbergensis</i> 'Heidelberg'	<i>Homo habilis</i> 'Handy Man'
<i>Homo neanderthalensis</i>	<i>Homo rudolfensis</i> 'Rudolf Man'
Neanderthal	
<i>Homo ergaster</i> 'Work Man'	
<i>Homo erectus</i> Erect Man (might include the un-named 'Denisova DNA species')	

There are scientists who, citing how recently our evolution has taken place and seeking uniform time-criteria for taxonomy, have proposed including chimpanzees *Pan* spp., even gorillas *Gorilla* spp., in *Homo*. This has not found, and remains unlikely to find, general acceptance. The genus *Homo*, by current definition, embraces a single living species – ourselves. All of us are, in a very basic sense, African mammals because the emergence and tenancy in Africa of our ancestors was probably about twice as long as Modern Human presence anywhere else (200,000–300,000 years in Africa versus <100,000 years outside Africa). Before the evolution of *Homo sapiens* (in the narrowest usage of that name), there were a variety of populations that lived in and outside Africa; these were mostly less gracile in body-build and, although unmistakably human, some had quite apish faces.

The oldest of these, at about 2 mya, was named from a ♀ specimen of a small species named *Homo habilis*, or 'Handy Man'. The name was coined because she was found close to a cache of stone tools, which she (at the time thought to be he!) had supposedly made. Such are the quirky beginnings of names, but the fossils they describe are a concrete archaeological reality. Likewise, the progression and spread of *Homo* clearly begins with a population of African humans of which *H. habilis* is the only one that is well represented in fossil form. A second hominid, usually allocated to the genus *Homo*, is *H. rudolfensis* 'Rudolf Man'. Known from fewer, and slightly earlier, sites on the shores of L. Rudolf (= L. Turkana) and L. Malawi, this flat-faced animal was appreciably larger than *H. habilis*. *Homo rudolfensis* may represent a regional or temporal variety belonging to the *habilis* group or might belong to a separate lineage. Such are the current uncertainties.

Post-*habilis* human evolution is then documented by an ever-wider, more numerous and diverse collection of bones and artefacts, bearing testimony to a succession of populations inside and outside of Africa. Whether any of these are direct ancestors to Modern Humans is rather less certain than that many varieties of humans have flourished in Africa over the past 2 million years.

The earliest specimens of *H. habilis* are hard to distinguish from the South African Man-ape *Australopithecus africanus* (especially since most of them are very fragmentary) and they are even more similar to the recently discovered South African fossil *Australopithecus sediba* (Berger *et al.* 2010). Both of these Man-apes appear to have been restricted to southern Africa. The most widespread species at any one time, and the best represented in any one region, are likely to be those best adapted to peculiarities of the time and of the locality. This means that many of the best-known fossils are not necessarily (indeed, are often unlikely to be) the direct ancestors of Modern

Reconstructed heads of three near contemporaries: (a) '*H.* *rudolfensis*'; (b) '*H.* *habilis*'; (c) '*H.* *ergaster (erectus)*'.

Humans. This makes deciphering the precise course of human evolution challenging because the actual fossils are usually best taken as illustrative of trends rather than documenting actual ancestry.

The proliferation of populations within the genus *Homo* continues to pose many problems but the radiation of *Homo* is as certain as that of any other of the many mammal radiations described in these volumes. As for other mammals, fossils are no longer the only sources of information; the genes of living people are a guide to what is now the most complex diaspora of mammals on earth. DNA has even been extracted from the bones and tissues of extinct humans (notably 'Neanderthal' *Homo neanderthalensis*) and, more recently, from the single bone of an unknown species from the Altai Mts, east-central Asia (Krause *et al.* 2010). Such discoveries hugely augment what we know, and can learn, about human origins.

It now seems highly likely that a population of early humans, possibly very similar to *H. habilis*, spread first to North Africa and the Arabian Peninsula, then much farther into Eurasia. Exactly where the next type of early human emerged (from a complex of populations of common ancestry with *H. habilis*) remains conjectural, but it was most likely to have taken place in, or near, the Afro-Arabian/Eurasian interface. Here, more open and strongly seasonal environments would have favoured larger body-sizes, lengthening of the legs, the adoption of more animal foods in the diet, and tighter, more secure social systems. The complex of fossil humans that would seem to broadly conform with this characterization have generally been lumped as *Homo erectus* 'Erect Human'. The discovery of *H. erectus* in Java in 1891 and *Homo pekinensis* 'Pekin Man' in China in 1927, led their discoverers and followers to believe that Asia was the ancestral land of humans. Since then the fossils of many other closely related humans have been discovered, of which the African type, *Homo ergaster* 'Work Man', is probably closest to the main line of subsequent descent than any other type (Groves 1989).

The *H. erectus* complex embraces a wide scatter of very different fossils and all testify to the rapid expansion of a highly successful type of pioneering human. With the help of fire, *H. pekinensis* types colonized cold northern habitats, while *H. erectus* (or even a close precursor) may well have invented rafts or boats in the SE Asian Peninsula. These local populations differentiated into distinctive forms to which authors have variously given specific or sub-specific

Three species (subspecies?) of *Homo erectus* type. Left: Work Man *Homo ergaster*. Centre: Pekin Man *Homo pekinensis*. Right: Erect Man *Homo erectus* (Java) (in part after De Beer 1964).

names, *erectus*, *soloensis*, *modjokertensis*, *ngangdongensis*, *trinilensis* and *sangiranensis* in Java, and *pekinensis*, *sinensis* and *hexianensis* in N China. In spite of persistent attempts to link such regional types of early humans with contemporary races of Modern Humans, recent research has been almost unanimous in dismissing what came to be called ‘the multiregional hypothesis’. None the less, it remains possible, even probable, that later human types occasionally hybridized with earlier ones and that some regional types might have retained or preserved older traits where these were adaptive.

Among the most interesting of Asian fossils is *Homo floresiensis* ‘Hobbit’, a diminutive and very primitive human from the island of Flores in Indonesia. Possibly linked to an Asian dispersal of *Homo habilis*-like populations as early as 2 mya, this species succeeded in crossing a deep water trench to colonize Flores more than 1 mya (Brumm *et al.* 2010). If this was the product of deliberate rafting it would be another instance of the capabilities of our early precursors or near-precursors being grossly underestimated by scientists. Accidental rafting during a tsunami, however, seems more probable.

Later human fossils are relatively rare, very unevenly scattered, and subject to much individual variation. As such, there has been a great proliferation of names. Among them, *Homo heidelbergensis*

‘Heidelbergers’ and allies have come to be regarded as the most convincing intermediate forms between *H. erectus* and fully Modern Humans (Groves 1989).

Apart from the incompleteness of the fossil record, the radiation of *Homo* is made much more complex by the influence of a factor that operates scarcely at all for most other mammals. Young *Homo* grow up in a physical world that is mediated almost entirely by artefacts. Instead of interacting directly with the climate, soil, trees and water, or with their food and prey, *Homo* put a great variety of interfaces between themselves and all these manifestations of nature. These interfaces consist of stone, wood, and other tools, string, skin blankets and leather clothes, containers, and diverse uses of fire to heat, cook, hunt and clear land. Long ago, the habitat of *Homo* ceased to be a particular vegetation type but rather a micro-habitat created around a camp or settlement, regardless of how briefly such sites were inhabited. Some of the many consequences of humans creating self-made habitats are explored in the following profile, demonstrating how faculties that evolved in Africa to cope with local challenges opened the way for an eventual colonization of the entire earth.

Homo sapiens MODERN HUMAN

Fr. Homme modern; Ger. Moderner Mensch

Homo sapiens Linnaeus, 1758. *Systema Naturae*, 10th edn, 1: 20.

Modern Human
Homo sapiens
adult male.

Taxonomy Monotypic species. Linnaeus described *Homo sapiens* in the tenth edition of his *Systema Naturae* in 1758. In this founding document of taxonomy he classified humans as one of four genera in the order Primates; the others were *Simia*, *Lemur* and *Vespertilio* (the latter being bats that, in his view, were primates!). The huge orang-utan *Pongo* spp. became the archetypal 'monkey' with the contradictory name *Simia pygmaeus* (because the type specimen derived from the remains of an immature captive). For a university lecturer in botany who belonged to a religious tradition that regarded humans as the singular creation of a single god, it took some courage to devise and publish a classification system in which humans were subsumed within a category that included apes, monkeys, lemurs and bats.

Since 1758, subdivision of the primates has been in continuous flux. As such, the placement of humans within the order has also varied and shifted substantially. Linnaeus's primary split into 'Simians' (*Simia*) and 'Prosimians' (*Lemur*) transmuted into Anthropoidea and Prosimii. Within Anthropoidea, *Homo* was the only genus in the family Hominidae. Today, *H. sapiens* is generally regarded as belonging to the suborder Haplorrhini (which embraces all tarsiers, monkeys and apes) and to the superfamily Hominoidea, a taxon we share with all the other apes. Combining evidence from fossils and molecular clocks reveals that Old World monkeys and anthropoid apes diverged in Africa about 30 mya (early Oligocene).

Front and rear views
Modern Human
Homo sapiens.

Myology of Modern
Human *Homo sapiens*
adult male.

We still occupy the family Hominidae, but molecular evidence makes it clear that all the great apes belong there too: we even share the subfamily Homininae with the African apes leaving only the tribe Hominini reserved for living and fossil humans and all the extinct bipedal apes (Groves 2001). Although other species of *Homo* exist as fossils, and there are occasional calls for the chimpanzees *Pan* spp. to be included in our genus, the general consensus is that we are the only surviving species of *Homo*. Groves (2001) lists >30 published names for proposed species or subspecies of living or extinct *Homo*. Most are of merely historical interest but some of the fossil forms provide rich and incontrovertible evidence for the reality of human evolution in Africa.

Of the other species of *Homo* that exist as fossils, the earliest, *Homo habilis* 'Handy Man', is known from about 2.5 mya and *Homo erectus* 'Erect Man' at 2 mya. There is good fossil and molecular evidence to suggest that our own species, *Homo sapiens* 'Modern Human', emerged only ca. 250,000–300,000 years ago.

The placement of *Homo sapiens* within current mammalian systematics is as follows:

- Class Mammalia
 - Subclass Eutheria
 - Order Primates
 - Suborder Haplorrhini
 - Parvorder Catarrhini
 - Superfamily Hominoidea
 - Family Hominidae
 - Subfamily Homininae
 - Tribe Hominini
 - Genus *Homo*
 - Species *Homo sapiens*

Lists of synonyms for *H. sapiens* are available in Groves (2001, 2005a). Modern Humans have 46 chromosomes, two less than chimpanzees *Pan* spp. and gorillas *Gorilla* spp., which have 48. However, this anomaly is due to the human chromosome 2 being an end-to-end fusion of two ape chromosomes, a fact revealed by the banding patterns on human chromosome 2 (Yunis & Prakash 1982).

Lateral, palatal and dorsal views of skull of adult Modern Human *Homo sapiens*.

Description A uniquely bipedal, large, primate with a peculiar distribution of hairy patches on the head and limb axia, but otherwise a general tendency to greatly reduced hairiness. Surface features, such as hair type, skin/eye/hair colour and nose shape, vary both individually and regionally. Sexual dimorphism is moderate; adult ♀ being, on average, smaller than adult ♂.

Modern Humans resemble the great apes closely in much of their anatomy and physiology (a fact that has led to the use of chimpanzees as human proxy experimental subjects in medical, pharmaceutical and cosmetic laboratories). The fossil record now offers evidence for many of the steps leading from our common ancestry with chimpanzees and gorillas. It is in the proportions of limbs and head that chimpanzees, gorillas and humans differ most; humans having elongated legs, shortened arms and face, and enlarged cranium. The hands of African great apes also differ substantially from those of humans and have probably become progressively more specialized for weight-bearing and climbing. The functional significance of some human peculiarities is discussed in 'Adaptations'.

Geographic Variation Modern Humans vary greatly in external appearance and this variation has both individual and regional roots. The majority of Modern Humans have skins that are various shades of light brown, with dark brown eyes and straight, black hair. Two

major departures from this primary type involve opposite trends towards 'super-pigmentation' or 'depigmentation'. A gene that plays a major role in depigmentation is the theomine gene SLC24A5, which Lamason *et al.* (2005) estimated to have arisen a mere 6000–12,000 years ago. The roots of this trait can be confidently located in the Baltic region of northern Europe and is typified by blonde hair and skin, and blue eyes. The opposite trend, with dark brown or black skin and eyes, spiralling hair and distinctive physiognomic features, is now most widespread in Africa but this genetic package of characteristics might have arrived there in prehistoric times after originating in Melanesia (Haddon 1919, Kingdon 1993, 2003). Eyes are also subject to significant differences in shape, some being the product of subcutaneous deposits of fat that probably serve to protect the eye-balls, insulating them from extremes of cold and shielding them from bright reflectance off snow. Such traits can sometimes be traced to selection for useful traits under extreme conditions, as in the higher reaches of the Andes and Tibet, where the thin air poses problems for pregnant women. Still other manifestations of regional

difference can be traced to founder-effects, as when a very small number of immigrants has colonized an island or spread widely over a continent.

Similar Species Humans are broadly sympatric with all six species of great apes. Resemblances with orang-utans, chimpanzees and gorillas offer many evolutionary insights but the erect posture, hairlessness and large cranium of modern humans prohibit any confusion in identification.

Distribution Modern Humans occur in all African biotic zones and inhabit every continent. A primary reason to include humans in a continental mammal inventory is that *Homo sapiens* evolved, exclusively, over millions of years, within African mammal communities. We can be sure that prehistoric distributions of primates represented complex patterns of ecological partitioning, exclusion, competition, constraints (and, possibly, facilitation) for almost every species of primate. At various stages of their evolution, proto-humans and extinct humans were integral to these patterns of interaction. Few surviving species, either primate or non-primate, have escaped the legacy of human competition/exploitation of commonly used resources. Furthermore, this human onslaught has been strung out, step-by-step, habitat-by-habitat and region-by-region.

It is, therefore, interesting to find some African Middle Stone Age industries (dated 250,000–45,000 years BP, and once commonly referred to as 'Stillbay') that were mainly confined to upland, temperate and semi-arid zones. Here, tool types were remarkably similar from the Cape to the Horn of Africa, suggesting a well-dispersed, mainly savanna-dwelling population that used relatively uniform techniques. Then, about 42,000 years ago, living sites became much more numerous and began to extend into low-lying and humid parts of central and West Africa (Anciaux de Faveaux 1955, Clark 1967, 1982, Isaac 1982). At this time, tool-kits became

Palaeolithic sequences and artefact types from African archaeological sites (diagram modified after Gowlett 1992).

more varied and numerous, representing many regional variants. The implications are of expanding, less habitat-specific populations (perhaps even 'tribes') devising a variety of new techniques to exploit an expanding range of environments. In spite of 42,000 years being deep in prehistory, that expansion of numbers and range could be seen as one of several starting points for the modern era. It suggests a substantial enlargement of our ancestors' capacity to exploit resources that were previously not used. Because equatorial lowlands are hotbeds of primate diseases, it is possible that disease-resistance in a particular human population was a decisive factor in this ecological expansion (Kingdon 1993). This expansion of range also seems to mark a significant leap in an invasive, 'niche-thieving' dynamic that has continued to typify human interactions with the rest of nature. The present era undoubtedly marks another, much more comprehensive and sudden, technological and demographic leap.

If such archaeological discoveries could be plotted through time, and investigated in terms of staged expansions into once unpopulated regions and into previously unexploited ecosystems, there would likely be important insights to our understanding of the biology of many mammal species. It may eventually be possible to reconstruct long-term patterns of ecological change and extinction induced by human activities. When such reconstructions are attained, it is

predicted that a deeper understanding of mammalian biology in Africa will emerge. The archaeological record provides reminders that the impact of human numbers, and of the ever-expanding technological inventiveness of humans, has deep roots, and that we are witnesses to but one moment in a very protracted human assault on the natural environment – and on all species that live in these environments.

Habitat Human habitats are essentially self-made and the invention of clothing, harnessing of fire, ability to make tools and to construct shelters and transport systems, etc., means that modern humans have come to occupy the entire range of contemporary terrestrial habitats. This ecological annexation has proceeded step-by-step, incrementally. It has long been recognized that when humans lack appropriate technologies, their ecological niches and impacts are narrower, even though prehistoric modern humans were no different in physique or intellect to contemporary people. Thus, the invasion of rainforests, deep swamps, high mountains and polar regions is probably relatively recent, whereas savannas, especially African savannas, represent an archetypal habitat for *Homo sapiens*.

When such insights are referred to actual species it can be appreciated that bovids, such as the Hartebeest *Alcelaphus buselaphus*, Wildebeest *Connochaetes taurinus* and Common Eland *Tragelaphus oryx*, evolved within savanna habitats where humans were already a factor in natural selection. Thus, human activities, such as grass-burning or intensive hunting around waterholes in dry seasons or during arid climatic phases, could have favoured one antelope versus another, and shaped some details of their behaviour and evolution (and may have caused the extinction of especially vulnerable species). By contrast, a forest bovine, such as the Bongo *Tragelaphus eurycerus*, or a desert antelope, such as the Addax *Addax nasomaculatus*, evolved in effectively human-free environments. In all instances, there are implications for our understanding of the species' biology and conservation status today.

Our historic and prehistoric interactions with predators also raise numerous questions. Many species of large predator have gone extinct in Africa as elsewhere. We can only guess at some of the reasons for these extinctions but once humans became effective predators in their own right it is certain that they became a significant factor shaping predator communities. From detailed studies of predator guilds in several parts of Africa (e.g. Serengeti N. P. in Tanzania, Kruger N. P. in South Africa, Bale Mountains N. P. in Ethiopia) we know there are highly structured specializations in prey type and killing technique, as well as systematic appropriation of prey. These may be the evolutionary outcomes of ancient interactions or 'arms races' between different predators, but the exact spectrum or balance of carnivores in any one place at any one time is the direct product of locality-specific competition. The constraints on early humans, and the two-way dynamics of human interaction with Lions *Panthera leo*, Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, Wild Dogs *Lycaon pictus*, Spotted Hyaenas *Crocuta crocuta*, Black-backed Jackals *Canis mesomelas* and other large, savanna-living, predators, have scarcely begun to be examined in this context.

It is even more important to understand the dynamics of our evolutionary interactions with close relatives, especially chimpanzees and gorillas. Assuming ancient periods of physical separation (because our common ancestor could not have speciated without that), there are likely to have been other times when expanding and contracting ranges (probably correlated with climatic changes as well

as technological innovation) brought formerly separate lineages into contact again. Of special interest are those ancient times when the burgeoning lineages of early Hominini and early *Pan* were a lot more alike than they are today. At such early times we can assume that ancestral chimpanzees and ancestral hominins retained some residual overlap in their ecological preferences. What happened during these early interactions is crucial for understanding the nature of our biological differences. Extrapolating from what we know about ecological partitioning in general, it is likely that direct competition within these early zones of overlap served to define ecological boundaries among the species. Thus, chimpanzees may well have been forced to become more decisively forest-dwellers and more specifically 'big tree climbers' as a direct consequence of ancestral exclusions by our own lineage (and, perhaps, other primates) in the distant past. In Africa, understanding the differing susceptibilities of antelopes, carnivores, or the great apes, whether prey, predator, or competitor, needs to be informed by the history or pre-history of their interaction with humans and proto-humans.

Abundance At about 7 billion (US Census Bureau 2007), humans are today, by far, the most abundant primate on earth. Humans are currently in an unprecedented phase of demographic expansion, especially in Africa. The UN estimated projections of future global population range from 7.6 and 9.8 billion for 2050, while projections for 2150 are as high as 30 billion. Increasing densities, unbalanced age distributions and newly urban societies have transformed, or destroyed, traditional economies and modes of behaviour. Nomadic foragers and hunters used to live in small, mobile, family-sized functional groups. Pastoralists also had to be mobile but tended to operate more expansive clan systems with the young men in warrior groups. Settled farming societies varied greatly but generally had enlarged family groups because their labour-intensive crops could support more children and plants needed more hands to be cultivated and harvested (Butzer 1971, Flannery 1973). City living, on the other hand, tends to favour nuclear families operating within large social aggregations that are controlled by clan-like kings, religious figures, or other leaders (Harris 1978). Some of the biological underpinnings of human societies are explored under 'Social and Reproductive Behaviour'.

Rapid increase in numbers and huge expansions in the geographic range of humans has involved the extirpation of many subspecies and several species of large mammals in Africa, notably the Blue Buck *Hippotragus leucophaeus* in South Africa and the Red Gazelle *Gazella rufina* in North Africa. A currently fashionable myopia promotes the idea that most human enterprises need not have adverse effects on the survival of mammals, large and small. On the contrary, an exponential increase in human numbers can only lead to further extirpation of species, most particularly those species that occupy small areas in localities with large (and/or lawless) human populations. Current trends suggest that burgeoning human populations will soon cause the extermination of some, or all, of the following species of mammals in their natural habitats: Pennant's Red Colobus *Procolobus pennantii*, Preuss's Red Colobus *Procolobus preussi*, Tana River Mangabey *Cercocebus galeritus*, Sclater's Monkey *Cercopithecus (cephus) sclateri*, Red-bellied Monkey *Cercopithecus erythrogaster*, Preuss's Monkey *Allochrocebus preussi*, Drill *Mandrillus leucophaeus*, Rondo Dwarf Galago *Galgoides rondoensis*, Golden-rumped Sengi *Rhynchocyon chrysopygus*, Ethiopian Wolf *Canis simensis*, Wild Ass *Equus africanus*, Grevy's Zebra *Equus grevyi*,

Aders's Duiker *Cephalophus adersi*, Hirola Antelope *Beatragus hunteri*, Dama Gazelle *Nanger dama*, Slender-horned Gazelle *Gazella leptoceros*, Scimitar-horned Oryx *Oryx dammah* and Addax *Addax nasomaculatus*, to name but a few. The activities of humans are, of course, also having a severe negative impact on the world's birds, amphibians, reptiles, fishes, plants, and species in other taxonomic groups.

Adaptations Primarily diurnal and terrestrial. Some of the adaptations that most distinguish Modern Humans are best appreciated by comparing characteristics (some obvious, others more cryptic) with equivalent features of modern apes and fossil hominins. *Homo sapiens* is the last survivor of a great diversity of extinct hominins that are becoming ever more richly documented by the fossil record. These fossils demonstrate the tangible reality of human evolution and often offer hints as to how some of our uniquely human adaptations were acquired.

The earliest of these fossils, 'Toumai' *Sahelanthropus tchadensis*, is a well-preserved 6–7 million-year-old hominid skull. This skull combines characteristics of Modern Humans, chimpanzees and gorillas, confirming Darwin's 1871 prediction that Africa was the most likely home of the *Homo sapiens* lineage, and that chimpanzees and gorillas are our closest living relatives. The somewhat younger 'Millennium Human Ancestor', *Orrorin tugenensis* (6 mya), has a much more fragmentary skull, but is probably closer to the human line of descent.

The next oldest hominin fossils belong to the 'Ground Apes', *Ardipithecus kadabba* and *Ardipithecus ramidus*, of Ethiopia. The earliest specimens of *kadabba* are ca. 5.8 mya, the youngest specimens of *ramidus* are ca. 4.4 mya. These eastern apes lived in riverine forests and woodlands in a relatively dry region of eastern Africa. Extrapolating from equivalent contemporary East African riverine forests and woodlands, the ground was likely to have been a richer source of forage than the treetops. As is summarized below, this detail hints at the driving force that initiated hominin divergence and the emergence of Modern Humans. Since genetic isolation is an essential part of speciation, eastern provenances for these and subsequent fossil hominins suggest that an arid corridor allowed the earliest hominins to diverge in isolation from the much larger populations of apes occupying central and West Africa.

In apparent concert with our upright stance, humans have developed strong, flexible 'waists' that separate and balance a slab-shaped thorax above a basin-like pelvis; chimpanzee and gorilla rib cages are splayed and conical, their lower margins bound closely to broad pelvic plates in a single, oblique and top-heavy body mass. These anatomical differences are now associated with bipedalism in humans and quadrupedalism in chimpanzees and gorillas. However, the initial divergence in body proportions, especially the slimming down of shoulders and chest, was likely to have begun with the adoption, by our earliest ground ape ancestors, of a 'squat-foraging' mode. This was a posture in which the upper body became less top-heavy and the vertebral column became more upright. The detailed adaptations of the *Ardipithecus* ground apes remains to be elucidated but it is clear that any 'squat-foraging' primate gleaning for small food items, both plant and animal, on the forest floor, must have employed increasingly dextrous fingers (Kingdon 2003).

The actual size of our hands is, proportionally, somewhat smaller than in chimpanzees and gorillas, but we should not equate

'Penfield homunculus' (adapted from brain maps in Penfield & Rasmussen 1950 and from a figure in Dawkins 2004).

anatomical size with functional significance. This has been illustrated in an original and interesting way. In 1950, Penfield & Rasmussen published a paper on the human cerebral cortex that offered a graphic demonstration of how important hands are for *H. sapiens*. These authors mapped two aspects of brain function: one represented the ratios of the brain devoted to controlling muscles, the other mapped equivalent ratios for the sense of touch. In each instance, the hands occupied hugely disproportionate parts of the brain. The 'homunculus' that emerged from this exercise was grotesquely 'hand-heavy', as were the parts of the face given over to vocalization: tongue, lips and jaws (see illustration above). A significant conclusion emerging from the evidence that hands were of paramount importance in human evolution is that skills in manipulation help explain the emergence of bipedalism. Once deft, food-gathering hands became the prime adaptive specialization of ground apes, and once the vertebral column began to be rebalanced, it was inevitable that bipedalism would develop. To gather and handle a wide variety of mainly small food items is not entirely without precedent (some African and South American monkeys are highly manipulative). What was new was the combination of direct finger-gathering with indirect tool-use (we can infer the latter from numerous instances of its existence, in rudimentary form, in chimpanzees). More important, this specialization in tool-assisted foraging represented an entirely novel way of interacting with the external world. Bipedality allowed the descendants of ground apes to become more mobile, but this was far from being an instant conversion. There is telling evidence from fossils to suggest that two-legged walking and running took a long time to improve, let alone perfect. Long, forager's arms had to shorten while apish squatter's legs took several million years to become long, powerfully muscled legs. Throughout this period, trees

and cliffs are likely to have continued to be important as sources of refuge and shelter, especially at night.

T. Butynski (pers. comm.) points out that the distributions of dry country monkeys (i.e. Patas Monkey *Erythrocebus patas*, savanna monkeys *Chlorocebus* spp., baboons *Papio* spp.), as well as some populations of Robust Chimpanzee *Pan troglodytes*, are dependent on surface water and on safe sleeping sites. Noting that (1) habitats away from drainage lines tend to produce much the same foods over large areas, and (2) that no monkey or ape exploits this vast supply of food, he envisages significant opportunity for, and selective pressures on, early hominins to exploit these foods, including meat. The expansion of the geographic range of early hominins into this enormous 'empty niche' was likely dependent on (1) the ability to carry resources (e.g. food, water, building poles and tools) that bipedalism allows for, (2) the ability to make water containers, build shelters, hunt large prey and avoid and/or defend against predators that tool-use and complex vocal communication enable, and (3) the ability to use fire for cooking, warmth, hunting and defence. In short, development of bipedalism, tool-use, complex language and control of fire among early hominins allowed for the much greater exploitation of the natural resources (especially food) of the vast, waterless, African savannas and bushlands.

The swollen braincase of Modern Humans is one of the last obvious innovations to emerge. We are fortunate to have a rich fossil record demonstrating progressive enlargement of human brains, most of which took place over the last 2 million years. People are often struck by how 'human' young primates are. This is to invert the situation: humans resemble big-headed baby primates because selection has to operate upon pre-existent traits and processes. So humans are 'neotenuous' or 'paedomorphic' primates in their bulging foreheads, reduced teeth, chewing muscles and, above all, in many aspects of their behaviour. Neoteny is essentially a consistent alteration in the timing of various developmental processes. For example, if brains are to enlarge, the bony plates that surround and protect them need to remain loose long enough to accommodate this enlargement. The mechanism allowing this to happen is retention and extension of the juvenile phase of development and suppression of some adult features, such as massive ♂ brow-ridges. Neoteny and the extension of childhood have a central role to play in the development of human social systems. These are further explored under 'Social and Reproductive Behaviour'.

Other adaptive peculiarities of *H. sapiens* do not fossilize, among them important physiological properties of the skin and hair. Most notable of these is the superabundance of eccrine glands in *H. sapiens*, a characteristic that is as diagnostic of Modern Humans as speech or bipedalism (Sokolov 1982). Eccrine glands are found in many mammal species with a soft skin interface between themselves and the ground or branches on which they walk or climb. The fine watery eccrine secretions that exude from the palms of primates, carnivores etc., are seldom found anywhere else but on finger-pads and paws. Their primary role seems to be to condition, protect and cleanse these sensitive, exposed, wound- and infection-prone surfaces from contamination or harm. Human eccrine secretions even possess antibiotic properties (Randerson 2001). Another important property is to increase the sensitivity and micro-traction of fingers and palms. This is a significant virtue for contemporary humans (a sensitivity greatly enhanced by dense mosaics of Meissner's corpuscles

embedded in the skin surfaces of primate fingers). Human hands, especially the fingertips, are so sensitive that skills such as reading Braille, sewing, servicing watches or computers, or playing small, complex musical instruments, can quickly be learned. (Incidentally, most of these talents would have had prehistoric equivalents in terms of finely tuned manual skill.) Finally, evaporation of the water in eccrine secretions also produces a pronounced cooling effect.

Today, this last property of eccrine secretions seems the most obvious advantage. 'Sweating' and cooling must have been a major evolutionary benefit when our ancestors moved into more exposed habitats and undertook high-exertion activities such as walking long distances while carrying food and water. However, it was probably the cleansing functions of eccrine glands that first favoured their initial spread and multiplication in apes and their near total replacement of other glands in Modern Humans. In terms of hair and skin hygiene, humans have effectively abandoned the relatively dry, oil-based system employed by many other mammals. Instead they have enlisted the water-greedy eccrine glands to cleanse and cool a relatively naked skin. A possible connection between nakedness and eccrine glands is discussed further under 'Social and Reproductive Behaviour'.

The adaptive property, which is most frequently thought to distinguish humans from other animals, is the development of a mind capable of articulating and sharing knowledge and feelings with others. In 1837, Charles Darwin made a jotting in his notebook: 'man is a species like any other. The mind is a function of body. He who understands baboons would do more towards metaphysics than Locke' (Browne 1995). Ever since, scientists have been exploring the many ways in which mind is a function of body – and baboons, like other African primates, continue to offer us insights into one of the most difficult of all evolutionary puzzles.

Foraging and Food Omnivorous. In their wild forms, most foods eaten by humans were or are shared with other species: fruits with fruit-bats, palm dates with palm civets, roots with root-rats, honey with Honey Badgers, and meat with Lions, Leopards and Spotted Hyaenas. In many instances, plants that are now cultivated and eaten by humans co-evolved with non-human consumer species that served the plant as disperser or pollinator. Where such animals have been entirely displaced by humans the latter could, in an evolutionary sense, be said to be 'thieves', but that could probably be said of many other instances of evolutionary displacement. Human perspectives invert this, so wild animals that attempt to share resources with us are dubbed 'pests'. Humans have developed a battery of devices that effectively withhold potential foods from other animals. We have typically mammalian instincts about attacking or excluding competition.

Conflicts between *H. sapiens* and other mammals pose fundamental problems for the long-term survival of many mammal species. As the texts of these volumes exemplify, food resources are often partitioned to some degree among the animals that consume them, and the consumers have prescribed tastes and genetically determined food-getting techniques that are unique to the species. Humans, instead, have emancipated themselves from a limited range of species-specific foods and have, with the help of various tool-assisted techniques, devised numerous ways of protecting, obtaining, preserving, processing and altering otherwise unavailable or inedible foods. These characteristics are part of our evolved repertoire. Thus,

skills in cultivating, breeding, processing, and protecting edible plants and animals are not new, nor is the capacity to consume a wide range of species (Ucko & Dimbleby 1969). So, is this merely a vastly enlarged expansion in tool-assisted omnivory? If it is argued that the consumption of a continuously expanding harvest has long been characteristic of our evolutionary career, can we project its momentum on into the future? Will we reach a point where there will be no plants or animals that are not, in some sense, consumable? Is such a state desirable? Perhaps unease with that question lurks in ideological arguments as to how 'naturally vegetarian' or 'naturally carnivorous' humans are? In many languages the word for meat is also used for animal (i.e. 'nyama' in Kiswahili) and 'going the way of all flesh' (dying) also includes humans in the same animal commodity.

Lee (1968) documented contemporary, subsistence-based, human hunter-gatherer societies eating far more, and larger, vertebrate prey than any other primate. In an effort to arrive at some (implicitly retrospective) averages, Lee (1968) sampled 58 such societies from many latitudes and in many parts of the world. With one exception, he found that all these societies derived at least 20% of their diet from hunting mammals (mean ca. 35%). He, therefore, postulated that, on average, prehistoric humans derived 30–40% of their diet from the meat of mammals. In spite of many prehistoric societies having scant, or only seasonal, access to fish, Lee added a mean of 26% of fish into postulated prehistoric diets. He concluded that mammals and fish comprised 61% of the diet of prehistoric humans. Given that other vertebrates and invertebrates were not considered, Lee's estimate of 61% of animal matter was a conservative value.

Butynski (1982c), reviewing vertebrate predation by contemporary primates, including humans, showed that while animal matter is a major component of the diets of many species of primates (sometimes 30–70% of the diet), almost all of this derives from invertebrates. Animal matter comprises only 1–4% of the diet of baboons and chimpanzees (far less than this in gorillas). The hunting of vertebrates by non-human primates is an uncommon, albeit widespread, behaviour. Butynski (1982c) points out that chimpanzees and humans are the only primates known to occasionally kill their prey by flailing it against a hard surface and to carry meat for distances of >1 km. No primate other than humans is known to prey upon animals larger than itself. Chimpanzees and baboons seldom kill prey weighing more than 6 kg, and 10 kg appears to be close to the upper limit. In contrast, humans often kill prey many times their weight. The frequent hunting and utilization of large mammals by humans appears to have been enabled by the addition of complex vocal communication, bipedalism, fire-use and weapon-use to a basic primate hunting pattern.

One probable outcome of this 'hominin hunting pattern' was the hunting of vertebrates (especially mammals) as a major activity and 'way of life'. This appears to have resulted in a dramatic (perhaps 30–35-fold) increase in the consumption of meat from vertebrates, an increase perhaps already evident >2.5 mya. The hominin hunting pattern comprises adaptations not shared with any extant non-human primate nor, presumably, with any pre-hominid ancestor. The hominin hunting pattern allowed for the exploitation of a new, very different, and vast food-niche (see above) in which there was little or no competition with other primates – although there was probably important competition with several large African predators (Butynski 1982c).

There is no consensus concerning the diet of early hominins. As such, anthropologists argue passionately about just how frugivorous, omnivorous or carnivorous prehistoric hominins were, notably for more recent periods, when diets reflected the local availability of plant and animal foods. The issues are certainly relevant to understanding hominin divergence from our common ancestor with the other apes but are still far from being resolved. Knowing that hands were used for food-gathering and that early hominin hands differed from those of other apes, we can safely infer that diet was involved. The most likely difference was that the ground apes were omnivorous and foraged for small items on the ground whereas ape ancestors were predominantly arboreal eaters of relatively large fruits.

It may be too much to hope that an appreciation for the initial divergence between the human and ape lineages being founded on small dietary differences could translate into greater sympathy for African apes and for their present plight. Even so, insisting that apes be recognized as fellow primates, our closest living relatives, has to be preferable to treating them as an exotic food, as they are in the restaurants of several West African and European cities (Peterson & Ammann 2003, Rose *et al.* 2003). Human appetites, not just gastronomic ones, threaten a great many of the mammals described in this work. If some recognition emerges that Modern Humans are an integral part of Africa's mammalian fauna, and that chimpanzees and gorillas are our cousins, then consumption of chimpanzees and gorillas may eventually come to be seen as closer to a form of genocidal cannibalism than to gourmet dining.

The ability of contemporary societies to ship ape and other carcasses to far away markets is an essentially modern and new challenge but it is part of a much larger trend. As all types of human impact on the environment grow, agriculture (for the most part primitive, but increasingly machine- and chemical-dependent) demands more and more land and excludes more and more species. In rich countries, trade, research and transport have spread access and knowledge of foods to an ever-expanding market. In poor countries, population growth and hunger drives continuous agricultural expansion and unsustainable exploitation of many local foods that were previously ignored or only eaten *in extremis*. As wild foods decline, the ultimate loss is of local ecological integrity and diversity, and an increasing and permanent impoverishment of the natural world. The great Australian writer and scientist, Tim Flannery, has dubbed us the 'Future Eaters' (Flannery 1994).

There are three major forces, which, if they continue to follow present trajectories, will extirpate many species of the larger mammals in Africa. One is the increasing numbers of humans with the need and, increasingly, the means, to inhabit virtually the entire land surface of Africa. Concurrently, the single most direct force exterminating large mammals is the widespread and unregulated commercial bushmeat trade. The third major force is the use of ever-increasing areas of land for commercial crops such as beef, sugar, oil-palm, cereals, coffee, tea, fruits and vegetables, timber, even flowers, and concomitant appropriations of water sources. Were we to articulate the interests of other mammals as though they were comparable with our own interests, or were we to entitle natural ecosystems the 'right' to survive, the progressive turn-over of all lands to the purposes and interests of a single species could only be called theft. The ultimate effect of additive theft by one species is denial of the 'right' of other species and natural communities to

exist. Of course, few humans can acknowledge such an extreme characterization of their actions but, in ecological terms, humans are actively stealing the niches of other animals. As such, we should at least consider what can be done to mitigate our destructive ecological role and evolutionary status as 'niche-thieves'.

At the international level, land-use policies are seldom ecologically based. Both national and international bodies concerned with feeding human populations continue to value the soils and climates of remaining non-agricultural land only in terms of their potential for crops or livestock. The ambassador of a major Western nation, on visiting a small African national park of almost unprecedented ecological diversity and of a natural biological richness that dwarfed that of his own country, enthused publicly about the area's potential for conversion to vineyards. (Although his advocacy of viticulture was not taken up, the size of the park was subsequently drastically diminished and the excised areas were, indeed, given over to agriculture, much of it for the production of alcohol.) For the ambassador nothing could conceivably transcend the value of wine. His mental imposition of a Western wish-landscape over a real, but unfamiliar, African one illustrated the imprinting power of culture. He also exemplified the almost total, worldwide, absence of ecological insight or training in contemporary public leadership.

Political leadership is still oblivious to some of the most policy-relevant findings of modern science. Studies of Africa's indigenous flora and fauna have demonstrated that no agronomic or pastoral system devised by humans has ever, or will ever, begin to compare with natural ecosystems for inherent productive efficiency and for the progressive diversification of ecological niches. Accelerating degradation of African landscapes by so-called 'modern' agriculture, and drastic over-grazing by livestock, must eventually persuade thoughtful people to seek knowledge of the natural structure of African ecosystems and induce respect for the rich landscapes that preceded today's spreading ecological deserts.

All aspects of human welfare and all domesticated plants ultimately depend upon our need to understand their evolutionary history. The realization is growing that all plants and animals, including ourselves and our domesticates, have spent significant periods of evolutionary time subject to precise ecological parameters and confinement to quite precise geographic regions. There are innumerable potentialities for human exploitation in the adaptations of highly specialized biota. There are also many foods and condiments that were once part of human resource use in Africa that are being displaced by imported plants (Maguire 1980, Peters *et al.* 1992, O'Brien & Peters 1998). The workings of the evolutionary process tie our time and place to past and future, and tie our survival to all the animals and plants on which we depend, fruit, oil-palm, rice, wheat, maize, livestock, fish and many more, every one of which owes its existence to the same over-arching process. Many out-moded and, originally, non-African agricultural and pastoral practices will eventually have to be scaled down or even abandoned. In the meantime, maintaining viable mammal communities is integral to the long-term objective of ensuring that Africa develops locally relevant, not primitive or exotic, systems of resource use.

Social and Reproductive Behaviour Social. In the past, human societies differed from those of other primates in the prolonged dependence and extreme vulnerability of their young, and in the

Reconstruction of the 'Idaltu Human', one of the earliest and most complete fossil skulls of a Modern Human *Homo sapiens*.

high level of dependence of mothers on a social system that enhanced security for all. Early human societies would also have differed from those of most apes in that both sexes and all ages were more similar in physique. If human ♂♂ show less difference from human ♀♀ (and all ages and sexes are neotenous compared to, say, ♂ gorillas or ♂ chimpanzees), what significance does this have for society?

For a start, as a result of exceptionally helpless babies, every member of a human social group was more vulnerable than its ape equivalent; even adult ♂♂, always a minority, shared an interest in finding security within a group of relatively helpless ♀♀ and children. If all classes were in some sense juvenilized, a group-wide, shared, sense of vulnerability would have selected for behaviour that put the whole group at an advantage. Many animal societies find security in numbers and coordinated activities, but human group activities have more than a simple defensive role. At an early stage, ancestral human groups probably modified originally defensive behaviour into a more deliberate, systematic and proactive engagement with any aspect of the environment that might provide food or other resources. Thus, human societies became oriented to the systematic 'removal of obstacles' (including overcoming the evolved defences of plants and animals) in order to gain group-access to resources. The development of scrapers, cutters, crushers and diggers by early humans are all evidence for skills that serve this central feature of the human ecological niche (Renfrew 1973, Gowlett 1992; see p. 79).

One manifestation of neoteny in recent human societies is the extension of childhood psychology and assumptions into adulthood. Perhaps the most fundamental social purpose served by the dependence of infants on parents is social subordination. Juveniles generally follow parental example and practice, and societies of all sorts benefit from any traits that subordinate individual behaviour to the immediate needs of the group. In small family-like groups, subordination to biological parents may last as long as the parent lives. Ancestor cults in many societies bear witness to the fact that even after the death of a parent their memory is a source of psychological authority that has been integrated into specific social structures. In larger groups, that subordination tends only to continue if the offspring benefits from the status of its parent, parents or long-dead ancestor. This does not mean that psychological dependence on protective adult authority disappears. Within an enlarged group, any leader can assume a pseudo-parental role and it is in the varied ways in which 'pseudo-parents'

Ritualized intimidation displays.

Left: Adult male gorilla *Gorilla* (accompanied by a bout of chest-beating).

Centre: Robust Chimpanzee *Pan troglodytes* (short noisy charge, sometimes waving branch).

Right: Adult male Modern Human *Homo sapiens* ('Haka').

manipulate infantile psychological dependency that neoteny finds social expression (Chagnon 1975). The ways in which leaders bolster their power by assuming parent-like authority varies greatly but some general patterns are shared across all cultures.

At the ontogenetic and psychological level, a sense of continued defence by parents comforts individuals and helps smooth the transition from safe juvenile to much more vulnerable young adult. At broader historical and social levels, the transfer of each child's individual dependence upon one or two mortal, ageing parents, to generic, socially sanctioned, parent-like leaders, was a relatively small step among groups with small family-like structures. In larger, more highly organized societies, this fundamental carry-over of childhood dependence provided opportunities for the emergence of chiefs or monarchs (Bloch 1966). Once such powers were consolidated, and social structures became multi-generational, veneration for a symbolic parent lost its association with single individuals. Typically, monarchs, intent on defending or extending their own and their descendants' power, have tended to install agents charged with disseminating acceptance of their leadership by whatever means (Carneiro 1970). The most effective way of achieving this objective was to stress the parental properties of the monarch or, if the monarch was old or dead, to deify their memory. In this way, symbolic parenthood became 'eternal' and metaphysical. Most societies devise elaborate coming-of-age rituals that are designed to appropriate the allegiances and energies of their youth. The transition into adulthood is emphasized, but the neotenous psychology of dependency on the groups' 'pseudo-parents' continues and is, if anything, intensified.

Allied with coercive force of arms, a dynasty's warriors, 'guards' and agents could impose veneration for their own pseudo-parent over a much wider area. With the development of media (initially books), the power of a local dynasty could be augmented and spread exponentially. Furthermore, it served the interests of dynastic agents

to extend the veneration of a pseudo-parent, both to themselves and to the books that had become the instrument of their success and power: thus even books, obviously human artefacts, became 'sacred' in some 'Cultures of the Book'!

Among contemporary societies, the North Korean dynasty and its apparatus is an instructive cartoon of this process. Elsewhere, one-time agents of dynastic power and privilege long ago became priesthoods of various denominations. All depend on some degree of entrenched veneration for a symbolic parent, and their priesthoods provide obvious opportunities for ambitious leaders, who, wittingly or unwittingly, exploit a neotenous mammalian trait for their own social ends. There are few social institutions that are untouched by this dynamic.

Physiological mechanisms mediate all animal life, and biochemical agents trigger or suppress most of the behaviours that dominate social relations among mammals. In terms of social structures, the primary function of aggression is to optimize the spacing of individuals or groups. As such, aggression is centrifugal in nature (Marler 1965, Freid *et al.* 1968). Aggression is controlled by hormones, particularly testosterone among ♂♂, which drive individuals to confront competing or intruding conspecifics (usually other ♂♂). Centripetal tendencies, instead, are mediated by hormones that induce conciliatory, even submissive behaviour. In their relationship to social behaviour in humans, hormones have not been significantly modified – in spite of their social utility being no longer obvious. Specific and local manifestations of these chemically driven behaviours have acquired abstract, culture-specific names, such as 'hate', 'anger', 'obsequiousness', 'capitulation' and, at the broader, social level, find expression in phrases such as 'the enemy', 'war-mongering', or 'religious intolerance'.

The most reductionist explanation for much animal behaviour, including human behaviour, is that it is 'territorial', but territorialism has many expressions. Humans, like other mammals, need access

to adequate water and food, and space secure and ample enough for reproduction, play, sleep, waste disposal, etc. Like any other mammal, humans require space – territory – and they, like any other mammal, will fight for it, at national, tribal, family or individual levels, against any entity that would deny them. A single mammalian species now regards Africa as its ‘own’ territory and has plans to use and ‘develop’ every hectare of Africa’s surface for its own purposes. Thus all large mammals in Africa (and most small ones too), as well as the entire ecosystems on which they depend, exist on borrowed time. They exist on borrowed time because they are powerless to defend their lives and livelihoods against all these human needs. They are helpless to defend their space from a species that is now equipped to take away their entire livelihood, even its physical substrate, shipping it away on flatbed logging trucks. The fact is, that over the greater part of the continent, wild mammals and wild places are not just memories, they are forgotten, and with that forgetfulness, 99.9% of human history has disappeared beyond recall.

Humans emerged as a singular component of the natural communities that are now being destroyed. At the present time, our knowledge of that immensely long and influential phase of our history and prehistory is minuscule because current political, social and intellectual cultures put no value on such knowledge. Most humans, today, are much more ignorant of nature than their precursors were. In the future, ‘neo-knowledge’ of ecological processes will have to become an important strand of scientific education. Such scientifically informed education systems will also need to reappraise fundamental assumptions about culture, race, history and identity. It is in understanding the ecological underpinnings of human societies that we can begin to explain many expressions of variation among human cultures, societies and religions. In every instance there had to be a resource base to support whatever permutations of human society evolved. In every instance, food, technology and demography have all been linked and in a constant state of flux and change (Renfrew 1974). In every part of the world that Modern Humans inhabit, external ecological constraints, as well as internal social ones, have shaped cultural evolution. In adapting to naturally complex ecosystems and to increasingly complex social environments, humans devised ever-greater complexity (Freid 1967, Sahlins 1972). Thus, as human numbers increased and as humans spread ever more widely, the organic evolution of biodiversity and biocomplexity has been paralleled, or mimicked, by the cultural evolution of increasing complexity in human societies.

In the context of this work, it is useful to remember that other mammals have had a huge historical influence on African peoples. For millions of years before any animal or plant was domesticated, mammals were a primary food resource for hunter-gatherer populations. Indeed, it appears that a major difference between humans and all other primates is the amount of meat in the diet, especially mammals, and the hunting patterns by which they acquired these prey (Lee 1968, Butynski 1982c; see ‘Foraging and Food’). Modern Humans have spent, by far, the greatest part of their existence as hunter-gatherers; a time in which human knowledge of plants and animals was much greater than it is for the majority of contemporary humans.

When cattle were first domesticated, some 10,000 years ago, peoples’ relationship with the land, particularly grassland, changed (Zeuner 1963). New pastoral societies with new land-management techniques, such as firing the savannas, emerged in Africa and their demographic fortunes changed radically because domestic stock

can generally support a higher density of people than hunting (Epstein 1971). In southern Africa, some Khoi-San peoples retained a foraging economy while others adopted pastoralism. The subsequent fortunes of the foraging San and the pastoral Khoi (near annihilation for the former, semi-integration into modern economies for the latter) are reminders of how vulnerable foragers become when non-foragers want the land they inhabit. The Khoi’s adoption of an economy that

People in the Sudd, S Sudan. Impressions from a sketch-book.

was perceived as intrinsically 'inferior' by the San ensured the Khoi's survival and an increase in their numbers while the San succumbed to more powerful economies. Within our lifetime, external forces have systematically dismantled the last vestiges of a way of life that sustained our ancestors for hundreds of thousands of years (Lee 1972). As a San hunter once put it, 'the string has been broken'.

Mammals of all sorts had hundreds of thousands of years to accommodate to sustained hunting by humans and this may help to explain why so many species have managed to survive in Africa. Elsewhere, notably in Australia and the Americas, many so-called 'naïve' mammal species became extinct soon after humans invaded their realms (Flannery 1994, 2001). For the indigenous African herbivores, the arrival of exotic livestock brought new elements of competition. For the larger carnivores, pastoral humans represented a shield denying them access to a source of meat that has continued to expand at the expense of their original prey base.

If carnivores have lost out to pastoralism, herbivores have lost even more to agriculture as their own attempts to consume cultivars have turned them into 'pests'. Even more significant, the expansion of agricultural peoples has progressively eaten into all sorts of natural ecosystems, in many instances obliterating the natural vegetation and faunas of entire regions.

Both the numbers of humans and the complexity of their societies have continued to enlarge. Recently created 'sovereign states' are already being drawn into a web of global institutions that are in the process of transforming the scale of basic human enterprises. Among these enterprises is the ancient practice of studying and enumerating resources. Within the bounds of their territories, foragers knew the whereabouts, habits, sometimes the numbers, of the animals and plants on which they depended (Roth 1897). Pastoralists kept a tally of all their animals and knew intimately their physical needs. Farmers monitored and recorded many details of their crops and livestock. Today, international bodies, such as United Nations Food and Agriculture Organization (FAO), have globalized these practices. The editors and authors of this work, together with organizations such as The Wildlife Conservation Society (WCS), IUCN, WWF, Fauna and Flora International (FFI) and the Zoological Society of London (ZSL), are engaged in the vast and endlessly incremental task of studying and conserving the mammalian communities of the world, communities of which *H. sapiens* is an organic and integral part. This volume is a contemporary expression of human concern and interest in the mammals of Africa. Many of these mammals helped sustain our ancestors: hopefully they will continue to sustain our descendants.

Reproduction and Population Structure Human gestation lasts about nine months. It is theoretically possible for human numbers to double in <20 years. In the contemporary world, societies differ widely in their birth and survival rates. Many of the factors determining the reproduction and demography of Modern Humans are culturally determined, but many parameters remain biologically constrained in ways that do not differ from those of other mammals.

With the onset of puberty, humans of both sexes, like other primates, develop an interest in sexual activity. While eventual reproduction is usually the outcome, social manipulation usually plays a decisive role in the pairing process, with parents, families and convention enforcing control over their youths' reproductive potential for whatever social advantage can be extracted. Such

controls have usually acquired both moral and socially strategic connotations that strongly influence the choice of partners. Numerous works of art, such as *Romeo and Juliet*, have explored the joys and tragedies of sexual attraction and its social manipulation.

In spite of births having been decoupled from seasons, in most societies there are still reported to be birth peaks after wars, or nine months after spring public holidays! As among other mammals, there is an intimate relationship between food and reproductive success, birth-weights, growth rates and survivorship. In all aspects of our reproductive biology – growth, maturity, longevity, birth, and mortality rates – we are typically mammalian and, more specifically, we are recognizably African primates.

Predators, Parasites and Diseases In Africa, humans have probably always been regular prey for Lions and other large carnivores. There is a fundamental difference between the attitudes and behaviour of people that have no experience of being threatened by Lions, Leopards or hyaenas and those who have. Rural people are frequently at risk (or may perceive themselves or their livestock as being so). Thus, with the spread of humans and their domesticates the pressure on potential predators mounts, leading to an attrition that has already led to widespread local extinction of carnivores. It is an attrition that has been greatly speeded-up by the availability of cheap poisons, firearms and traps.

Disease is still a major selective factor in human biology, no less than it is for other mammals (Black 1975). To mention only two examples, the impact of malaria and AIDS on the well-being of African human populations is enormous. It is essential to understand the biology of such diseases if we are to mitigate the suffering they cause. Other African mammals are highly relevant to that task: for example, there is a type of malaria that is specific to a particular species of African murine rodent (Vincke 1950). This is one example of a self-contained host–parasite relationship that can be reproduced and studied in miniature form in the laboratory.

AIDS is a disease that has jumped from its original hosts, several African primate species, into the one African primate that has a world-wide population. Thus, *H. sapiens* has served the virus well in spreading it widely and in providing millions of hosts (and the epidemic is still far from peaking). Only a much greater knowledge of African ecology and of the primates that also harbour AIDS will allow us to come to grips with this disease and understand its deep evolutionary roots.

While indigenous diseases will undoubtedly continue to pose threats to humans and their domesticated animals, disease reservoirs in domesticates are now an increasingly common threat to wild animals. Disease has always been a universal for mammals and, as the leading agent of natural selection, disease has profoundly shaped what an animal is. Disease has certainly shaped *H. sapiens*, sometimes in unexpected ways.

It is likely that prehistoric population densities and resource-use patterns had a direct influence on human biology (Armalegos & McArdle 1975), and on the evolution of one of our most species-specific characteristics – nakedness. For example, epidemiological challenges must soon have arisen when foraging groups of early *Homo* assembled for any significant period of time in particularly resource-rich localities. This is because large groups soon accumulate waste and excreta, and these, in turn, quickly attract a variety of noxious

organisms, especially in the tropics. Since diseases and parasites are among the most influential and fastest agencies in natural selection, greater exposure to contamination would soon select for the individual humans that were most resistant to opportunistic skin infections. The skin-cleansing and antibiotic role of eccrine glands, one of our primary peculiarities, was pointed out earlier and the possibility was mentioned that eccrine gland multiplication in humans is linked with decreased hairiness. It is not simply that eccrine glands have increased and the size and density of hairs have decreased. The decrease in hairiness combines with a drastic decline, in humans, of the apocrine and sebaceous glands that are directly attached to hair follicles in most mammals. These fatty glands have disappeared from extensive areas of the human body and, in many peoples, so has a dense growth of thick hair. However, the high level of variation in degree of hairiness in Modern Humans supports the idea that hair reduction might be a relatively recent and incomplete evolutionary development. If there is a direct connection between reduced hair cover, increased eccrine glands and more exposure to skin infections, self-cleansing must be part of the explanation. We may be naked for no more glamorous a reason than that our ancestors were a dirty lot!

Conservation IUCN Category (2012): not listed. CITES (2012): not listed.

When a world leader proclaims, 'the planet is not at risk, WE are!', the possibility that *Homo sapiens* might be an 'endangered species' is quite explicit (Havel 2007). Emergent diseases, nuclear war, climate change, over-population, or the impact of volcanics or an asteroid are all possibilities, but the core of Havel's argument is that we must study and respect the natural processes that govern life on earth in order to survive as a species. He identifies, as the central problem, the comprehensive appetites of our species and all the industries that serve them.

'Conservation' is a word and a concept created by the intellect and emotions of contemporary humans. It is diametrically opposed to many of the consumptive appetites of humans so that practical conservation, whether it is for the long-term well-being of humanity or for the survival of other species, comes into unavoidable conflict with all the human institutions and practices that serve those appetites. In Africa, the conservation of mammals has a species-specific dimension that is rarely appreciated because so few people are willing to acknowledge their status as one more African mammal, still less acknowledge the possibility of our own extinction.

Understanding human origins in Africa is a discipline in its infancy. Integral to the growth of that understanding will be the reconstruction of human and pre-human ecological niches using existent plant and animal communities of Africa as living models and exemplars. Even if there were no other motive for conservation (and there are many reasons), this self-centred reason would be sufficient to justify current efforts to conserve the entire spectrum of African mammals and their habitats.

In terms of rationales for conservation, these have been iterated and re-iterated by distinguished thinkers and by leading conservation bodies, world-wide. In the contemporary world, we have frequent reminders of our commonality with other mammals; reminders that come from innovations in medicine, from frequent new fossil discoveries and from the laboratories of geneticists, all reinforcing the message of genetic commonality with the rest of nature. These

reminders are welcome for many reasons, but especially because they awaken a more general recognition that we need to develop universal human ethics and practices that include an awareness of the existential needs of animals. After all, the vast majority of our ancestors were governed by just such underpinnings of their existence; yet the extermination of species continues to gather momentum.

How can humans develop ethical attitudes towards other animals and towards the environment? And how can we develop ethical institutions and legislations to ensure that mammals, and the environments that sustain them, survive an unprecedented increase in human numbers? Plans for the future can be predicated upon little more than hope: hope that the present nationalistic era of economic, political and religious barbarism will eventually evolve into a more rational and benign relationship with the global environment and with other species. That evolution will depend upon the spread, rather than the suppression, of biological self-knowledge and a heightened awareness of our commonality with other forms of life. In spite of many discouraging trends, there are reasons for qualified optimism. The most promising sign of change is the articulation of a new philosophical position by a new breed of world leaders. In a 2007 address entitled 'The planet is not at risk. We are', Vaclav Havel (2007) wrote: 'We must return again and again to the roots of human existence and consider our prospects in centuries to come ... equally important is support for education, ecological training and ethics – a consciousness of the commonality of all living beings and an emphasis on shared responsibility. We will either achieve an awareness of our place in the living and life-giving organism of our planet, or we will face the threat that our evolutionary journey may be set back thousands or even millions of years.'

There is, therefore, a growing recognition of indebtedness to nature for all our plant and animal products, and for a range of natural services from water and living space to processes such as natural pollution control, pollination, seed dispersal and soil fertility. That indebtedness requires payment and compensation no less than to a local council or police force. As the annual payment of land and property taxes becomes ever more universal, there must be an explicit provision for conservation. 'Must' because all land has ultimately been taken from some natural ecosystem, and because long-term human interests demand that all such ecosystems should be preserved in some parts of their natural range. A share of taxes is the surest, most principled, equitable and practical way of funding both the conservation of ecosystems and their in-depth study.

At the local level we are already seeing that anyone's so-called right to own and use land is being qualified as more and more countries and local authorities tax both the ownership and the tenancy of land and property. Even more important, most countries now put a time-limit on ownership by imposing substantial death duties on land and property. Wherever this is enforced, the act of purchasing or inheriting land has ceased to be a final and absolute indulgence to be protected by force or by inequitable laws. The right to own and use land is being replaced by a much healthier principle in which 'owning' changes into something more like a secure form of 'borrowing'. Liability for land or property taxes, payable to the state or other local authorities, is, therefore, becoming an entrenched practice that will certainly continue to spread and is likely, in the long run, to become global. Furthermore, the switch from traditional ideas of outright, heritable ownership towards concepts of stewardship of borrowed

assets is increasingly being applied regardless of whether the land is in individual, communal or corporate hands.

Implicit in such change is acceptance of an individual owner's fiscal responsibility to a wider world: the tax payer is helping fund the infrastructure that surrounds his property. A wholly anthropocentric interpretation of an owner's responsibilities and privileges limits the owner's debt to the human services that are enjoyed. Now there is the dawning awareness that owners are borrowing from much older 'infrastructures'. In Africa, where subsistence has been much more obviously wrested from nature by force, it is to nature that future debts will have to be paid.

The relative costs and benefits of feckless, reckless exploitation of all and every natural resource for immediate gain will eventually come under formal assessment and judgement. As all natural resources, particularly biota and habitats, become rarer and more restricted, it will become essential, if they are not to disappear altogether (as so many already have), to preserve and fund their preservation, not as voluntary responses to eccentric lobbyists, but as necessary acts in the public interest. Funding will depend upon an equitable taxation system. Taxes are needed that would directly fund the conservation and study of all that is being destroyed, not just in forests, not just in Africa, but world-wide. The beneficiaries of taxes, as well as the payers and dispensers, will have to be involved at local, national and global levels.

The beneficiaries of taxation of land and property could be primarily within the country or region within which such taxes are generated, but this ought to be qualified by the nature of the lands' products. Thus, tax on cattle ranches in Argentina or Australia should also contribute to research and conservation of ruminants in continents and countries where bovids are indigenous, rather than to artificially sustained, imported exotics. More significant and complex in terms of revenues and their allocation would be a 'conservation share' of taxes on consumer goods. Consumers will eventually have to pay tax on all goods that have ultimate origins in nature. Such goods will be taxed on the principle that the natural ecosystems within which such products evolved (or the ecosystems displaced by their cultivation or production) must be conserved, and the level of tax graded not only by the value of the product itself but also by the value of what the product has displaced. Thus, consumers of any product will contribute materially towards the preservation of the conditions within which that product was able to evolve as well as to the ecosystems its production has displaced. A significant part of the revenue generated by such taxes would return to the regions of origin of such products. Thus, taxes on coffee and palm-oil products, world-wide, would generate funds both for the conservation and study of African forests, where coffee and palm-oil originated, and for the conservation of South American or South-east Asian forests, which have been decimated by clearance for coffee or palm-oil plantations. Likewise, consumers of beef, milk or leather products will be taxed in order to sustain the ecosystems in which large herbivores evolved and continue to evolve. At present such consumers are actively contributing to the rapid extermination of wild herbivores and the destruction of their habitats, especially in Africa. To call such a situation short-sighted or immoral is an understatement; at present both the consumption and production of these goods enjoy far too many subsidies and bonanzas, and the enormous real costs have been concealed for far too long. The time for calling the producers' bluff is overdue, and revealing their deceit may require

some forceful expressions of public dismay at the behaviour of these industries and their apologists.

There are central issues of equity involved. Those who benefit from the products of nature and those who benefit from the land that has been taken from nature should contribute to the systematic preservation and study of viable samples of all the world's major ecosystems. Although the enterprises that are currently permitted to steal and profit from nature without having to pay anything in return will initially throw tantrums, they will be the first to boast of their largesse and take pride in the results once such taxes are put in place. And put in place they eventually will have to be, however long it takes. An ever-growing and ever-more-influential minority is becoming aware that the conservation of natural communities and ecosystems is far too important an enterprise to be left to charity alone. In the world we live in, systematic and sustained taxation on the exploitation of nature is the only form of compensation, barring charity, that we can realistically expect. As for the scale and rating of such compensation, it should be sufficient to permanently maintain and protect viable and widely scattered samples of all natural ecosystems across the whole of Africa and across other continents as well. The pioneer mentality that once applauded the seizure and conversion of so-called 'wilderness' will eventually have to change and mutate. The descendants of 'pioneers' will about-face and supervise, tax, or even outlaw such behaviour as being against the common good. This will be, or already is, a difficult transition as yesterday's heroes are made to stand accused in today's dock.

We employ police, detectives, judges and prison systems to deal with thieves or vandals that steal or destroy the carefully husbanded goods of more prudent persons or ancestors. We now need to enlarge the remit of such institutions to deal with thieving from Nature, our ancient but perennial parent. The conservation of natural ecosystems and species is, therefore, not some aesthetic folly of the rich and privileged, it is a profound expression of the will of intelligent humans to survive through knowledge. Only knowledge can save humans from their own follies and from becoming one more endangered species.

Measurements

Homo sapiens

Total Height (♂ ♂): 170 (95–215) cm (max. 272 cm)

Total Height (♀ ♀): 160 (91–>200) cm

HB (both sexes): est. (73–83) cm

T (both sexes): 0 cm

HF (both sexes): est. 22 (15–33) cm

E (both sexes): est. 63 (22–55) mm

WT (♂ ♂): 80 (35–>100) kg (max. 419 kg)

WT (♀ ♀): 66 (30–>100) kg (max. 730 kg)

Marked regional and temporal variation, from small, light-weight Twa and San to tall Nuer and Dinka people. Upper weights distorted by dietary habits and hormonal condition. Maximum weights cited are from exceptionally obese, effectively immobile individuals. Figures given here averaged from diverse sources. For detailed figures see Ruff (2002).

Superfamily CERCOPITHECOIDEA – CERCOPITHECOIDS: OLD WORLD MONKEYS

Cercopithecoidea Gray, 1821. London Medical Repository 15: 297.

Myology of Olive Baboon *Papio anubis* sub-adult male.

The superfamily Cercopithecoidea includes a single living family, Cercopithecidae, which embraces the subfamilies Colobinae ('leaf monkeys') and Cercopithecinae ('cheek-pouched monkeys'). Cercopithecoidea also includes at least one extinct family, Victoriapithecidae.

While the split between cercopithecoids and hominoids (apes) poses questions, the split clearly took place within Africa. There are two sources of information for dating the divergence between the cercopithecoid and hominoid lineages. The first, inferred from fossils, produces an estimate of 23.3 mya (late Oligocene) (Walker & Shipman 2005). The second method, using molecular clocks, gives a substantially earlier (late Eocene–early Oligocene) estimate of 30.5 (36.4–26.9) mya (Steiper & Young 2006) and 31.6 mya (Perelman *et al.* 2011), although Roos *et al.* (2011) provide an estimate of 26.5–21.9 mya, which is similar to the estimate based on fossils.

It may be significant that the end of the Eocene (33.9 mya) saw a marked change in climate, and that much of the Oligocene was drier and cooler, with forest retreating to the equatorial region (see Chapter 4 in Volume I). Among the Cercopithecoidea there are indications that their common ancestor was less than wholly arboreal, and that their emergence was probably linked to substantial and extensive aridity. In both fossil and living cercopithecoids, the primary indications of a less arboreal ancestral phase are an elongation of the back combined with more fore–aft movement in the limbs. Both of these alterations are correlated with fast movement on the ground. A terrestrial ancestry is unambiguous both for Cercopithecinae (many of which are still strongly terrestrial) and for Colobinae (in spite of being almost entirely arboreal today). Apart from a relatively rich fossil record, which confirms their early terrestrial bias, colobines share many

Colobinae. Colobus monkeys (red colobus *Procolobus*).

Cercopithecinae. Cheek-pouched monkeys (baboon *Papio*).

anatomical features with cercopithecines (quadrupedal adaptations of the postcranial skeleton and, in particular, the striking bilophodonty of the molar teeth). In spite of the great dietary specialization of most contemporary species of Colobinae, a few extant species retain enough ecological flexibility to betray their common origins with Cercopithecinae (particularly evident in the semi-terrestrial *Semnopithecus* spp. langurs of South Asia).

As for an intra-African separation between proto-cercopithecoids and proto-hominoids, the latter were the first to leave Africa and this has phylogenetic as well as biogeographic implications. Thus, at the time of their emigration during the early Miocene (ca. 20 mya), Hominoidea seem to have had a more northerly and equatorial range in Africa while the earliest Cercopithecoidea were, putatively, differentiating in the drier, more temperate south-east (which, at that time, was farther south and more extensive than today).

The features that colobids and cercopithecids have in common are dietary: not only the bilophodont cheekteeth, but also, apparently, an ability to detoxify plant secondary compounds in the gut. This is an ability that hominoids lack and which gave the Old World monkeys a marked ecological advantage.

Anatomical reflections of 'branch-running' and brachiating.

In quadrupedal branch-running, the monkey long serratus muscle and scapula are approximately vertical (a, d and f).

In brachiating, the ape serratus muscle and scapula wrap around the trunk (b, c and e).

In addition, there are cranial and dental features indicative of a dietary shift in which a frugivorous diet had to accommodate to more seeds/nuts. This would have been consistent with greater seasonality in the south. Cercopithecoid bilophodonty has been analysed in terms not only of increasing the surface for grinding harder foods but also the construction of reinforced, wedge-like cusps that could crack and open nut shells and break-up hard seeds (Kay 1975, Maier 1977, Benefit & Pickford 1986). The entire skull had to withstand occlusal forces and provide the anchorage for more powerful mandibular muscles (Benefit 1999). This led to loss of the maxillary sinus and more heavily reinforced buttressing of the

mandibles. Thus, all Cercopithecoidea share locomotory, digestive, dental and cranial specializations. It is possible that these traits evolved in response to a diminished choice of foods, especially fruit, in south-east Africa. These traits may have begun to evolve before colobines and cercopithecines diverged, and before any movement out of their south-eastern enclave. However, the first cercopithecoid lineage to move back into the equatorial belt would have had to face competition from their abundant and diverse tropical precursors, the apes. This competitive challenge may have given the proto-colobines a selective advantage, which led to further accentuation of the dietary trait. Just such a break-out of south-eastern isolation could

have generated the phylogenetic split within the Cercopithecoidea and initiated a distinctive colobine lineage. Meanwhile, the parent population, still isolated in the south-east, would have been free of competition from apes but subject to its own selective forces (mostly in relation to predation and socially driven pressures in habitats that were harsher and more seasonal).

Such a staged history would be consistent with colobines getting out of Africa later than the apes, yet several million years earlier than the cercopithecines. Thus, south-eastern origins for the Cercopithecoidea would not only account for the primary split

in a common anthropoid ancestor, it also helps explain why apes were the first to leave Africa and why colobine ancestors were next (because they were the first to move north-east). Eventually, colobines and cercopithecines both had Eurasian diasporas, which then radiated extensively, especially in tropical South-east Asia. More detailed accounts of the features that distinguish colobines from cercopithecines are given in their respective profiles and in the species profiles.

Family CERCOPITHECIDAE

CERCOPITHECIDS: OLD WORLD MONKEYS

Cercopithecidae Gray, 1821. London Medical Repository 15: 297.

| | | |
|--|--|--------|
| Colobinae (2 genera with 2 subgenera, or 3 genera; about 12 species) | Colobus Monkeys (Colobine Monkeys) | p. 93 |
| Cercopithecinae (13 genera, 56 species) | Cheek-pouched Monkeys (Cercopithecine Monkeys) | p. 155 |

Until recently, cercopithecine monkeys and colobine monkeys were generally distinguished at the familial level (i.e. Cercopithecidae and Colobidae). Thus, most references before 2000 use Cercopithecidae in this sense. With the rise of molecular phylogenetics and a gradually improving fossil record, the objective dating of evolutionary divergences at various higher taxonomic levels has become, for the first time, possible. This offers taxonomists a temporal criterion to determine the taxonomic rank to which any one group can be allocated. In the provisional temporal ranking of taxa suggested by Goodman *et al.* (1998), the emergence of a family should take place in the late Oligocene (28–25 mya), while subfamilies should emerge in the early Miocene (23–22 mya). Fossil and molecular data combine in suggesting that the cercopithecine monkeys and colobine monkeys diverged from a common ancestor in the early to mid-Miocene (14–18 mya; Perelman *et al.* 2011, Roos *et al.* 2011), which, on the new criteria, precludes the two taxa from being ranked any longer as families. We, therefore, adopt Cercopithecidae as the sole extant family within the Cercopithecoidea, the other potential taxa being extinct fossil lineages (notably the lineage or ‘plesion’ to which *Prohylobates* belonged and another to which Victoriapithecine monkeys might have belonged).

The family Cercopithecidae embraces some 23 genera within a very diverse group of African and Eurasian monkeys. These include the colobine monkeys or ‘leaf-monkeys’, subfamily Colobinae, and the cercopithecine monkeys or ‘cheek-pouched monkeys’, subfamily Cercopithecinae. The Cercopithecinae includes two tribes: the long-tailed African guenons and their allies, Cercopithecini, and the large-muzzled African baboons, drills and other baboon-like monkeys, Papionini. The Papionini also includes the predominantly Asian genus *Macaca*, which is thought to be of African origin and to have emigrated

Frontal and lateral view of skull of Miocene *Victoriapithecus macinnesi* (Maboko Island, Kenya).

to Asia before 5 mya (late Miocene) (Stewart & Disotell 1998).

Features distinguishing Cercopithecidae from Hominidae are quadrupedal locomotor apparatus, with arms not much shorter than the legs, somewhat elongated lumbar spine, and bilophodont cheekteeth, which initially operate as a series of transverse ridges along the toothrow and, with wear, leave a series of enamel loops that prolong the life of the teeth.

Among *living* groupings, Cercopithecidae effectively share all their characteristics with Cercopithecoidea. Therefore, consult the Cercopithecoidea profile for the characteristics that distinguish Cercopithecidae in its new, post-2000, sense. The features of subfamilies and genera are presented under the appropriate taxonomic headings.

Colin P. Groves & Jonathan Kingdon

Subfamily COLOBINAE – Colobines: Colobus Monkeys

Colobinae Jerdon, 1867. Mammals of India, p. 3.

| | | |
|--|---|--------|
| <i>Colobus</i> (5 species) | Black Colobus Monkey,
Black-and-white Colobus
Monkeys | p. 95 |
| <i>Procolobus</i> (The 2 subgenera are
often ranked as full genera) | Olive Colobus Monkey,
Red Colobus Monkeys | p. 120 |
| (<i>Procolobus</i>) (1 species) | Olive Colobus Monkey | p. 121 |
| (<i>Piliocolobus</i>) (6 or more species) | Red Colobus Monkeys | p. 125 |

Colobus monkeys are medium-sized, variously coloured monkeys with big bodies and small heads. One species is all black, some black-and-white, some have red and orange tints, and one species is dull olive. At close quarters their most distinctive peculiarity is a lack of thumbs. Amputation of digits is a mutilation for humans, hence the monkeys' anthropocentric name, from the Greek, *kolobos*, meaning 'mutilated'. Thumblessness and dietary specialization represent the two adaptations that most clearly separate the extant African colobines from other cercopithecoid monkeys. The progressive development of these peculiarities over time poses questions of the greatest biological interest (Hartwig 2002).

There are a dozen recognized species in the African branch of Colobinae and these belong to three genera or subgenera, the Black-and-white Colobus-Group *Colobus*, the Olive Colobus *Procolobus* (subgenus *Procolobus*) and the Red Colobus-Group *Procolobus* (subgenus *Piliocolobus*). There are seven Asian genera, all of which derive from an African source following an emigration at about 12–11 mya (mid-Miocene; Perelman *et al.* 2011, Roos *et al.* 2011). Molecular phylogenetic evidence indicates that the African colobine radiation started by the late Miocene with the Black-and-white Colobus-Group splitting from the Olive Colobus/Red Colobus-Group by 9.9–6.8 mya (Ting 2008a, b, Perelman *et al.* 2011, Roos *et al.* 2011). The last common ancestor for Olive Colobus and Red Colobus is estimated at 6.4 mya (Ting 2008a, b) and 6.9 mya (Perelman *et al.* 2011, Roos *et al.* 2011). The chromosome count for all African colobines that have been examined thus far is $2n = 44$ (Romagno 2001).

Today, African colobus monkeys are almost exclusively equatorial and wholly arboreal, but the fossil record and their emigration to Asia demonstrate that, in the past, their ecology was more diverse, their geographic distribution much greater and their diversity more rich. Fossil colobines from the late Miocene and Pliocene show that they were then semi-terrestrial, and some are thought to have been wholly terrestrial, while at least one fossil species, *Mesopithecus* from the late Miocene of Eurasia, had a sizeable thumb. Jablonski (2002) and Leakey & Harris (2003) provide an exhaustive review of current knowledge of the fossil colobines and summarized the evidence available for African colobines.

The earliest fossils date from the late Miocene (Benefit 1999) and several fossil genera have been described, notably *Microcolobus* (according to Elton 2007 the earliest fossil colobine at about 9 mya), *Kuseracolobus*, *Rhinocolobus*, *Dolichopithecus* and *Cercopithecoides*. An exceptionally large Pliocene form, *Paracolobus chemeroni*, was likely predominantly terrestrial, as was *Dolichopithecus* (Delson 1994, Benefit & Pickford 1986). To date, no fossil colobines have been

reliably allocated to the living genera or subgenera, and most fossil forms did not give rise to extant species.

The divergence between Cercopithecinae and Colobinae has been variously estimated at ca.14 mya (Stewart & Disotell 1998) and 16.2 mya (17.9–14.4) (Raaum *et al.* 2005); the latter range seems more likely when it is remembered that by 11 mya well-developed colobines were probably present in Asia (Stewart & Disotell 1998, Tosi *et al.* 2005). The beginning of the mid-Miocene coincided with a period of warming just before a more general period of global cooling. Such an amelioration of climate might have allowed the colobine ancestor to detach itself from its parental population, putatively in south-eastern Africa, and move into the equatorial belt. This may help explain why colobines had such a substantial head-start over cercopithecines, not only in colonizing Asia but also in reaching outlying areas north of the equator. The first fossil cercopithecoid in North Africa was a late Miocene colobine, *Libypithecus*. The colobine emigration to Asia took place about 11 mya, whereas the eastward spread of *Macaca* was 4 million years later.

It seems plausible, therefore, that when the colobine ancestor moved north-west to share evergreen equatorial forests with a variety of mostly larger (and possibly more strategic-minded) proto-apes, their advantage lay in being 'digestion specialists' that could cope with food types that were too difficult for the proto-apes, such as plants that protected their seeds and leaves with distasteful or toxic secondary compounds (Montgomery 1978). Later, when colobines and cercopithecines came into direct competition, the colobines' dietary specializations became even more pronounced. This development gains some credence when it is remembered that at least one Asian genus, the partly terrestrial *Semnopithecus*, retains a less specialized digestive physiology. Further evidence for this progressive, staged, digestive specialization is registered in changes in the dentition of colobine fossils during the Pliocene (Benefit 1999). Judging from the relative abundance of their fossils, Colobinae were only overtaken by Cercopithecinae (in Ethiopia, which must have been very much of a peripheral outpost for them, even then) as late as 4.0–3.5 mya. At the early Pliocene site at Aramis, Ethiopia, White *et al.* (1994) calculated that colobines were 12 times as abundant as cercopithecines, but they had become much rarer by 3.3 mya (Benefit 1999).

The mainly Pliocene radiation of Cercopithecini, particularly of guenons, which embrace a range of body sizes similar to colobines, seems to have progressively narrowed the niche for colobines. This is most obvious in Africa, where colobines originated and have the longest history of interaction with other monkeys.

Thumblessness and dietary specialization represent the two adaptations that today separate the African colobines from other cercopithecoid monkeys. Only in monkeys wholly committed to living in dense forest would the hands become modified into flexible hooks. Many fossil colobines were not only more terrestrial, living in less than true forest, but they had thumbs. The evolution of hands, such as those possessed by modern African colobines, involved the alignment of the long fingers into a single, narrow, curved arc (where a thumb would actually obstruct its branch-gripping function).

Peters's Angola Colobus *Colobus angolensis palliatus*.

Because their hands have lost the ability to manipulate isolated, droppable objects or living prey, colobus prefer to take material off a plant directly into the mouth. Thus thumblessness implies that colobines became almost wholly arboreal and vegetarian at much the same time; but when? It is likely that these were relatively late developments, probably strongly influenced by competition from cercopithecines (but see Ting 2008a, b). The rise of cercopithecines eventually excluded colobines from all their earlier, more terrestrial niches, at the same time leading to still stronger selection for specialized digestion of chemically protected plant parts.

The complex, sacculated stomach of colobus monkeys holds up to one-third of their total body-weight in food. They are 'foregut-fermenters' and digestion requires long rests to allow bacterial fermentation of a sort that is similar to that of ruminants and other purely herbivorous animals (except that colobines do not regurgitate and chew cud). The bacteria are short-lived and protein from their dead bodies provides a large proportion of easily absorbable nutrients for the monkey (R. Hofmann pers. comm.). There is clearly a history of co-evolution between African colobines and the trees in their disparate habitats. A prominent part of most colobine diets consists of leguminous plants, the leaves and fruits of which are exceptionally well protected by chemicals. Because of this peculiar chemistry, and because legumes have dominated African forests, the processing of legume toxins must have been an important factor in the evolution of African colobine digestion (Oates *et al.* 1977, Montgomery 1978, Moreno-Black & Bent 1982). Although long referred to as 'leaf-monkeys', colobines are better described as 'processors of difficult plant material' and their diet includes fruits, seeds, petioles and flowers, as well as leaves, but most species actively avoid ripe,

soft, colourful fruit, preferring unripe fruits, seeds and seed-pods (Oates *et al.* 1977). There are significant differences among colobine species in the proportions of fruits and seeds that they eat, as is well exemplified in the profiles that follow.

While colobines share the primary feature of a toxin-processing and leaf-digesting chambered stomach, the members of the Black-and-white Colobus-Group have the most advanced digestive capacity and a correspondingly extensive distribution through moist evergreen forests. The Olive Colobus *Procolobus verus* with, apparently, a less advanced ability to cope with fibrous old leaves and plant secondary compounds, is much more restricted in its small West African range. Monkeys belonging to the widely scattered, but patchily distributed, Red Colobus-Group appear to be intermediate.

Colobine teeth are only moderately modified for a leafy diet, being essentially higher-cusped and higher-crowned specializations on the general cercopithecoid pattern (Strasser & Delson 1987). Generic modifications do occur. For example, the cheekteeth of *Piliocolobus* and *Procolobus* tend to be relatively narrower than those of *Colobus*. In *Procolobus*, the third lower molar is usually six-cusped, whereas in the other genera it is, as in most other cercopithecoids, five-cusped. The central incisors in both jaws are short and broad in *Procolobus* and *Piliocolobus*, but long and comparatively narrow in *Colobus*. The unworn lateral incisors are caniniform; in *Procolobus* and *Piliocolobus* their points are acute and are directed laterally, but in *Colobus* they are more obtuse and are directed medially. In *Procolobus* the incisors have a prominent lingual cingulum with a distinct lingual tubercle. The unusually robust teeth of Black Colobus *Colobus satanas* may be seen as adaptations to considerably more hard seeds in the diet (Oates & Trocco 1983).

Apart from the dental characters mentioned above, there are well-marked differences among the three African colobine groups in the skull. *Procolobus* develop sagittal crests in adult ♂♂, whereas *Colobus* never do. In *Piliocolobus* the orbits are angular, with thick supraorbital ridges interrupted by a notch or channel; there are well-marked suborbital fossae; and the choanae and interpterygoid fossa are deep and narrow. In *Colobus* the orbits are more rounded, with supraorbital ridges that are usually less marked and generally run uninterrupted above each orbit without marked notches; the facial skeleton is relatively flat on either side of the nasal aperture, without suborbital fossae; and the choanae and interpterygoid fossa are low and wide. In most respects, *Procolobus* resembles *Colobus* cranially, except that, like *Piliocolobus*, there are marked suborbital fossae. Differences among the three groups were first described in detail by Verheyen (1962), although some of the characters he ascribed to *Piliocolobus* apply only to central African species.

There are also characteristic differences among species both within *Colobus* and *Piliocolobus*. In particular, the skulls of *C. satanas* and Guereza *Colobus guereza* are very distinctive (see illustrations pp. 98 & 113).

Lumping all colobus monkeys under a single genus, *Colobus*, was common practice until recently. Indeed, all our principal authors have, over time, shifted positions on colobine taxonomy. In their earlier works Groves (1970), Kingdon (1971) and Struhsaker (1975) all followed the authorities of that time (Booth 1954, 1958a, b, Verheyen 1962, Napier & Napier 1967) in referring to various regional forms of red colobus as subspecies of the Western Red Colobus *Colobus badius*. Initially, the arrival of molecular taxonomy scarcely changed this: Cronin & Sarich (1975) divided colobines into three equal genetic lineages, the African *Colobus*, and the Asian *Pygathrix* and *Presbytis*.

Tentative phylogenetic tree of extant colobines (after Ting *et al.* 2008a).

Groves (1989) subdivided African colobines into two genera, *Colobus* and *Procolobus*, and he further subdivided the latter into the subgenera *Procolobus* and *Piliocolobus*. Since 1989, the generic or subgeneric name, and further subdivisions, of red colobus monkeys have been at variance (Grubb *et al.* 2003, Groves 2007b, Ting 2008a, b, Roos *et al.* 2011). Readers should be aware that opinions on the taxonomic status of red colobus and the number of species contained within this entity are still contentious, even among the editors and authors of this work.

In adopting the subgenera *Procolobus* (*Procolobus*) and *Procolobus* (*Piliocolobus*) the editors and authors of this work have arrived at a provisional compromise. In this volume, T. Struhsaker, P. Grubb and K. Siex treat *Piliocolobus* as a subgenus of *Procolobus*; they have written profiles of the three taxa designated as *P. rufomitratus*, *P. gordonorum* and *P. kirkii*. Further profiles, designated as *P. badius*, *P. pennantii* and *P. preussi*, are presented by other authors. Of the forms described herein as subspecies of *P. rufomitratus*, C. P. Groves, J. Kingdon and T. Butynski recognize that complex, and the not easily explained interactions (perhaps hybrid zones) that exist between the best-defined regional populations. They suspect, however, that some of the forms within *P. rufomitratus* merit full species status (notably *tholloni*, *foai*, *tephrosceles*, *oustaleti*). Readers will appreciate that little is known about red colobus biology in general, especially at the

molecular level, and that, as such, colobine taxonomy remains in a state of flux (Grubb *et al.* 2003, Groves 2007, Ting 2008a, b, Roos *et al.* 2011).

Regardless of current controversies, the red colobus diaspora embraces a complex of 18 or more identifiable populations that have long posed major puzzles for scientists. Red colobus are recognizable by their distinctive colouring, with red caps or red patches on the crown being the norm in almost all species. Crown hair forms complex crests and crisp whorls in some species (notably *badius*, *pennantii*, *tephrosceles*, *rufomitratus*), but can be lank and unstructured in other species. A black band between orbits and ears is obvious in most populations and spreads up onto the brows or down onto the cheek in some eastern and central Congo Basin populations (notably *rufomitratus*, *tephrosceles*, *tholloni*) and in the Niger Delta population *epieni*. The distribution of red or black patches on the body and limbs is highly variable; some populations are quite drab, such as *P. rufomitratus* and *P. pennantii*, while others (notably *P. kirkii*, *P. gordonorum*, *P. tholloni*) are brightly coloured. *Procolobus gordonorum* has two main morphs, one rather drab and blackish, the other more colourful and contrasty in pattern, but both typically have red crown hair forming a 'toupee'. The relevance of this polymorphism, which occurs within groups throughout their range, would be worth study, especially in relation to the selective effects of differing levels of predation and population densities. *Procolobus foai* is also highly variable; it may be that what are now classified as the four or five subgroups of this taxon are actually hybrid swarms occupying zones in between the distributions of formerly more distinct taxa (Colyn 1991).

Other features of the Colobinae are presented in the genus and species profiles.

Jonathan Kingdon & Colin P. Groves

GENUS *Colobus*

Black-and-white Colobus Monkeys

Colobus Illiger, 1811. *Prodromus Systematis Mammalium et Avium*, p. 69.

Western Guereza *Colobus guereza occidentalis*.

Polytypic genus endemic to the forests of tropical Africa. Until recently it was common to find the name *Colobus* applied to all extant African colobines, including some fossil species (see Subfamily Colobinae). The Black-and-white, or Pied, Colobus-Group of the genus *Colobus* consists of five species: Black Colobus *Colobus satanas*; Angola Colobus *C. angolensis*; King Colobus *C. polykomos*; White-thighed Colobus *C. vellerosus*; and Guereza Colobus *C. guereza*. Apart from the bold black-and-white colouring, this genus is distinguishable from *Piliocolobus* and *Procolobus* by its conjoined ischial callosities, by the absence of sexual swellings in ♀♀ and by the absence of perineal organs in ♂♂. All species have very loud calls ('roars') that emanate from an enlarged larynx and subhyoid sac that are unique to *Colobus*. The stomach has three chambers that offer, within the colobines, the most advanced mode of digestion of difficult vegetation types. The skulls are different from species to species and, to a lesser extent, from population to population (Hull 1979). For detailed discussion and diagnosis of the significance of features unique to *Colobus*, see Oates *et al.* (1994). With the exception of *C. satanas*, the infants of all species are white at birth.

Tentative phylogenetic tree for extant *Colobus* spp. (after Ting 2008a).

Colobus species include much mature green leaf in their diet. This enlargement of the dietary range has allowed two species, *C. guereza* and *C. angolensis*, to range well outside the main forest block into forest mosaics, galleries and degraded evergreen vegetation in eastern, north-eastern and south-central Africa. Both of these species have been particularly successful in colonizing montane forest habitats, where they grow thicker, longer pelage. Earlier expansions, presumably during wetter, warmer periods, have left isolated populations on mountain massifs in eastern Africa and some of these are distinct subspecies. *Colobus satanas* and *C. polykomos*, specialized seed-eaters, are much more restricted to high forest, though their preferred diets enable them to subsist in swamp forest and other forests with extremely poor soils.

Taking the ability to digest chemically protected plant material as the primary adaptation in Colobinae, *Colobus* is clearly the most advanced genus. As such, the other African genera must derive from earlier branches of the colobine tree. Awaiting further study are differences among populations of the same *Colobus* species within and outside the main forest block. Other monkey species, including other colobine genera and guenons, are relatively few outside the main forests, whereas competition from the large guilds of primates within equatorial forests is intense. Comparing *C. angolensis* in the

Western Guereza *Colobus guereza occidentalis* neonate.

Top: Skeleton of Guereza Colobus *Colobus guereza*.

Above: Myology of Western Guereza *Colobus guereza occidentalis*.

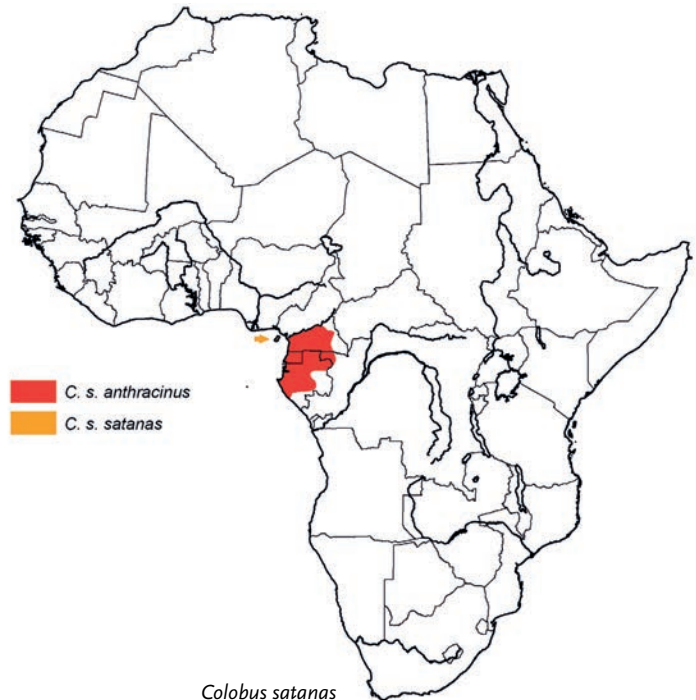

southern Congo Basin with *C. angolensis* in NW Tanzania could be revealing, as could comparisons between *C. guereza* east and west of the Eastern (Gregory) Rift. In the Semliki and north Rwenzori forests, SW Uganda, *C. angolensis* lives in montane forest and *C. guereza* lives in lowland forest. *Colobus guereza* has possibly played a role in the recent disappearance of *Procolobus* in this area (the main influences being hunting, forest clearance and degradation).

In the coastal littoral and 'Eastern Arc' montane and forested areas of East Africa there is a north-south partition between *C. guereza* and *C. angolensis*, the latter occupies all the coastal and gallery forests of S Kenya and Tanzania, while *C. guereza* occupies forests north and west of the Pare Mts up to 2900 m (notably Mt Kilimanjaro, Mt Meru, Mt Kenya and the Aberdares) (T. Butynski pers. comm.). This suggests a dynamic in which a possibly more physiologically advanced *C. guereza* expanded from the west (and only north of the Congo R.), possibly displacing *C. angolensis* in some localities but not in others, although there are areas of overlap between the two *Colobus* species in E DR Congo (e.g. Ituri Forest). Such localities could be rewarding for the study of niche formation in competitive primate communities. *Colobus*, therefore, offers numerous opportunities for study of dynamics in African ecosystems (Struhsaker 1975).

Recent molecular evidence indicates that the five extant *Colobus* spp. diverged between 3.5 mya (mid-Pliocene) and 0.2 mya (end of the Pleistocene) with *C. satanas* being the first extant species to diverge and *C. polykomos* and *C. vellerosus* being the last to diverge (Ting 2008a, b).

Colobus satanas BLACK COLOBUS

Fr. Colobe noir; Ger. Schwarzer Stummelaffe

Colobus satanas Waterhouse, 1838. Proc. Zool. Soc. Lond. 1837: 57 [1838]. Fernando Po (=Bioko I.), Equatorial Guinea.Black Colobus *Colobus satanas* adult female.*Colobus satanas*

Taxonomy Polytypic. Two subspecies (Grubb *et al.* 2003). Formerly considered a subspecies of King Colobus *Colobus polykomos* (e.g. Haltenorth & Diller 1977), but the distinctive phenotypic, cranial, dental and vocal features warrant species status (Dandelot 1974, Hull 1979, Oates & Trocco 1983). The full species status of *C. satanas* is now widely accepted (Groves 2001, 2005c, 2007b, Grubb *et al.* 2003). Grubb (1978) suggested that *C. satanas* represents an ancestral form of *Colobus* spp. This is supported by recent molecular evidence that indicates that within the Black-and-white Colobus-Group, *C. satanas* was the first to diverge (Ting 2008a, b). Synonyms: *anthracinus*, *limbarenicus*, *metternichi*, *municus*, *zenkeri*. Chromosome number: $2n = 44$ (Gregory 2008).

Description Large, black, arboreal monkey with heavy body and long limbs and tail. Entirely black (including bare skin areas). Sexes identical in colour. Adult ♀ *C. s. satanas* about 80% as heavy as adult ♂ (Butynski *et al.* 2009). Head with crest of hairs. Ears with extremely irregular outline. Tail with tuft of hairs at base but not at tip. Dorsal outline of braincase in lateral view is saddle-shaped. Skull less prognathous than for other *Colobus* spp. (Groves 2001). Individual with aberrant coat colour (white and black areas irregularly mixed) described from Bioko I., Equatorial Guinea (González-Kirchner 1997a). Infants brown.

Geographic Variation

C. s. satanas Bioko Black Colobus. Bioko I. endemic. Pelage long and thick. Smaller; tail ca. 16% shorter; hindfoot ca. 10% shorter, body weight about 10% less (see below).

C. s. anthracinus Gabon Black Colobus. Mainland Africa. Pelage short and thin. Larger.

Similar Species None within geographic range.

Distribution Endemic to western central Africa. Rainforest BZ. Restricted to rainforests of Bioko I., Equatorial Guinea, Cameroon south of Sanaga R., south through coastal Rio Muni (Equatorial Guinea) to SW Gabon, and east to W Congo. Eastern and southern limits poorly known (Groves 2001). Early in the 20th century one specimen collected east of 14° E and two specimens collected north of 03.5° N (Napier 1985). There are no data to suggest that the Black Colobus is still present this far east or north. On Bioko I. now apparently occurs in two populations: one centred on the Pico Basilé (central part of the island) and one in southern one-third of the island (Butynski & Koster 1994). Three populations in Rio Muni: one on left bank of Uoro-Mbini R. between Niefang and Macizo de los Montes Mitra, one in the mountains near Cabo San Juan (ca. 01° 15' N, 09° 30' E) and one in the Nsoc-Nzomo area (ca. 01° 55' N, 11° 00' E) (González-Kirchner 1994). Distribution patchy in Gabon; in Monts de Cristal and in Minkébé area. Not known whether present between these two areas. In south present in the Massif du Chaillu. In west present between Monts Doudou and Atlantic coast. Distribution limits to east uncertain. Not known between left bank of Ivindo R. and right bank of Ogooué R. Present in Lopé N. P. and adjacent Forêts des Abeilles (Malbrant & Maclatchy 1949, Blom *et al.* 1992, Lahm 1993, White 1994, Brugière *et al.* 2002). In Congo possibly restricted to area between

eastern boundary of Odzala N. P. and Gabon border (Carpaneto 1995, M. Fay pers. comm.).

Habitat Primary and old secondary moist forest. Coastal forests to montane forest to heathland on Bioko I., from sea level to 3000 m (Butynski & Koster 1994). On the mainland, observed from sea level to 800 m (in Waka N. P., C Gabon; Abitsi 2006, F. Maisels pers. comm.). Absent in degraded and young secondary forests but in gallery forests. Presence of tall trees essential as the species preferentially uses the upper canopy: 36% and 40% of time is spent higher than 30 m at Makandé, central Gabon (Fleury 1999), and on Bioko I., respectively (González-Kirchner 1997b). Mean annual rainfall for sites at which *C. satanas* occurs ranges from ca. 1500 mm (Lopé, Gabon; White 1994) to >10,000 mm (south Bioko; Butynski & Koster 1994).

Abundance *Colobus s. anthracinus* common in non-hunted areas but abundance can vary markedly within a given area. For example, in the Lopé N. P., densities vary from 11 ind/km² in primary forest (Brugière 1998) to 30 ind/km² in gallery forest (Harrison 1986). Over the species' geographic range, densities vary from 7 ind/km² in Forêt des Abeilles, Makandé (Brugière *et al.* 2002) to 30 ind/km² in Douala Edea F. R., Cameroon (McKey 1978).

On Bioko I., *C. s. satanas* encountered at the rate of 0.02 groups/km along 373 km of transect during an island-wide survey in 1986 (Butynski & Koster 1994). Other encounter rates on Bioko are as follows: 0.18 groups/km in 2008 along 44 km of transect in Gran Caldera de Luba; 0.14 groups/km in 2008 along 49 km of transect on south slope of Pico Basilé; and 0.39 groups/km in 2009 along 48 km of transect and 0.32 groups/km in 2010 along 50 km of transect at Badja North, SW Bioko (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. obs.). These last-mentioned three sites are remote and receive relatively low levels of hunting. Also, there has been little to no anthropogenic impact on the habitats at these sites. As such, these encounter rates are likely close to what can be expected for undisturbed populations of *C. s. satanas*.

Adaptations Diurnal and arboreal. The Black Colobus is the most granivorous of all *Colobus* spp. Seed eating is an adaptive strategy as seeds are high in nutrients and more palatable than leaves. Polyspecific associations of Black Colobus with Cercopithecidae monkeys permit a higher consumption of seeds (Gautier-Hion *et al.* 1997). Geophagy occurs when the consumption of leaves is high. Chemical analysis shows that the soils eaten have sodium and magnesium contents significantly higher than non-eaten forest soils (Fleury 1999).

When the tree species composition of the forest induces both seasonal food shortage and episodic intra-annual severe bottlenecks in food supplies (as in forest dominated by the irregular mass fruiting Caesalpiniceae tree species), Black Colobus shift to a semi-nomadic ranging behaviour over a large home-range (Fleury & Gautier-Hion 1999). This is the least costly strategy to cope with the low carrying capacity of the habitat.

Black Colobus spent 37–60% of the daylight hours in inactivity, 22–27% handling and ingesting food, 4–32% moving and 4–10% in social interactions (McKey & Waterman 1982, Fleury 1999). Grooming is the predominant social interaction (38%), while

Lateral and palatal views of skull of Black Colobus *Colobus satanas* adult male.

agonistic interactions account for only 7%. Typical daily activity pattern includes the following sequence (from sun rise to sun set): moving (short distance), feeding, resting, moving (long distance), feeding and resting (Fleury 1999).

Foraging and Food Granivorous-folivorous. At Makandé (Gabon, 00°40'S, 11°54'N) foraging activities peak between 07:00h and 08:00h, and 15:00h and 17:00h. This corresponds to the most active period of the day. Black Colobus often remained within small areas for several days while intensively exploiting a few individual trees. This is followed by days when they move farther, to other food patches in which they linger (Fleury & Gautier-Hion 1999). Mean distance travelled/day is 852 m (range 20–1980, n = 24) at Makandé, 510 m (range 40–1100) at Lopé (Gabon, 00°30'S, 11°40'E) and 459 m (range 100–800) at Douala-Edéa (Cameroon, 03°20'N, 10°00'E). Daily travel distance increases with increasing seed intake and decreases with increasing leaf intake at Makandé and Lopé (Fleury & Gautier-Hion 1999). In contrast, at Douala-Edéa, daily travel distance increased with increasing mature leaf intake because mature leaves were rare and patchily distributed plant species (McKey 1979). Home-range size at Makandé (573 ha) was three times that of a group at Lopé (184 ha) and eight times that of a group at Douala-Edéa (69 ha) (McKey 1979, Harrison & Hladik 1986, Fleury 1999).

Seeds and leaves (young and mature) account, respectively, for 56% and 38% of the diet at Makandé, 64% and 26% at Lopé and 53% and 38% at Douala-Edéa (McKey 1978, Harrison 1986, Gautier-Hion *et al.* 1997). Consumption of leaves increases when availability of seeds decreases. Mature leaves are eaten when young leaves are scarce. Foods rich in minerals and nitrogen, but low in lignin and secondary compounds, are preferred (McKey *et al.* 1981). Seed consumption increases when Black Colobus feed in mixed-species groups with (frugivorous) Putty-nosed Monkeys *Cercopithecus*

(n.) *nictitans*, Crowned Monkeys *Cercopithecus (m.) pogonias* and Grey-cheeked Mangabeys *Lophocebus albigena* (Gautier-Hion *et al.* 1997). At Makandé, the three most often eaten plant food species are *Petrocarpus soyauxii* (Fabaceae), *Dialium pachyphyllum* (Caesalpiniaceae) and *Aucoumea klaineana* (Burseraceae), but their use varies among years (Fleury 1999).

Opportunistic observations on Bioko I. suggest that Black Colobus there eat few, if any, seeds. Here, the flower buds of *Tabernaemontana brachyantha* (Apocynaceae) and the leaves of *Schefflera mannii* (Araliaceae) appear to be particularly important foods. On Bioko I., Black Colobus sometimes come to the ground to feed (T. Butynski pers. comm.).

Social and Reproductive Behaviour Social. Groups have 2–6 adult ♂♂ and 2–7 adult ♀♀. Mean group size 13 (range 5–30, $n = 13$; Sabater Pi 1973a, McKey, Eisentraut in Oates 1994, Fleury 1999). Adults always more numerous than immatures (at Makandé, mean percentage of immatures/group is 30% ($n = 3$). Allomothering observed several times at Makandé.

Group home-ranges overlap. At Makandé up to seven groups shared the same space. Overlap of a group's home-range by other groups reaches 65% (Fleury & Gautier-Hion 1999). At Makandé encounters between Black Colobus groups occurred more often than expected by chance. Encounters mainly occur at food patches and are peaceful. Short chases and counter-chases occur, are rare, and involve from one to five adult ♂♂ in each group (Fleury & Gautier-Hion 1999). Males transfer between groups more often than do ♀♀. Integration into the new group is instantaneous (Fleury 1999).

At Makandé, Black Colobus were in association with one or more other species of primate (*C. nictitans*, *C. pogonias*, Moustached Monkey *Cercopithecus (c.) cephus* and *L. albigena*) 14% of the time ($n = 3$ groups). At this site a single *C. pogonias* (♂) was integrated into a group of Black Colobus and interspecific grooming with that individual occurred (Fleury & Gautier-Hion 1999).

The Black Colobus is less vocal than are other *Colobus* spp. and the vocal repertoire is less extensive. A high volume, low frequency (0.5–1.5 kHz) loud-call (the 'roar') is produced by both sexes. The roar is given mainly in response to potential or identified danger. Other vocalizations include 'squeals' that are often produced before roars, and 'caws' that are given during agonistic encounters (Fleury 1999). The roar is not used as a territorial loud-call as in other *Colobus* spp. (Fleury 1999). Oates & Trocco (1983) found that among *Colobus* spp., *C. satanas* has the most distinct roar.

On Bioko I., roars often heard at night, especially during the hour before dawn. Once the male(s) of one group begins to roar, the ♂♂ of 1–3 distant groups often begin to roar. A 'soft honk' is frequently given as an intragroup contact call that can be heard to ca. 50 m. A 'loud, sharp honk' is given as an alarm/warning call that can be heard to >150 m. The loud, sharp honk often elicits a bout of roaring and 'aint' alarm/warning calls from other members of the group (T. Butynski pers. comm.).

Reproduction and Population Structure Black Colobus ♀♀ have a slight raising of the bare black area adjacent to the perineum during the mating and birth periods (Oates & Trocco 1983, Fleury 1999). Females solicit copulations using a

Adult Black Colobus *Colobus satanas*.

presentation posture. Length of gestation unknown. At Makandé (Fleury 1999) and Douala-Edea (McKey 1979), most births occur during the second half of the year, but the sample is low ($n = 12$). Only one infant born at a time. At Makandé the inter-birth interval is longer than two years ($n = 7$ ♀♀). Suckling occurs for at least eight months. Age of maturity not known, but estimated at >4 years (Fleury 1999).

The overall ♂ : ♀ ratio for one group at Makandé over two years varied from 1 : 1.3 to 1 : 1.8. When adults only are considered, the ♂ : ♀ ratio varied from 1 : 1.2 to 1 : 1.4 at Makandé (Fleury 1999), 1 : 2.0 to 1 : 5.0 at Douala-Edéa (McKey 1979), and 1 : 2.5 to 1 : 5.0 at Lopé (M. Harrison pers. comm.).

The adult/immature ratio for one group at Makandé over two years varied from 1 : 0.2 to 1 : 0.5. Birth rate in this group was 0.29 births/year/adult ♀. No deaths occurred in this group during the 2-year study (Fleury 1999). Birth-weight not known; a 2–3-week-old infant weighed 770 g (Fleury 1999). Longevity not known.

Predators, Parasites and Diseases Leopards *Panthera pardus* are known predators (Henschel *et al.* 2005, 2011). Robust Chimpanzees *Pan troglodytes* and African Crowned Eagles *Stephanoaetus coronatus* are probable predators. Predation rates probably low as no case of predation observed during the monitoring of groups at Makandé, Lopé or Douala-Edéa. Diseases and parasites unknown.

Conservation IUCN Category (2012): Vulnerable as *C. satanas* and as *C. s. anthracinus*. Endangered as *C. s. satanas*. CITES (2012): Appendix II.

Main threats are logging, forest clearance for agriculture and hunting by humans. Populations persist in logged forests as long as logging does not significantly alter the structure and composition of the forest (Brugière 1998). The Black Colobus is unable to thrive in degraded secondary forest but persists in a mosaic of secondary and primary forest. It is highly vulnerable to hunting because of its large body size, its relative inactivity and the relative lack of fear of humans. From 1998 to 2005, between 170 and 380 Black Colobus were sold each year at the Malabo Market, Bioko I. (Hearn *et al.* 2006). See also Fa *et al.* (2000), Fa & Garcia Yuste (2001), Kumpel *et al.* (2008) and Mora *et al.* (2009).

The Black Colobus occurs in protected areas in Cameroon: Douala-Edea Faunal Reserve (1283 km²) (not present in Dja Faunal Reserve; probably extirpated from Campo-Maan N. P.); in Gabon: Lopé N. P. (4910 km²), Monts de Cristal N. P. (1200 km²), Minkébé N. P. (7567 km²); in Equatorial Guinea, Bioko I: Pico Basile N. P.

(330 km²), Gran Caldera & Southern Highlands Scientific Reserve (510 km²); in Rio Muni: Monte Alén N. P. (2000 km²). There are no Black Colobus in the world's zoos.

Measurements

Colobus satanas

C. s. satanas

HB (♂ ♂): 595 (510–675) mm, n = 37
 HB (♀ ♀): 576 (500–680) mm, n = 48
 T (♂ ♂): 759 (690–840) mm, n = 37
 T (♀ ♀): 742 (600–825) mm, n = 47
 HF (♂ ♂): 174 (160–188) mm, n = 38
 HF (♀ ♀): 170 (154–190) mm, n = 46
 E (♂ ♂): 32 (28–40) mm, n = 38
 E (♀ ♀): 30 (26–36) mm, n = 47
 WT (♂ ♂): 10.3 (7.3–13.1) kg, n = 12
 WT (♀ ♀): 8.2 (6.6–10.0) kg, n = 7
 Upper Canine (♂ ♂): 15 (10–18) mm, n = 28
 Upper Canine (♀ ♀): 6 (4–10) mm, n = 43
 Lower Canine (♂ ♂): 11 (6–14) mm, n = 28
 Lower Canine (♀ ♀): 5 (3–8) mm, n = 43
 GLS (♂): 108 mm, n = 1
 GWS (♂): 80 mm, n = 1
 GLS (♀): 105 mm, n = 1

GWS (♀): 74 mm, n = 1

Colobus polykomos KING COLOBUS (WESTERN PIED COLOBUS, WESTERN BLACK-AND-WHITE COLOBUS)

Fr. Colobe magistrat; Ger. Weißbart-Stummelaffe

Colobus polykomos (Zimmermann, 1780). Geogr. Gesch. Mensch. Vierf. Thiere 2: 202. Sierra Leone.

Taxonomy Monotypic species. Between 1927 and 1983, *polykomos* and White-thighed Colobus *vellerosus* were considered subspecies of *C. polykomos* (Rahm 1970, Hull 1979), because W. P. Lowe had collected specimens of an intermediate subspecies, *C. polykomos dollmani* in 1927 in Côte d'Ivoire (Oates & McGraw 2009). Oates & Trocco (1983) conclude that *vellerosus* and *polykomos* are separate species and that *dollmani* represents a hybrid swarm. Groves *et al.* (1993) argue that *dollmani* is more closely related to *C. vellerosus* than to *C. polykomos*. Groves (2001, 2005c, 2007b) and Grubb *et al.* (2003) list *dollmani* as a synonym of *C. vellerosus*. Groves (2007b) lists *ursinus* as a synonym of *C. polykomos*. Synonyms: *comosa*, *polycomos*, *regalis*, *tetradactyla*, *ursinus*. Chromosome number: 2n = 44 (Gregory 2008).

Description Large, long tailed, thumbless, black-and-white, arboreal monkey. Sexes alike in colour but ♂ ♂ have slightly longer canines (Plavcan 1999). Adult ♀ about 84% as heavy as adult ♂. Face furless and black. Nose slightly bent, long. Top of head, sides of face and throat greyish-white. Front of shoulders and forearms with straggly, long greyish-white hair. Body and limbs black. Tail long ca. 170% of HB, not tufted. Males have small testes compared to *Procolobus* spp. (Oates 1994). Callosities of ♂ ♂ joined and fringed by one large white triangle, which sometimes continues to the genitalia, while ♀ ♀ have two smaller triangles. Infants predominantly white for first 41–53 days. Full adult colouration attained at 97–120 days (Mearns & Pidgeon 1978).

Geographic Variation None recognized but see Oates & McGraw (2009).

Similar Species

Colobus vellerosus. Perhaps parapatric in vicinity of Bandama R. Face encircled by thick ruff of white fur. Shoulders lack epaulettes or with a few white hairs. Thighs with broad white stripe on proximal two-thirds.

Distribution Endemic to coastal West Africa. Rainforest BZ.

Historical Distribution The forest zone along the coast of Côte d'Ivoire, Liberia, Sierra Leone, Guinea, Guinea-Bissau and scattered forest patches in Senegal, up to 14°N (Booth 1954, 1958b, Rahm 1970, Oates & Trocco 1983). Reports of skins in Gambia are questionable (Oates & Trocco 1983). Eastern boundary: Sassandra R., Côte d'Ivoire (starting at 06°W).

Current Distribution Guinea (Barnett *et al.* 1994, Ziegler *et al.* 2002, Eriksson & Kpoghomov 2006), Sierra Leone (Harding 1984a), Liberia (Waitkuwait 2003), Côte d'Ivoire (Oates *et al.* 1990, Oates 1994), and a few remaining sites in Guinea-Bissau (C. Sousa pers. comm.). Extinct in Senegal. *Colobus polykomos-vellerosus* hybrid population between Sassandra R. and Bandama R. is likely restricted to one site (Gonedelé Bi *et al.* 2006, 2012), if it still exists (Oates & McGraw 2009).

King Colobus *Colobus polykomos* adult male.

Habitat Lowland forests: wet evergreen, moist evergreen, moist semi-deciduous and dry semi-deciduous forest. Also in riparian forests in savanna and patches of dry forest well outside the major moist forest blocks (Oates 1977b). Mean annual rainfall and mean annual temperature range from 3000 mm and 27°C at Tiwai and Gola, Sierra Leone, to 1830 mm and 26.5°C at Banco, Côte d'Ivoire, to 300 mm with 24.5°C in Nimba Mts, Liberia and Guinea

(Korstjens & Dunbar 2007). Range in altitude from near sea level to 800 m at Mt Nimba (Galat-Luong & Galat 1990).

Abundance Common where habitat available and hunting pressure low. About 5.6 groups/km² (50 individuals/km²) in undisturbed forest at Tiwai, Sierra Leone (Dasilva 1989, Oates *et al.* 1990), and 2.8 groups/km² (47 individuals/km²) in Tãï, Côte d'Ivoire (Korstjens 2001, but see Galat & Galat-Luong 1985 who calculated 23.5 ind/km², n = 2, in Tãï based on their home-range estimates). Densities drop dramatically for areas where poaching is common, such as in Tãï N. P. away from research areas (Refisch & Koné 2005, A. Korstjens pers. obs.).

Colobus polykomos

Adaptations Diurnal and arboreal. *Colobus polykomos* spends ca. 52% of time in closed canopy, ca. 33% in emergents and ca. 15% in lower strata both at Tãï (Galat & Galat-Luong 1985, n = 2242; see also McGraw 1996, 1998a, McGraw & Sciulli 2011) and at Tiwai (Dasilva 1989). Comes to ground to forage on fallen seeds of *Pentaclethra macrophylla*, to cross forest clearings and for conspecific inter-individual chasing. Regularly found at forest fringes. Remains inactive for long periods and hides in thick tangles of lianas. Sits while feeding and often sprawls over a bough while resting (McGraw 1998c). In Tãï spends ca. 40% of time on boughs, ca. 47% on medium-sized branches and only ca. 13% on thin branches (Galat & Galat-Luong 1985, n = 2117; see also McGraw 1996, 1998b, c). Postures, such as hunching and sunbathing (spends 39% of time in the sun; A. Galat-Luong pers. obs.), and travel distances optimize energy intake and expenditure according to climatic conditions and food availability (Dasilva 1992, 1993). Annual activity budget in Tãï and Tiwai, respectively: resting 54–55% and 61%, feeding 16–31% and

28%, moving 13–23% and 9%, and socializing 6–8% and 1% (Galat-Luong 1983, $n = 2233$; Dasilva 1989, Korstjens 2001). Rests 53% of time out of reach of leaves (A. Galat-Luong pers. obs., $n = 522$) and prefers tall bare trees for sleeping but does not regularly use the same sleeping-trees (Dasilva 1989, A. Korstjens pers. obs.).

Foraging and Food Folivorous–frugivorous. Forages primarily on leguminous trees and lianas. In Tāi (Korstjens *et al.* 2007) and Tiwai (Davies *et al.* 1999) the annual diets were, respectively, 28% and 30% young leaves, 20% and 27% mature leaves, 48% and 36% fruits (33% hard seeds and 3% whole fruits in Tiwai) and 3% and 3% flowers. In Tāi Galat & Galat-Luong (1985) found 53% leaves, 32% fruits, 4% flowers and 10% miscellaneous (e.g. lichen) ($n = 209$ food item intakes). In Tāi and Tiwai the most frequently consumed food is *Pentaclethra macrophylla* seeds (Dasilva 1989, 1994, Korstjens 2001, Korstjens *et al.* 2007). The long canines are used to strip open the wooden pods of these and similar unripe fruits to reach the hard seeds inside (A. Korstjens pers. obs.). In Tāi the number of food species is low compared to sympatric Western Red Colobus *Procolobus badius badius* and Olive Colobus *Procolobus verus* (Korstjens 2001, Korstjens *et al.* 2002). Mean daily travel distance is 677 m (range 200–1241 m, $n = 54$; Korstjens 2001, Korstjens *et al.* 2007) in Tāi and 860 m (range 350–1410, $n = 72$; Dasilva 1989, 1992) in Tiwai. Daily travel distances increase during the months in which *P. macrophylla* seeds are the main food and decrease when high quality food is scarce at Tāi and Tiwai. Detailed lists of plant food species are presented in Dasilva (1992, 1994) and Korstjens (2001).

Despite similar mean group sizes (see below), mean annual home-range size is 77.4 ha (range 71.5–83.3, $n = 4$) in Tāi (but see Galat & Galat-Luong 1985, who found mean home-range size of 37.5 ha [range 29–46 ha, $n = 2$] in Tāi) and 22 ha ($n = 1$) in Tiwai (Dasilva 1989, Oates 1994). Home-ranges of conspecific groups overlap 20–22% in Tāi. Due to similar percentage overlap with three to five groups, no group had an area of exclusive access in its home-range (Korstjens *et al.* 2005).

Social and Reproductive Behaviour Social. Lives in groups of 5–19 individuals, mean = 16.2 ($n = 10$) in Tāi and 12.5 in Tiwai ($n = 2$), with 1–3 adult ♂♂ (in Tāi eight of ten groups had one ♂, and 1–3 adult ♂♂ in Tiwai where most groups had two adult ♂♂) and 4–6 adult ♀♀ (Galat & Galat-Luong 1985, Dasilva 1989, Korstjens 2001). A few solitary ♂♂ have been seen in Tāi but none in Tiwai (Galat & Galat-Luong 1985, Dasilva 1989, Korstjens 2001).

Agonistic interactions among adult ♀♀ are rare (Dasilva 1989, Korstjens *et al.* 2002) but, with 0.60 interactions/focal observation hour in Tāi, more common than in *C. vellerosus* (P. Sicotte pers. comm.) or in Black-and-White Colobus *C. guereza* (Fashing 2001c). Aggression among adult ♀♀ is most frequent during foraging, especially over items that require a long handling time such as seeds from wooden pods (Korstjens *et al.* 2002). Aggression between the sexes is rare, but adult ♂♂ displace adult ♀♀ (Dasilva 1989, Korstjens 2001). Clear dominance relationships exist among adult ♂♂ (Dasilva 1989). Proximity between individuals: Tāi, 35% of time is spent within 2 m of conspecifics; Tiwai, 48% within 2.5 m of conspecifics. Grooming is the main affiliative interaction (see ‘time budget’). Adult ♀♀ groom up to ten times more and spend up to twice as much time with neighbours than adult ♂♂ (Dasilva 1989,

Adult King Colobus *Colobus polykomos*.

Korstjens 2001). Males spend little time together and are often at the periphery of the group.

Inter-group interactions occur once every 6.6 and 8.0 observation days in Tāi and Tiwai, respectively. Inter-group encounters range from simple proximity (12% of 83 encounters in Tāi and 33% of nine encounters in Tiwai), to displays (25% and 0%), or fights and chases (63% [Korstjens *et al.* 2005] and 67% [Dasilva 1989]). Female participation in inter-group conflicts, generally rare in colobus monkeys (Oates 1977c, Struhsaker & Leland 1979, Fashing 2001c), is common in Tāi (52% of 83 encounters [Korstjens *et al.* 2005]) but was not observed in Tiwai (Dasilva 1992). In Tāi, ♀♀ are more often aggressive during the months when they eat *P. macrophylla* seeds. Adult ♂♂ perform forays to other groups (average of once every 20 days in Tāi) and chased members of the target group in 75% of 16 forays. One to six adult ♀♀ joined the ♂ in 25% of the forays, but ♀♀ never attacked the target group. Forays were especially frequent when the target group had young infants (see Sicotte & MacIntosh 2004 for similar observations on *C. vellerosus*). Males often threaten ♂♂ from other groups with a ‘stiff-legged display’ and by bouncing through the trees.

Vocalizations are rare and most are soft. The most conspicuous vocalization is the loud-call (‘roar’). The roar has similar general characteristics in the different *Colobus* species, but has a faster pulse rate and higher pitch in *C. polykomos* compared to *C. vellerosus* and *C. guereza* (Oates & Trocco 1983, Oates *et al.* 2000b). Roars occur throughout the day, and unlike in *C. guereza* (Marler 1969), morning choruses are relatively rare in *C. polykomos* (Dasilva 1989, A. Korstjens pers. obs.). Most roars are produced in response to a predator threat. Roar characteristics differ according to the type of predator (i.e. Leopard *Panthera pardus* or African Crowned Eagle *Stephanoaetus coronatus*) that is perceived (Schel *et al.* 2009). Roars are often contagious (i.e. other groups respond with a roar). Although most complete roars are performed by ♂♂, ♀♀ do sometimes roar in Tāi in response to a threat (A. Korstjens & A. Galat-Luong pers. obs., E. C. Nijssen pers. comm.). Roars are rarely given during inter-group encounters (Dasilva 1989, A. Korstjens pers. obs.). Females and ♂♂ jointly threaten, mob and alarm-call when threatened by humans or predators but ♂♂ are the more aggressive (Korstjens *et al.* 2005).

Females disperse at least occasionally and ♂♂ disperse as a rule (Dasilva 1989, Nijssen 1999, Korstjens 2001). Sexual behaviour is rarely observed. Females in all reproductive states (cycling, pregnant, lactating) copulate. Females have no sexual swellings and

solicit copulations by presenting. Copulatory vocalizations do not occur (Dasilva 1989). In Tiwai all three ♂♂ in a three-male group mated with ♀♀ (most mates were pregnant/lactating ♀♀ [Dasilva 1989]); in Tai, only the dominant ♂ was observed to mate in a bi-male group (A. Korstjens pers. obs.).

Infant handling is common and is most often performed by juvenile and nulliparous ♀♀. Lactating ♀♀ whose infants are being handled seem to be able to devote more time to feeding (Dasilva 1989, E. C. Nijssen pers. comm.). *Colobus polykomos* spent 28% of time in a polyspecific association (both in Tai and Tiwai), which is no more than expected by chance (Whitesides 1989, Höner *et al.* 1997). However, in Tai, encountered primate groups often contain *C. polykomos* (68% of encounters of groups, $n = 37$); associations with Diana Monkeys *Cercopithecus (d.) diana* and red colobus being the most frequent (Galat & Galat-Luong 1985). Red colobus solitary ♂♂ and solitary ♀♀ regularly associate for several days or weeks with *C. polykomos* groups (Korstjens *et al.* 2007). Inter-specific social interactions include grooming, playing and aggression (Galat-Luong 1983, Deffernez 1999). *Colobus polykomos* sometimes handle Olive Colobus infants (A. Korstjens pers. obs.) and ♀ red colobus sometimes handle *C. polykomos* infants (Fimbel 1992); in both cases, both parents try to get the infant back (A. Korstjens pers. obs.).

Reproduction and Population Structure Inter-birth interval: mean \pm S.D. = 25.5 ± 5.0 months; median = 25.0 months (Tai, $n = 4$; A. Korstjens pers. obs.); mean = 24 months (Tiwai, $n = 4$; Dasilva 1989). Births occur throughout the year ($n = 6$) in Tai (A. Korstjens pers. obs.), but only during Dec–Feb (i.e. dry season) in Tiwai ($n = 9$) (Dasilva 1989). Gestation: ca. 165 days (147–178, $n = 5$) at Jersey Zoo (Mallinson 1973). Birth-weight is 597 g (Ross 1991). One infant is born; twins not reported. Infants feed from their mothers for at least five months and rarely suckle after one year (Dasilva 1989, Korstjens 2001). One of four ♀♀ in Tai had their first infant at four years of age, but the other three did not reproduce for the first 6–7 years (after which they disappeared from their natal group). Females are receptive for 3–7 days and can have five consecutive receptive periods (A. Korstjens pers. obs.). Maximum recorded life-span in captivity is 30.5 years (Ross 1988).

Predators, Parasites and Diseases Main predators in Tai Forest are Robust Chimpanzees *Pan troglodytes* (Boesch & Boesch-

Achermann 2000), African Crowned Eagles (Shultz *et al.* 2004), Leopards (Hoppe-Dominik 1984, Zuberbühler & Jenny 2007) and humans (Refisch 2000). Robust Chimpanzees are estimated to catch 1.4% (Korstjens 2001), Leopards 7.0% and African Crowned Eagles 2.1% (Shultz *et al.* 2004) of the *C. polykomos* population each year in Tai. Although viraemia is longer in *C. polykomos* than in cercopithecines, the role of *C. polykomos* in Yellow Fever transmission should be less important because the proportion of immature individuals is lower (Galat & Galat-Luong 1997).

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Local populations of *C. polykomos* are threatened throughout the range due to habitat loss and hunting by humans (McGraw 2007b). Human consumption of *C. polykomos* in the Tai region is 1.4 ind/km²/year (11.7 kg/km²/year) while maximal sustainable harvest is estimated at 0.9 ind/km²/year (Refisch & Koné 2005). *Colobus polykomos* is the fourth primate species to disappear from the Tai region because of human activity (Galat & Galat-Luong 1997). In this region high population densities are only maintained near research stations (Refisch & Koné 2005). Tai N. P., Nimba MAB Reserve, National Park of Upper Niger (Guinea) and Tiwai are the main refuges. Survive also in ‘sacred woods’ in Côte d’Ivoire and Guinea (Galat & Galat-Luong 1997, Gonedelé Bi *et al.* 2006, 2012).

Measurements

Colobus polykomos

HB (♂♂): 1530, 1590 mm, $n = 2$

T (♂♂): 900, 940 mm, $n = 2$

HF (♂♂): 190, 200 mm, $n = 2$

E (♂♂): 20, 25 mm, $n = 2$

WT (♂♂): 9.9 (8.0–11.7) kg, $n = 5$

WT (♀♀): 8.3 (6.6–10.0) kg, $n = 10$

Body measurements: Côte d’Ivoire and Liberia (O’Leary 2003)

WT: Tiwai, Sierra Leone (O’Leary 2003)

Colobus angolensis ANGOLA COLOBUS (ANGOLA BLACK-AND-WHITE COLOBUS, ANGOLA PIED COLOBUS)

Fr. Colobe noir et blanc d’Angola; Ger. Angola-Mantelaffe

Colobus angolensis Sclater, 1860. Proc. Zool. Soc., Lond. 1860: 245. 483 km inland from Bembe, Angola.

Taxonomy Polytypic species. Seven subspecies: Colyn (1991) described five subspecies in the Congo Basin. Dandelot (1974) and Hull (1979) recognized a subspecies from Kenya and Tanzania. There is an unnamed subspecies in W Tanzania (Nishida *et al.* 1981). Subspecies are distinguished by pelage, cranial measurements (Hull 1979), habitat type and geographical distribution (Groves 2007b). Molecular data support recognition of *sharpie* (McDonald & Hamilton 2010). Synonyms: *adolphi-friederici*, *benamakimae*, *cordieri*, *cottoni*, *langheldi*, *maniamae*, *mawambicus*, *nahani*, *palliatius*, *prigoginei*,

ruwenzorii, *sandbergi*, *sharpie*, *weynsi*. Chromosome number: $2n = 44$ (Dutrillaux *et al.* 1981, Wienberg & Stanyon 1998).

Description An arboreal, black-and-white monkey with long white cheek-hairs and white ‘epaulettes’. Sexes alike in colour. Adult ♀ about 80% as heavy as adult ♂. Crown and neck black. Face black across the orbital region and nose. Narrow line of white hairs form a ‘brow-band’ above the eyes. Ears black. Pelage under chin grizzled. Long, flowing white hairs (‘whiskers’, 6–10 cm)

Peters's Angola Colobus *Colobus angolensis palliatus* adult male (Southern Highlands, Tanzania).

extending from temples and cheeks, and from shoulders and upper forelimbs ('epaulettes', 15–30 cm long). Thumb absent. Dorsum, ventrum and flanks black; forelimbs and hindlimbs black. Tail black in basal region and mid-section, gradually lightening onto the distal region with a terminal tuft of white hairs. Ischial callosities pink, fringed with white hairs; callosities fused into a central ridge in ♂♂. Subspecies differ in the length and extent of epaulettes, and white hair coverage on the brows, cheeks, tail and callosities. Three subspecies (*angolensis*, *ruwenzorii* and *palliatus*) have a white 'pubic band' of hair between the legs. Pubic band absent in the other four subspecies. In newborn infants the face is pink and pelage completely white. Infants' face and pelage change colour gradually; they acquire the black-and-white pattern characteristic of adults by the age of 3.5–4.0 months (Bocian 1997).

Geographic Variation The following seven subspecies are recognized by Groves (2001, 2007b) and Grubb *et al.* (2003). Descriptions presented here are based on Colyn (1991) and Groves (2001):

- C. a. angolensis* Sclater's Angola Colobus. Synonyms: *benamakimae*, *maniemae*, *sandbergi*, *weynsi*. DR Congo, Angola and perhaps NW Zambia; Congo Basin, south and west of the Congo/Lualaba R., extending south-west through the Kasai and Kwango Basins (Colyn 1991) to the Luando R., Angola (Machado 1969). May be present in north-western tip of Mwinilunga District, Zambia (Ansell 1974). Extreme south-east record is from the Lusiji R. area (SE Baluba Province, DR Congo; Colyn 1991). White 'whiskers' and broad white epaulettes, forming a continuous band on each side of the body and sometimes covered by long black hairs. Narrow medial stripe of white hairs in the pubic region. Distal 30–70% of tail white. The rest of the body is black.
- C. a. cottoni* Powell-Cotton's Angola Colobus. Synonyms: *mawambicus*, *nahani*. DR Congo; east bank of the Congo R., extending north to the Uele R. Range delimited in the west by the Itimbiri R. basin; in the south by the Lindi R.; in the east by the forest/savanna ecotone extending from L. Albert to L. Edward (Colyn 1991). White cheek-whiskers well-developed, more so than epaulettes, with which they form a continuous narrow band on either side; no white in pubic region; distal half or so of tail greyish to greyish-white. *Colobus a. cottoni* × *ruwenzorii* hybrids occur near the south-east limit of *cottoni* distribution (Colyn 1991).

Subspecies of Angola Colobus *Colobus angolensis*: (a) Sclater's Angola Colobus *C. a. angolensis*. (b) Powell-Cotton's Angola Colobus *C. a. cottoni*. (c) Cordier's Angola Colobus *C. a. cordieri*. (d) Prigogine's Angola Colobus *C. a. prigoginei*. (e) Rwenzori Angola Colobus *C. a. ruwenzorii*. (f) Peters's Angola Colobus *C. a. palliatus*.

- C. a. cordieri* Cordier's Angola Colobus. DR Congo. South from the Ulindi R. to the Elila R., and from the Lualaba R. east to Shabunda, Bukavu and Mwenga. Cheek whiskers poorly developed, forming a continuous band with epaulettes; no white in pubic region; tail wholly greyish except for proximal 5–8 cm. *Colobus a. cordieri* × *ruwenzorii* hybrids occur along east limit of *cordieri* distribution (Colyn 1991).
- C. a. prigoginei* Prigogine's Angola Colobus. DR Congo. Holotype from Mt Kabobo (=Misotshi-Kabogo), ca. due west of Kigoma on the west side of L. Tanganyika. Unconfirmed, but may be present between L. Tanganyika and L. Mweru (Ansell 1974). Similar to *C. a. cordieri* but tail yellowish-white instead of greyish; pelage long and silky.
- C. a. ruwenzorii* Rwenzori Angola Colobus. Synonym: *adolphi-friederici*: Western Rift, from DR Congo and Uganda south to Rwanda, Burundi and NW Tanzania. Cheek whiskers and epaulettes forming a broad, continuous white band, sometimes overlain with long black hairs; a 6–10 cm wide band of white or greyish hairs in pubic region; distal 5–10 cm of tail greyish.
- C. a. palliatus* Peters's Angola Colobus. Synonyms: *langheldi*, *sharppei*. SE Kenya and Tanzania. Not in Malawi (Ansell 1974, Ansell & Dowsett 1988). Epaulettes large; white pubic band broad in ♂♂, narrow or absent in ♀♀. Distal 30% of tail white; white band on forehead broad and continuous with full cheek-whiskers; occipital hairs lengthened; coat long, thick and soft.
- C. a. ssp. nov.* Mahale Mountains Angola Colobus. Mahale Mts, W Tanzania. Pelage similar to that of *C. a. palliatus* and *C. a. ruwenzorii* but lacks white pubic band. Tail greyish only at the tip (Nishida *et al.* 1981, Groves 2001, 2007b, Grubb *et al.* 2003).

Similar Species

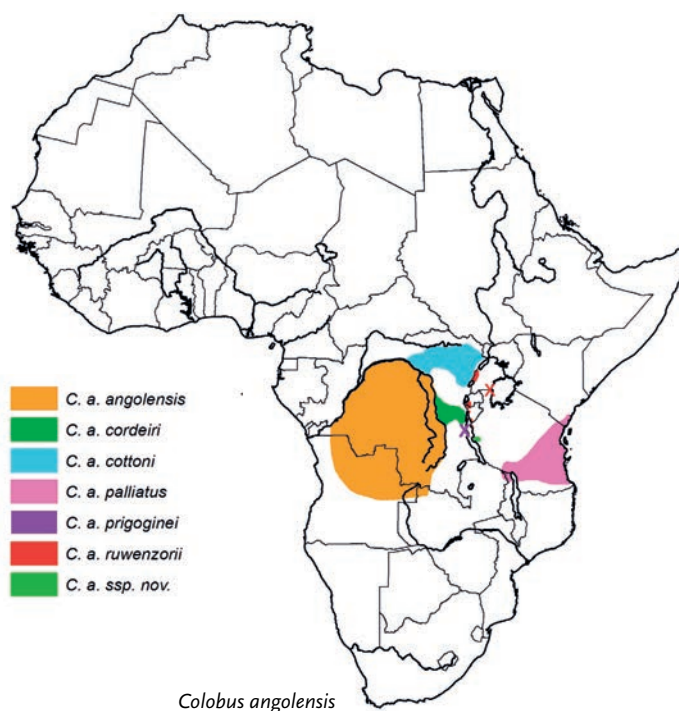

Colobus guereza. Sympatric in the N Congo Basin. White hair coverage of tail is far greater; longer epaulettes form a continuous mantle (cape) across the shoulders, flanks and back. Muscle development on head of ♂♂ is marked, giving 'double-humped' appearance.

Distribution Endemic to equatorial Africa. Rainforest, Afro-montane–Afroalpine and Coastal Forest Mosaic BZs. Forested habitats from the central Congo Basin east to the Rwenzori Mts and L. Victoria, then south to W Rwanda, W Burundi, and north-west side of L. Tanganyika. An isolated population in Mahale Mts N. P. on the east side of L. Tanganyika. From Congo/Lualaba R. and Itimbiri R., south to NW Angola and, perhaps, NW Zambia. Colyn (1991) reports a hiatus in *C. angolensis* distribution east of the Congo/Lualaba R. in the area between the Lindi R. and Ulindi R. Hart & Sikubwabo (1994), however, saw *C. angolensis* in Maiko N. P. It is, therefore, possible that the northern boundary of the hiatus lies farther south at either Maiko R. or Lowa R. Also present in the coastal forests of S Kenya and E Tanzania, through the Eastern Arc Mts and Selous G. R. to the Southern Highlands, perhaps into NE Zambia. Ansell (1974) and Ansell & Dowsett (1988) unable to substantiate reports of presence in N Malawi (e.g. Misuku Hills).

Habitat Restricted to forests and forest fragments. Across the species' geographical distribution, mean annual rainfall ranges from ca. 1100–1800 mm; average annual minimum and maximum temperatures are ca. 11 °C and ca. 26 °C; altitude ranges from sea level in East Africa to 2415 m in Nyungwe Forest, Rwanda (Bocian 1997, Anderson *et al.* 2007c, Fashing *et al.* 2007b).

Lowland subspecies of the Congo Basin (*angolensis*, *cottoni* and *cordieri*) inhabit evergreen and semi-deciduous forest, including swamp and seasonally flooded areas. Distribution associated with forests dominated by leguminous trees, particularly the Caesalpinioideae. Most populations of *C. a. ruwenzorii* inhabit montane forest of the Western Rift, although also in gallery forest on the western edge of L. Victoria. *Colobus a. prigoginei* and *C. a. ssp. nov.* in montane forest. *Colobus a. palliatus* in montane forest, coastal forest, coastal scrubland and mangrove. In the Ituri Forest, DR Congo, a high density of mature, broad- and deep-crowned trees, including *Cynometra alexandri*, *Julbernardia seretii*, *Gilbertiodendron dewevrei*, *Erythrophloeum suaveolens* and *Cassia mannii* results in a relatively closed-canopy forest. Canopy height reaches 30–40 m, with emergents >40 m. Caesalpinioideae accounts for ca. 47% of sampled trees (Bocian 1997). *Colobus a. cottoni* prefers mature mixed forest where its preferred food trees are common, particularly *C. alexandri*, *Celtis mildbraedii*, *Alstonia boonei* and *E. suaveolens*. Monodominant stands of *G. dewevrei* occur throughout Ituri (Hart *et al.* 1989), but *C. a. cottoni* is uncommon in this forest type (Bocian 1997). In forest inhabited by *C. a. angolensis* in Salonga N. P., DR Congo, Caesalpinioideae accounts for 39% of sampled trees. Soil here is very acidic (pH = 4.13), sandy (87%) and nutrient-poor (Maisels *et al.* 1994).

In the Diani Forest, Kenya, *C. a. palliatus* is common in tall (>10 m), closed-canopy coastal forest; uncommon in coastal shrub; rare in mangrove and bush-farmland. *Colobus* occupancy of forest fragments is determined by fragment size and degree of canopy cover. In unprotected areas beyond the Shimba Hills National Reserve groups occupy fragments as small as 1–3 ha (Anderson

2005). Primarily dependent on indigenous tree species for food, but can survive in heavily degraded forest patches if favoured tree and shrub species are still present. *Colobus a. palliatus* is adaptable; in modified habitats like Diani, it has incorporated exotic tree species into the diet (e.g. *Azadirachta indica*, *Delonix regia*), and will travel through bush-farmland to gain access to relict indigenous trees in degraded cultivated areas (Anderson 2005).

Abundance Surveys for *C. a. palliatus* conducted in Kenya during 2001 found 55 isolated populations in coastal forest fragments. Total Kenyan population is estimated at between 3100 and 5000 individuals. Density varies widely among sites and is significantly affected by forest area, forest loss over 12 years and the availability of 14 major food tree species. The Shimba Hills National Reserve protects both the largest forest and largest *C. angolensis* population in Kenya; density in the reserve is estimated to be 2.9 ± 0.52 groups/km² or 15.3 ± 2.88 ind/km². Density in the Diani Forest estimated to be 31 ind/km²; in the Mwache F. R., six ind/km²; colobus are absent from some forest fragments (Anderson *et al.* 2007c). Surveys in Tanzania from 1971–76 found 42 isolated *C. a. palliatus* populations (Rodgers 1981). There are at least 10,000 individuals in Udzungwa Mts, SC Tanzania (Rovero *et al.* 2009). Estimates of *C. angolensis* abundance are not available for populations in the Congo Basin or Western Rift. In the Okapi Faunal Reserve (central Ituri Forest, DR Congo) density in mature mixed forest is estimated to be 1.2 ± 0.38 groups/km² or 16.7 ± 5.28 ind/km²; density in *Gilbertiodendron*-dominant forest is estimated to be 1.1 ± 0.45 groups/km² or 7.0 ± 2.88 ind/km² (Bocian 1997).

Adaptations Diurnal and arboreal. Like other colobines, *C. angolensis* shows morphological and physiological adaptations to a folivorous diet; i.e. a sacculated stomach in which leaves can be retained separately for fermentation, and molars with high shearing crests that are effective in tearing leaves.

Lateral and palatal views of skull of Angola Colobus *Colobus angolensis* adult male.

Intensive feeding bouts begin at sunrise and continue until mid- to late morning, followed by a resting period. In Ituri, *C. a. cottoni* begins a second series of feeding progressions in mid-afternoon, continuing to travel and feed until 17:30–18:30h, then settling into sleeping trees for the night (Bocian 1997). At Diani *C. a. palliatus* rests and feeds alternately from 06:00–18:30h. Resting always occurs in the primary and secondary canopy layers in particular trees within easy access to food sources (Moreno-Black & Maples 1977). Similarly, individual sleeping trees are consistently used throughout the year. Intensive periods of ‘sun-basking’ behaviour occur, particularly following feeding bouts (and rainy periods), with a plethora of resting positions observed (J. Anderson pers. obs.). In the Nyungwe F. R. (Rwanda), *C. a. ruwenzorii* forms unusually large groups of >300 individuals; the abundance of high quality mature leaf forage is thought to facilitate such group formation (Fimbel *et al.* 2001).

In response to aerial predators (e.g. African Crowned Eagle *Stephanoetus coronatus*) *C. angolensis* conceals itself in dense tree crowns, remaining motionless and silent until the predator is gone (C. Bocian pers. obs.).

Foraging and Food Folivorous. Feeds primarily on leaves and seeds, although fruit pulp, flowers and lichens are also consumed. In the Ituri Forest *C. a. cottoni* consumes more leaves than seeds (leaves, 51% of feeding observations; seeds, 22%; flowers, 7%; fruit pulp, 5%; lichen, 0.4%; $n = 2457$ observations). Preferred food items include *Amphimas pterocarpoides* flowers, *C. mildbraedii* leaves, *Celtis zenkeri* leaves and *Lecaniodiscus cupanioides* seeds. Peak seed consumption occurs in Aug and Sept (58% and 70%, respectively, of feeding observations) coinciding with high availability of *C. alexandri* and *E. suaveolens* seeds. Peak leaf consumption occurs in Nov and Mar (82% and 73%, respectively; Bocian 1997). Daily travelling distance of *C. a. cottoni* increases when availability of primary food is low. In this habitat *C. a. cottoni* roams extensively in search of food (mean daily travel distance is 983 m, range 312–1914 m, $n = 52$ days); cumulative home-range of the study group was still increasing in size, beyond 371 ha, after one year (Bocian 1997).

In the Salonga N. P. *C. a. angolensis* consumes more seeds than leaves (seeds, 50% of feeding observations; leaves, 27%; fruit, 17%; flowers, 6%; $n = 486$; Maisels *et al.* 1994). Here the forest is a mosaic of swamp, seasonally flooded and well-drained ground. Leguminous species, dominant here and in the Ituri Forest, have protein-rich seeds but poor-quality mature leaves (Maisels *et al.* 1994, Bocian 1997). In the Congo Basin frequently consumed food plants include *C. alexandri*, *E. suaveolens*, *A. pterocarpoides*, *Dialium* sp., *Guibourtia demeusei*, *Angylocalyx pinnaertii*, *Millettia* sp., *Piptadeniastrum africanum*, *Albizia* sp. (all Leguminosae), *C. mildbraedii*, *C. zenkeri*, *Ongokea gore*, *Strombosiaopsis tetrandra*, *Strombosia* sp., *Alstonia boonei*, *Xylopia aethiopica* and *Pycnanthus angolensis* (Maisels *et al.* 1994, Bocian 1997).

In Kenya *C. a. palliatus* is predominantly folivorous (leaves, 57%; fruit, 21%; seeds, 11%; flowers, 11%; Moreno-Black & Maples 1977). Frequently consumed plants include *Adansonia digitata*, *Lannea welwitschii*, *Cussonia zimmermannii*, *Combretum schumannii*, *Drypetes* spp., *Trichilia emetica*, *Milicia excelsa*, *Millettia usaramensis*, *Zanthoxylum* sp., *Lecaniodiscus fraxinifolius*, *Lepisanthes senegalensis*, *Sideroxylon inerme*, *Grewia* sp. and *Ficus* sp. (Lowe & Sturrock 1998, Anderson *et al.* 2007a).

In the Nyungwe Forest one group of *C. a. ruwenzorii* was primarily folivorous (leaves, 66%; fruit, 17%; petioles, 6%; flowers, 5%; lichen, 5%; $n = 14,259$; Fimbel *et al.* 2001). A nearby group, however, consumed a more varied diet in which leaves (38%), lichen (32%) and seeds (20%) were all major components; other items eaten included whole fruits, petioles, bark, flowers and soil (Vedder & Fashing 2002). This population, in which groups sometimes exceed 300 individuals, relies heavily on an abundant supply of high-quality mature leaves, particularly the common terrestrial scrambler *Sericostachys scandens* (Fimbel *et al.* 2001). Home-ranges are enormous at Nyungwe, with one group occupying 26.5 km² over a 2-year period before suddenly moving 13 km south of their former range. This ranging behaviour is unprecedented among *Colobus* spp. and may be linked to the need to allow time for depleted food patches to regenerate after large groups have foraged in them (Fashing *et al.* 2007b).

In Kenya, *C. a. palliatus* groups move through mangrove, perennial crops and wooded shrubland to forage on indigenous food trees. Leaf buds and young leaves of *Rhizophora mucronata*, *Heritiera littoralis* and *Ceriops tagal* are also consumed (Anderson *et al.* 2007b).

With the exception of *C. a. ruwenzorii* at Nyungwe, *C. angolensis* feeds mainly in the mid canopy (21–30 m high) and, to a lesser extent, at lower levels (11–20 m high) in mature mixed forest; *C. a. cottoni* and *C. a. palliatus* rarely come to the ground, and only do so to eat soil (Bocian 1997, J. Anderson pers. obs.) or to move between forest fragments.

Social and Reproductive Behaviour Social. *Colobus a. cottoni* in the Ituri Forest lives in groups of 6–20 individuals. In mature mixed forest mean group size is 13.9 animals; groups typically consist of 2–5 adult ♂♂, 2–8 adult ♀♀, 0–2 subadults and 0–5 immature animals ($n = 8$ groups; Bocian 1997). Groups of *C. a. angolensis* in Salonga N. P. range in size from 3–7 individuals ($n = 5$ groups; Maisels *et al.* 1994). Groups in the Udzungwa Mts comprise 2–14 individuals (Rovero *et al.* 2009). *Colobus a. palliatus* in Kenya live in groups of 2–13 individuals (mean = 6, $n = 136$). Groups are typically comprised of one adult ♂, two adult ♀♀ and an array of subadults, juveniles and infants. Single-male groups are far more common (88% incidence) than multimale groups (11% with two

♂♂, 1% with three ♂♂; $n = 190$; Anderson *et al.* 2007c). This demographic pattern may be maintained by a high degree of adult ♂ dispersal (solitary ♂ to group ratio 1 : 7).

At Nyungwe, at least two groups of >300 *C. a. ruwenzorii* individuals have been observed (Fimbel *et al.* 2001, Fashing *et al.* 2007b). Oates (1974) reported much smaller groups of *C. a. ruwenzorii* in the Sango Bay Forests (Uganda): one group of at least 30 and another of at least 51 individuals; this second group was judged to be an association of three smaller groups. Nishida *et al.* (1981) reported a group of about 30 *C. angolensis* (now named *ssp. nov.*) in the Mahale Mts.

Social bonds are strong among adult ♀♀ in the same group, who commonly groom each other and rest near each other in clusters with young animals. Grooming and resting in proximity is also common among adult ♂♂ in the same group, who appear to maintain a dominance hierarchy (Bocian 1997). In Ituri Forest encounters between two groups are common, often leading to the formation of temporary aggregations or 'super-groups'. These associations, during which groups rest, feed and/or travel in proximity (<50 m of each other) may last for several hours or for more than one day (Bocian 1997). Aggressive interactions during group encounters occur when one or more adult ♂♂ of one group attempt to 'infiltrate' a cluster of animals in the other group. Extra-group ♂♂ are chased away by a 'team' consisting of several adult ♂♂ or of adult ♂♂ and ♀♀. Persistent attempts provoke confrontations between ♂♂, which may involve snarling, grappling and sometimes biting (Bocian 1997). Similarly, in the Diani Forest, adult ♀♀ within a group mount defensive attacks against invading satellite ♂♂ who attempt group takeovers (J. Anderson pers. obs.).

Colobus a. cottoni groups do not have areas of exclusive use, nor do they exhibit territorial behaviour. Group ranges are completely overlapped by those of other conspecific groups (Bocian 1997). Although Fimbel *et al.* (2001) suggest that some *C. angolensis* populations exhibit a fission–fusion type of social organization, we found no evidence of this in either *C. a. cottoni* in Ituri Forest or *C. a. palliatus* in Diani Forest. *Colobus a. palliatus* groups are territorial in undisturbed mature forest and do not tolerate other conspecific groups within their home-range (J. Anderson pers. obs.). Territorial displays (e.g. exaggerated jumping, roaring and 'stiff-leg' displaying) by adult ♂♂ are common (D. L. Patel pers. comm.). However, in degraded or disturbed habitat, such as in Diani Forest, groups tolerate home-range overlap with neighbouring groups, while ♂♂ are unusually 'silent', rarely partaking in daily territorial roaring (J. Anderson pers. obs.). In Ituri Forest several adult ♂♂ in a *C. a. cottoni* group will engage in a group display of jumping and roaring, but this behaviour is infrequent and has only been observed in response to alarming or arousing stimuli (Bocian 1997). An earlier study of *C. a. palliatus* in Diani Forest also reports that ♂ roaring is rarely heard (Moreno-Black & Bent 1982). In contrast, roaring displays occur daily in *C. a. ruwenzorii* groups in the Nyungwe Forest; many adult ♂♂ in a group participate in such displays that include branch-shaking, leaping and chasing (Fimbel *et al.* 2001).

Courtship and mating behaviour differs considerably between the two subspecies for which information is available. Adult ♀ *C. a. cottoni* typically do not solicit copulations; rather, adult ♂♂ grab ♀♀ and appear to copulate forcibly. Mating is not monopolized by one adult ♂ (Bocian 1997). In *C. a. palliatus* the adult ♂ (and alpha-

males in multimale groups) monopolizes all mating with ♀♀ in his group. Copulation is solicited by the ♀, with increased approaching, grooming of the ♂ and presenting during this time (J. Anderson pers. obs.).

Female *palliatus* leave the group to give birth alone, although sometimes the ♀ is accompanied by a related subadult or juvenile ♀. Infant handling by other group members (including adult ♂♂) is extremely common. Frequency of this behaviour diminishes as the infant's coat colour changes from white, through grey, to black and white at about three months of age. Subadult ♀♀, however, continue their interest in carrying infants far longer than other group members (J. Anderson pers. obs.). This 'aunting' behaviour also occurs in *C. a. cottoni* ♀♀ (Bocian 1997). Small subadults, juveniles and older infants frequently play with each other, although juveniles also play with adult ♂♂ and adult ♀♀. Juveniles and infants huddle with adult ♀♀ during rest periods and storms (Bocian 1997).

Roaring vocalizations are produced by adult ♂♂ as part of a display, or in truncated form during agonistic encounters among ♂♂ (Bocian 1997, Oates *et al.* 2000b). Other than roaring, the only other vocalizations noted in the species are the squeals of infants and young juveniles. Non-vocal sounds produced include snorting (which seems to indicate surprise or mild alarm) and 'tongue-clicking'. The latter sound is like an exaggerated opening of the mouth with a lip-smack. Tongue-clicking is frequently used between group members before approaching one another, and is given in both affiliative and aggressive contexts (J. Anderson pers. obs.).

In Diani Forest *C. a. palliatus* commonly associates with Sykes's Monkeys *Cercopithecus (n.) mitis* throughout the day; the two species frequently gather together in the evenings to rest in adjacent trees. Although rare, interactions occur between juvenile *C. a. palliatus* and Vervet Monkeys *Chlorocebus pygerythrus*. *Colobus a. palliatus* frequently respond to alarm calls of *C. m. albobularis* and will cooperate in ousting Yellow Baboons *Papio cynocephalus* or predators from their territories (J. Anderson pers. obs.). They will also chase Silvery-cheeked Hornbills *Bycanistes brevis* from feeding and sleeping trees. Interspecific play occurs between *C. a. palliatus* and *C. m. albobularis* juveniles (J. Anderson pers. obs.) and, in Ituri Forest, between *C. a. cottoni* and Blue Monkey *C. m. stuhlmanni* juveniles (C. Bocian pers. obs.). Also in Ituri *C. a. cottoni* frequently rest or feed in proximity to Guerezas *Colobus guereza*, Blue Monkeys *C. m. stuhlmanni*, Red-tailed Monkeys *Cercopithecus (c.) ascanius*, Wolf's Monkeys *Cercopithecus (m.) wolfi* and Grey-cheeked Mangabeys *Lophocebus albigena*; they are seen less often in association with Western Red Colobus *Procolobus badius* and Agile Mangabeys *Cercocebus agilis* (Bocian 1997).

Reproduction and Population Structure In *C. a. cottoni* sexually mature ♀♀ show a slight perineal swelling for several days each month (Bocian 1997); menstrual cycles are not always synchronized among all group ♀♀. Although ♀ *C. a. palliatus* have no perineal swelling the ischial callosities become slightly redder prior to labour and birth (J. Anderson pers. obs.). Gestation not known. There is no distinct birth season in the Ituri, Nyungwe and Diani Forest populations (Bocian 1997, Fimbel *et al.* 2001, Anderson 2005). Females give birth to a single offspring, although one case of twinning occurred in Diani Forest (the second infant died, however, after a few weeks) (J. Anderson pers. obs.). Infants are usually weaned at one year, although suckling can extend to 18–24 months

(J. Anderson pers. obs.). Females are fully-grown by 5–6 years of age; ♂♂ by about seven years of age. Sexual maturity is probably reached before full growth is attained. Infanticide occurs in *C. a. palliatus*. Invading adult ♂♂ will kill one or all of the infants and juveniles up to three years of age within the group (J. Anderson pers. obs.). Infanticide not observed in *C. a. cottoni*.

In Diani Forest average *C. a. palliatus* adult ♀ : ♂ ratio in groups is 2.3 : 1.2. Immature to adult ♀ ratios in groups average 2.1 : 2.3 (n = 56; Anderson 2005). Longevity in captivity is up to 36 years, but much less in the wild. Average interbirth interval in captivity is 441 days (range 348–567, n = 11; Anderson, L.K. 2001). Birth and mortality rates not known.

Predators, Parasites and Diseases In Ituri Forest predators include Leopards *Panthera pardus* and African Crowned Eagles; *C. guereza* and *C. angolensis cottoni* make up 1% of the composition of Leopard scats (Hart, J. A., et al. 1996). During Bocian's Ituri study an African Crowned Eagle killed a *C. guereza* adult ♀ and infant and a *C. ascanius* adult ♂. Circumstantial evidence suggests Robust Chimpanzees *Pan troglodytes* kill and eat *C. a. ruwenzorii* at Nyungwe; black or brown and white hairs (believed to be from *C. angolensis ruwenzorii* or l'Hoest's Monkey *Cercopithecus lhoesti*) were found in seven chimpanzee scats (Fashing et al. 2007b). In East Africa predation by Leopards and raptors is also probable; the high density of human settlements in this region have also resulted in *C. angolensis* deaths via domestic dogs and by road traffic accidents (Anderson et al. 2007b).

Ectoparasites of *C. a. palliatus* include *Sarcoptes scabiei*. Endoparasites include nematodes *Trichuris* spp., *Strongyloides* spp. (including *S. fulleborni*), *Enterobius vermicularis* and *Trichostrongylus* spp., and protozoa *Entamoeba coli*, *Entamoeba histolytica*, *Balantidium coli* and *Cyclospora colobi* (Obadha 1999, Eberhard et al. 2001, Okanga 2004, Gillespie et al. 2005b).

Conservation IUCN Category (2012): Least Concern as a species; *C. a. ruwenzorii* – Vulnerable; *C. a. prigoginei* – Endangered. CITES (2012): Appendix 2).

C. a. prigoginei appears to be the most threatened subspecies. This 'Endangered' subspecies is endemic (as far as is known) to the forests of Mt Kabobo (=Misotshi-Kabogo). A one-month biodiversity survey of these forests in 2007 by a large team encountered *C. a. prigoginei* but once. The one observation was made from camp. None were observed along 133 km of transect/reconnaissance walk (Plumptre et al. 2008).

Indigenous Mbuti in the central Ituri Forest are net-hunters and probably have little impact on primate populations; however, where guns are available, they are used for hunting in other parts of Ituri. It is likely that humans are hunting *C. angolensis* throughout eastern DR Congo, Rwanda and Burundi due to prolonged instability and violence in the region since the 1994 war. The movement of refugees into DR Congo has resulted in forest degradation and habitat loss for *C. angolensis*. Subspecies *C. a. cottoni* and *C. a. cordieri* will continue to lose habitat as settlements move deeper into the moist forest zone. In Tanzania continued degradation and fragmentation of forest habitat is the major threat to *C. angolensis* (Rovero et al. 2012). In Kenya there is a major degree of resource overlap in coastal forest fragments between human extraction of lumber, charcoal, fuel wood,

building poles and carving wood, and *C. a. palliatus* food resource requirements; major food tree species such as *M. usaramensis*, *C. schumannii* and *L. fraxinifolius* are particularly targeted. Forest clearance for tourism development and agriculture is ongoing. As the area and quality of coastal forests declines, colobus crop-raiding and resultant human wildlife conflict may become an additional problem (Anderson et al. 2007a). Illegal hunting for pelts is still reported in Tanzania and Kenya (Anderson et al. 2007c, Rovero et al. 2012).

Priority conservation actions include: improved forest protection in East and central Africa to incorporate coastal mangrove within existing habitat preservation and *C. a. palliatus* conservation strategies; promote alternative wood resources for local and tourism sectors; encourage local efforts to enrich agricultural matrix among forest fragments through tree planting schemes; promote existing cultural values of *C. a. palliatus* and its habitat, including benefits through small-scale eco-tourism; and conduct a detailed assessment of the distribution, abundance and conservation status of *C. a. prigoginei*.

Measurements

Colobus angolensis palliatus

HB (♂♂): 665 (520–740) mm, n = 17

HB (♀♀): 563 (480–660) mm, n = 15

T (♂♂): 794 (560–897) mm, n = 17

T (♀♀): 782 (720–853) mm, n = 15

HF (♂♂): 172 (130–210) mm, n = 17

HF (♀♀): 158 (130–180) mm, n = 15

E (♂♂): 44 (30–85) mm, n = 28

E (♀♀): 44 (30–70) mm, n = 28

WT (♂♂): 8.9 (6.0–11.5) kg, n = 16

WT (♀♀): 7.1 (5.0–8.5) kg, n = 15

Angola Colobus *Colobus angolensis* adult male.

Colobus vellerosus WHITE-THIGHED COLOBUS (GEOFFROY'S PIED COLOBUS, URSINE COLOBUS)

Fr. Colobe de Geoffroy; Ger. Geoffroy-Stummelaffe

Colobus vellerosus (I. Geoffroy, 1830). Bulletin des Sciences Naturelles et de Géologie 22: 318. Type locality not known.White-thighed Colobus *Colobus vellerosus* adult male.

Taxonomy Monotypic species. Analyses of cranial morphology, coat colour and ♂ loud-calls ('roar') confirm that the White-thighed Colobus is a separate species from the King Colobus *Colobus polykomos* (Oates & Trocco 1983, Groves 2001). *Colobus vellerosus* ♂ loud-calls are closest to those of the Guereza *Colobus guereza* (Oates *et al.* 2000b). Groves (2007b) lists *ursinus* as a synonym of *C. polykomos*. Synonyms: *bicolour*, *dollmani*, *leucomeros*. Chromosome number: $2n = 44$. Composed of metacentric and submetacentric chromosomes (Dutrillaux *et al.* 1981, Romagno 2001).

Description Arboreal, medium-sized, black-bodied monkey with long, all-white, slightly tufted tail. Tail 124–152% of HB (Groves *et al.* 1993). Sexes alike in colour pattern. Adult ♀ about 80% as heavy as adult ♂. Face encircled by broad white ruff. Thigh with grey patch. White epaulettes absent, but shoulder hair of ♂ ♂ markedly longer than hair on the rest of the body (10–15 cm), marginally longer in ♀ ♀ (Booth 1958b). In ♀ ♀ there is white fur around callosities broken at the perineum and underside of tail base. In ♂ ♂ there is no break. Infants white at birth and gradually change to various shades of grey (7–11 weeks of age). Black-and-white pelage by 12 weeks.

Geographic Variation Hybrids with *C. polykomos* occur, or did occur, between Sassandra R. and Bandama R. in Côte d'Ivoire (Groves *et al.* 1993, Groves 2007b, Gonedelé Bi *et al.* 2006, 2012, Oates & McGraw 2009, Oates 2011). These hybrids are phenotypically much closer to *C. vellerosus* than to *C. polykomos* (Groves *et al.* 1993).

Similar Species None within geographic range.

Distribution Endemic to West Africa. Rainforest BZ. From Comoe R., SW Burkina Faso, and the Bandama R. and Nzi R., Côte d'Ivoire, east through Ghana, Togo, Bénin to W Nigeria (Booth 1958a, Oates & Trocco 1983, Sayer & Green 1984, Happold 1987, Groves 2001, Galat & Galat-Luong 2006b, Gonedelé Bi *et al.* 2010, Oates 2011). In the north the range follows riverine forests into the Guinea savanna (Sayer & Green 1984, Grubb *et al.* 1998, Fischer *et al.* 2000). Historic range estimated at 381,000 km² (Eeley & Foley 1999).

Habitat Mainly in primary evergreen and semi-deciduous forests, but also secondary forests and riverine forests. In inundated (swamp) forests in extreme SE Côte d'Ivoire, SW Ghana (W. S. McGraw pers. comm.) and Bénin (Sinsin *et al.* 2002a, Assogbadjo & Sinsin 2007).

Abundance Declining and uncommon. In Côte d'Ivoire McGraw *et al.* (1998a) surveyed five Forest Reserves (Bossematie, Mabi, Yaya, Songan and Ehy); only in Yaya were there confirmed sightings of *C. vellerosus*, although subsequent surveys confirmed *C. vellerosus* in Ehy Swamp Forest (W. S. McGraw pers. comm.). Up to

*Colobus vellerosus*

1996 sightings of *C. vellerosus* were frequent in Comoé N. P., but the species has become rare since; ♂ roaring also ceased to be heard in recent years (Fischer *et al.* 2000). See Gonedélé Bi *et al.* (2010, 2012). In Ghana *C. vellerosus* was common in Bia N. P. and Ankasa Resource Reserve (Asibey 1978). Already rare in Bia N. P., Ankasa Resource Reserve and Kakum N. P. in 1993 (Struhsaker & Oates 1995). However, the population in Boabeng-Fiema Monkey Sanctuary (BFMS) is increasing and was estimated at 275 individuals in 19 groups in 2007 (Wong & Sicotte 2006, K. Kankam pers. comm.). Forest pockets around BFMS also support small populations (90 individuals in ten groups in 2007; B. Kankam pers. comm.). The local people's perception of *C. vellerosus* is that it is rare or locally extinct (Ntiama-Baidu 1998). Other recent sightings include Krokosua Hills F. R., Attandanso Resource Reserve, Yoyo F. R. (Oates *et al.* 2000a) and Mole N. P. (T. Saj pers. obs.), but the population status at these sites is unknown. In Togo reported in Keran and Fazao-Malfacassa National Parks (Asibey 1978) and recently confirmed in Fazao-Malfacassa and Yikpa-Gigbé (Campbell *et al.* 2008b). In Bénin, in Forêt Classée de Lama (Nobimé & Sinsin 2007), Lokoli Forest (Sinsin *et al.* 2002a, Assogbadjo & Sinsin 2007) and Kikélé Sacred Grove (Inoussa & Nobimé 1997). Reported, but not confirmed, at other sites (Campbell *et al.* 2008b).

Status in Bénin is unknown. At least one group sighted in the Forêt Classée de Lama (G. Altherr pers. comm.) in 2002, and one group of 5–7 animals in the Lokoli Forest near Bohicon in 2001–02 (Sinsin *et al.* 2002a). Also reported recently in Mont Kouffé Forest, Wari Maro Forest (B. Sinsin pers. comm.), Kikélé Sacred Grove (Inoussa & Nobimé 1997) and Pénessoulou Forest (G. S. Djossou pers. comm. to J. A. Teichroeb & G. Campbell pers. comm.). In W Nigeria *C. vellerosus* was common until the 1960s near the border with Bénin, but it is now possibly extirpated (Happold 1987). Between 1997 and 2001, I. Faucher (pers. comm.) travelled extensively in SW Nigeria and did not observe *C. vellerosus* despite looking for primates and sighting several other species.

Adaptations Diurnal and arboreal. Adaptations similar to other black-and-white colobus.

Foraging and Food Folivorous. At BFMS the main food items are: mature and young leaves (79%), fruits and seeds (11%), flowers and buds (6%), seedpods (4%). These are taken mainly from middle and upper storey of trees in the families Moraceae, Bombacaceae and Mimosaceae. Main seasonal difference in diet relates to the proportion of mature leaves, which (for one group) varied from 100% of monthly feeding records in the wet season to 0% in the dry season. Seeds and unripe fruits are consumed when available in the dry season (e.g. *Albizia zygia*, *Aubrevillea kerstingii*, *Trilepisium madagascariense*) (Saj 2005). This is similar to the finding of D. K. Olson for *C. vellerosus* in Bia (cited in Oates 1994). At BFMS groups travel ca. 300 m a day (range 65–604 m, $n = 96$ days for two groups). In Bia mean daily range was 307 m (range 75–752 m; Curtin & Olson 1984 cited in Oates 1994). *Colobus vellerosus* travel on the ground when arboreal routes are lacking (Booth 1956b, Jeffrey 1975, T. L. Saj & P. Sicotte pers. obs.) and can apparently move between forest fragments (Wong & Sicotte 2006).

The mean activity budget for three groups at BFMS (Aug–Nov 2000 and 2001) shows resting in 59% of records, feeding in 24%, moving in 15% and social behaviour (primarily grooming and

Lateral and palatal views of skull of White-thighed Colobus *Colobus vellerosus* adult male.

copulations) in 3% of records. Resting occurs frequently throughout the day. Feeding increases slightly in the early morning, at mid-day and at the end of the afternoon (Teichroeb *et al.* 2003).

Social and Reproductive Behaviour Social. Mean group size is 15.1 in BFMS and 10.3 in surrounding fragments (range 3–38, $n = 21$ groups; Saj *et al.* 2005, Wong & Sicotte 2006). These numbers are consistent with information in Jeffrey (1975), Martin (1991) and from B. Sinsin (pers. comm.). Galat & Galat-Luong (1980) and A. Galat-Luong (pers. obs.) observed groups of 3, 4, 6, 10 and 11 individuals (mean = 6.8) in Comoé N. P., as well as a solitary adult ♂. Single-male and multimale groups occur. In BFMS and surrounding fragments the ♀ : ♂ ratio ranges from 0.9 to 1.5, whereas the percentage of immatures in the population ranges from 28% to 44%. All-male groups occur (Saj & Sicotte 2005). There are low frequencies of aggression and affiliation within groups. The range of agonistic interactions over food per adult in two groups was 0.005–0.013/h (459 h of observation). The range of agonistic interactions for all contexts per adult in two groups was 0.007–0.036/h (459 h of observation). Time spent grooming between adults varied from 0.8% to 1.2% in two groups. Between 79% and 98% of this grooming took place between ♀ ♀ (Saj 2005). Males and ♀ ♀ use the 'stiff-leg' display, a low intensity aggressive behaviour (Oates 1977c). Inter-group encounters (in which ♂ ♂ are more aggressive than ♀ ♀) range from mere proximity to severe aggression (Sicotte & MacIntosh 2004). Loud-calls are rarely heard during encounters, rather they are heard at dawn and dusk, and during the day in the absence of encounters.

At Bia N. P., a wet semi-deciduous forest, a group of 13–18 individuals had an annual home-range of 31 ha (Olson 1986). One study group also used a smaller area of their home-range in the dry season (Curtin & Olson 1984 cited in Oates 1994). In BFMS, a dry semi-deciduous forest, home-range sizes for 11 months for groups

of 8 and 33 individuals was 11 ha and 12 ha, respectively. Minimum known total home-range overlap for two groups with neighbouring groups ($n = 5$) ranged from 43% to 46% (Saj 2005). Population density at BFMS is 119 animals/km² (Wong & Sicotte 2006).

One association in Comoé N. P. comprised groups of *C. vellerosus*, Lesser Spot-nosed Monkey *Cercopithecus (c.) petaurista*, Lowe's Monkey *Cercopithecus (m.) lowei* and White-naped Mangabey *C. lunulatus* (A. Galat pers. comm.). *Colobus vellerosus* associates occasionally with Campbell's Monkey *Cercopithecus (m.) campbelli* (W. S. McGraw pers. comm.). In BFMS *C. vellerosus* responds to alarm calls from *C. campbelli*. Play and aggressive interactions also take place between individuals of both species.

Females have no sexual swellings, frequently solicit copulations and when multiple ♂♂ are in the group, mate promiscuously (Saj & Sicotte 2005). Extra-group copulations occur (Teichroeb *et al.* 2005). About 38% of infant mortality at BFMS during 2003–2005 was due to infanticide by non-resident adult males, one result of which was reduced interbirth intervals for the mothers (Teichroeb & Sicotte 2008, Teichroeb *et al.* 2009).

Reproduction and Population Structure Length of gestation about six months. Breeding does not seem to be seasonal. One young born at a time. Twins not reported. Infants are white for 5–6 weeks after birth ($n = 5$). Time to weaning is unknown. Infant handling by adult and subadult ♀♀ occurs up to 12 weeks. Youngest infants are the most attractive, although grey infants are handled the most (Brent 2005, Brent *et al.* 2007).

Longevity, birth and mortality rates unknown. In BFMS, ♂ tenure is short (mean 15.8 months, range = 3–>52, $n = 29$). All the ♂♂ observed from infancy to adulthood ($n = 10$) dispersed from their natal group. Female transfer also occurs (Saj & Sicotte 2005, Teichroeb *et al.* 2009).

Predators, Parasites and Diseases Leopards *Panthera pardus* and Lions *Panthera leo* prey on *C. vellerosus* in Comoé N. P. (Bodendorfer *et al.* 2006). African Crowned Eagles *Stephanoaetus coronatus* and Robust Chimpanzees *Pan troglodytes* are predators of colobus at other sites and probably also prey on *C. vellerosus*. At BFMS *C. vellerosus* reacts by grunting and crouching when large birds fly close to the canopy. Human hunting is undoubtedly the primary source of predation.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

See Abundance above. *Colobus vellerosus* is hunted for its coat and meat. In the 1890s an estimated 190,000 skins were exported from Ghana. In the early twentieth century the trade averaged 17,000 per year (Grubb *et al.* 1998). Since the 1970s *C. vellerosus* has been protected by law in Ghana and Bénin, and partially protected in Côte d'Ivoire, Togo and Nigeria (De Klemm & Lausche 1987). However, poaching occurs and specimens are sometimes found in local markets (Côte d'Ivoire: McGraw *et al.* 1998, Fisher *et al.* 2000, Gonedelé Bi *et al.* 2010, 2012; Ghana: Ntiemoa-Baidu 1998; Bénin: P. Neuenschwander pers. comm.; W Nigeria: Happold 1987).

Loss of habitat is the other primary threat. Forested habitats are now rare in Togo, Bénin and SW Nigeria. Wolfheim (1983) suggests that *C. vellerosus* may be able to adapt to low levels of logging, but a comparison of the population densities in four Forest Reserves and in Bia N. P. in Ghana found that even low level timber exploitation was associated with a reduced population density (Martin & Asibey 1979 cited in Martin 1991). Better enforcement of hunting laws, better habitat protection and more protected areas are necessary. Where local taboos against hunting *C. vellerosus* are effective, populations can increase. Small-scale ecotourism programmes may encourage further conservation efforts (e.g. BFMS, Ghana; Kikélé, Bénin). Outside West Africa, *C. vellerosus* is not reported to occur in zoos (Reichler 2001).

Measurements

Colobus vellerosus

HB (♂♂): 663 (600–670) mm, $n = 4$

HB (♀♀): 623 (600–670) mm, $n = 4$

T (♂♂): 865 (830–930) mm, $n = 4$

T (♀♀): 834 (730–904) mm, $n = 4$

HF (♂♂): 196 (190–210) mm, $n = 4$

HF (♀♀): 183 (175–190) mm, $n = 4$

E (♂♂): 33 (31–38) mm, $n = 4$

E (♀♀): 35 (31–38) mm, $n = 4$

WT (♂♂): 8.5 (range unknown) kg ($n = 3$)

WT (♀♀): 6.9 (range unknown) kg ($n = 5$)

Body measurements: W Ghana (Jeffrey 1975)

Colobus guereza GUEREZA COLOBUS (BLACK-AND-WHITE COLOBUS, ABYSSINIAN COLOBUS)

Fr. Colobe guéréza; Ger. Guereza

Colobus guereza Rüppell, 1835. Neue Wirbelt. Fauna Abyssin. Gehörig. Säugeth., p. 1. Damot region, Gojjam, Ethiopia.

Taxonomy Polytypic species. Nine subspecies recognized by Rahm (1970), six by Dandelot (1974) and eight by Napier (1985), Groves (2001, 2007b) and Grubb *et al.* (2003). Long referred to as *Colobus abyssinicus*, following Oken (1816), who named it *Lemur abyssinicus*. In 1956, however, the International Commission on Zoological Nomenclature ruled (Opinion 417) that Oken's name was invalid (Napier 1985). Synonyms: *abyssinicus*, *albocaudatus*,

brachychaites, *caudatus*, *dianae*, *dodingae*, *elgonis*, *escherichi*, *gallarum*, *ituricus*, *kikuyuensis*, *laticeps*, *managaschae*, *matschiei*, *occidentalis*, *percivali*, *poliurus*, *roosevelti*, *ruppelli*, *rutschuricus*, *terrestris*, *thikae*, *uellensis*. Chromosome number: $2n = 44$ (Bigoni *et al.* 1997).

Description Large, robustly-built, arboreal colobine monkey, with striking, glossy, black-and-white pelage and a 'roar' loud-call.

Western Guereza *Colobus guereza occidentalis* adult male.

Distinguished from other *Colobus* species by mantle (or cape) of long white hairs that extend from shoulders to flanks and across the lower back. Adult ♀ about 68–84% as heavy as adult ♂, depending on the subspecies. Lower brow, cheeks, chin and throat white, forming a circumfacial ruff. Crown, upper back, limbs, hands, feet and ventrum jet black. Tail with white tuft on tip. Extent of white on tail, length and bushiness of terminal tuft and length of mantle vary with subspecies. Sexes similar in colour, except ring of white pelage circling the ischial callosities is complete in ♂♂ and incomplete in ♀♀. Infants have an entirely white pelage and pink skin. Adult pelage and black skin appear by 14–17 weeks. In adults crown of head has double-humped appearance resulting from muscle development, especially marked in adult ♂♂, whose crowns are up to 1.5 times as large as those of adult ♀♀. Photographs of *C. guereza* from sites in Kenya and Tanzania available at: www.wildsolutions.nl

Geographic Variation The following eight subspecies are recognized by Napier (1985), Groves (2001, 2007b) and Grubb *et al.* (2003). Data on percentage of the tail that is white were provided by P. Grubb (pers. comm.) based on the examination of 132 specimens at the BMNH.

- C. g. guereza* Omo River Guereza. Ethiopian Highlands west of Rift Valley, south to lowlands in the Omo Valley. Mantle hair relatively long, covering ca. 20% of tail. Tail much longer than HB: proximal part of tail grey; distal ca. 53% silvery white (S.D.=6.4, range=38–62, n=13).
- C. g. gallarum* Djaffa Mountains Guereza. Ethiopian Highlands east of Rift Valley. Proximal part of tail black with scattered grey hairs increasing distally; distal ca. 55% white and bushy (S.D.=6.7, range=45–61, n=5).
- C. g. occidentalis* Western Guereza. Donga River Valley, Nigeria, south through Cameroon to NE Gabon and Congo, and east through Central African Republic to N DR Congo, SW Sudan and W Uganda. Hair of mantle and tail tip creamy-white. Tail ca. 40% longer than HB: distal ca. 40% creamy-white (range=25–51, n=64).
- C. g. dodingae* Dodinga Hills Guereza. Imatong Mts, SE Sudan. Hair of mantle slightly creamy. Similar in pelage and craniometrics to *C. g. occidentalis*, with which it was grouped by Dandelot (1974).

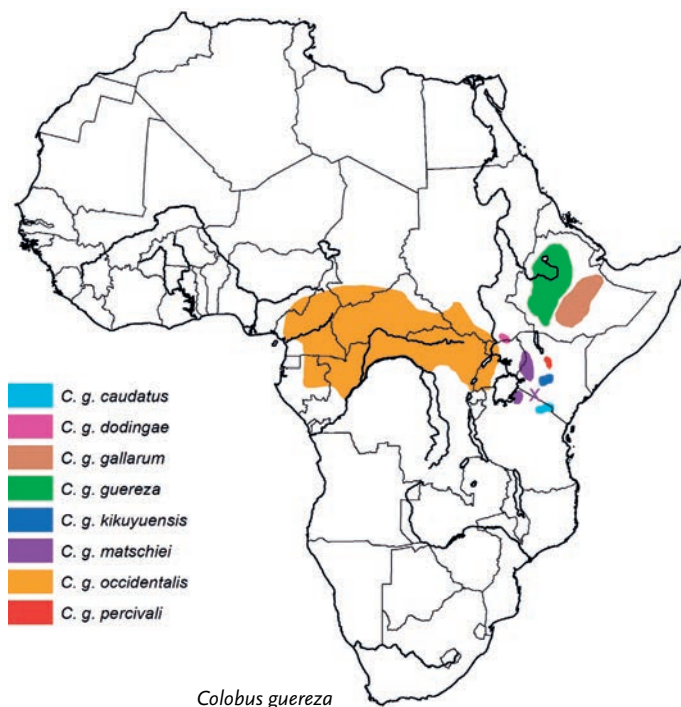

Tail about same length as HB: distal ca. 46% creamy-white and not very bushy (S.D.=4.5, range=40–55, n=10).

- C. g. percivali* Mt Uargues Guereza. Mathews Range (=Waragess =Uargess), C Kenya. Mantle hair long, creamy-white, covering 20–25% of tail. Tail longer than HB: distal ca. 72% (n=1) white and bushy.
- C. g. matschiei* Mau Forest Guereza. Kenya, Uganda and Tanzania, from Mt Elgon east to Rift Valley (including Kakamega Forest, Mau Forest, and forests near L. Nakuru and L. Naivasha) and south-west to Grumeti R. of western Serengeti in NW Tanzania. Tail longer than HB: proximal part black; distal ca. 47% white (S.D.=55, range=36–58, n=16).
- C. g. kikuyuensis* Mt Kenya Guereza. Kenya, east of Rift Valley including Mt Kenya, Aberdares Range and Ngong Hills. Mantle long and luxuriant, covering ca. 25–30% of tail. Tail relatively short, length about equal to HB: proximal part grey or black with scattered grey hairs increasing distally; white tuft very bushy. Distal ca. 78% of tail white (S.D.=3.5, range=71–83, n=19).
- C. g. caudatus* Mt Kilimanjaro Guereza. N Tanzania, including Mt Kilimanjaro and Mt Meru. Mantle even longer than on *C. g. kikuyuensis*. Male loud-call ('roar') higher pitched than *C. g. occidentalis* (Oates *et al.* 2000b). Proximal part of tail black with scattered grey hairs; white tuft comprising ca. 80% of tail length. Tail longer than HB: distal ca. 82% of tail white (S.D.=7.7, range=71–88, n=4).

Similar Species

Colobus angolensis. Angola, Congo Basin, SW Rwanda, SW Uganda, SE Kenya and Tanzania. Lacks white mantle (veil) and well-developed tail tuft (Oates 1994).

Distribution Endemic to equatorial Africa. Rainforest and Afromontane–Afroalpine BZs. The most widespread of the black-and-white colobus monkeys, the Guereza occupies woodlands and

Colobus guereza

forests from E Nigeria (ca. 10° E) across the northern fringe of the Congo Basin to eastern Africa, as far east as ca. 42° E in Ethiopia. The northern limit is ca. 14° N in Ethiopia and the southern limit is ca. 03° S in Tanzania. In western Africa the southern limit is just south of the Equator in Gabon and Congo. Guerezas occur from ca. 200 m asl in Cameroon to at least 3300 m in Ethiopia (Oates 1977b). Present from 1900–2900 m on the Aberdares Range, C Kenya (Butynski 1999), and from 1800–2900 m on Mt Kilimanjaro, N Tanzania (T. Butynski pers. comm.). A ‘mummified’ individual found at 4700 m on Mt Kenya (Young & Evans 1993), and a carcass found at 4680 m in a cave on Mt Kilimanjaro (Guest & Leedal 1954), but both records are well above the typical range for this species at these two sites. Subspecies distributions given above under Geographic Variation.

Habitat Guerezas inhabit a wide array of forest types, including lowland and medium-altitude moist forest, montane forest, swamp forest, dry forest, gallery forest and disturbed forest (Oates 1994, 2011, Fashing 2007, Fashing *et al.* 2012). Mean annual rainfall varies considerably across this range of habitats, from 700 mm in N Central African Republic (Fay 1985), to 1100–1200 mm in gallery forest in East Africa and Ethiopia (Oates 1977a, R. Dunbar pers. comm.), to 2220 mm in Kakamega, Kenya (Cords 1987b).

Abundance Guerezas often attain higher densities than most of the primates with which they are sympatric. Densities tend to be particularly high in small patches of forest along lakes and rivers (315 animals/km²: Bole, Ethiopia [Dunbar 1987]; 347 animals/km²: Kyambura Gorge, SW Uganda [Krüger *et al.* 1998]; 396 animals/km²: L. Naivasha, Kenya [Rose 1978, M.D.]; 800 animals/km²: Murchison Falls, Uganda [Leskes & Acheson 1970]), and particularly low in large areas of undisturbed moist forest (3 animals/km²: Ituri Forest, DR Congo [Bocian 1997]; 4.5 animals/km²: Kibale Forest (Ngogo), SW Uganda [Struhsaker 1997]). Guerezas attain intermediate densities in moist forest areas that have been subjected to low to moderate levels of human disturbance (100 animals/km²: Kibale Forest (Kanyawara) [Oates 1974]; 150–168 animals/km²: Kakamega Forest, W Kenya [Fashing & Cords 2000, Fashing *et al.* 2012]; four to >10 groups/km² in the montane forest of the Aberdares Range [Butynski 1999]).

Adaptations Diurnal and arboreal. Because they reach such high densities in many gallery forests and forest fragments, Guerezas are believed to be specially adapted to life in these forests (Oates 1977a, 1994). They thrive on the colonizing deciduous tree species and lianas characteristic of these forests, possibly because these plant species invest their energy more in rapid growth than in secondary compounds and lignin for their leaves (Oates 1977a). Even in continuous moist forests, Guerezas prefer areas of secondary growth and forest edge (Butynski 1985, Thomas 1991, Bocian 1997). For example, in the moist montane forest at Bwindi, Uganda, Guerezas are confined to the edge of the forest and appear to be absent at distances >2.8 km into the forest (Butynski 1985).

Like other colobines, Guerezas are characterized by an enlarged forestomach in which microbial fermentation of food occurs (Kay & Davies 1994). They may be especially good at digesting high-fibre food items; a study by Watkins *et al.* (1985) found that

Lateral, palatal and dorsal views of skull of Western Guereza *Colobus guereza occidentalis* adult male.

captive Guerezas fed on a high-fibre diet exceeded the digestive efficiency predicted for ruminant mammals of the same body size. Their capacity for subsisting on mature leaves during times of preferred food scarcity (Oates 1977a, Fashing 2004) may explain why Guerezas are sometimes able to achieve extraordinarily high densities (e.g. Leskes & Acheson 1970, Dunbar 1987, Krüger *et al.* 1998).

As a result of their relatively leafy diet and digestive adaptations, Guerezas also have a particularly sedentary life-style; they spend at least half of the day resting at all three sites where their activity patterns have been studied extensively (Kibale Forest, Uganda [Oates 1977a]; Ituri Forest, DR Congo [Bocian 1997]; Kakamega Forest, Kenya [Fashing 2001a]). Their tendencies to lead inactive life-styles, sunbathe in the canopy during the cool early morning and hunch over during rainstorms (Oates 1977a, Fashing 2001a) suggest that Guerezas may be adopting a strategy of behavioural thermoregulation similar to that of their West African congener King Colobus *Colobus polykomos* (Dasilva 1993).

In many habitats Guerezas sometimes travel and feed on the ground. This behaviour is particularly noticeable in forest galleries in savanna, where they move hundreds of metres on the ground between forest patches (Oates 1977a, c, Fay 1985), but it has also been observed in moist forest habitats, where they sometimes come to the ground to consume swamp plants or soil (Oates 1978; Fashing *et al.* 2007a).

In a craniometric study Hull (1979) found Guerezas to differ markedly from other black-and-white colobus species in their teeth, palate and jaws. For instance, Guerezas have relatively smaller incisors and longer molars than the other species, dental features that may be correlates of a more leafy diet.

Foraging and Food Folivorous. Extensive studies of Guereza diets have been conducted at four field sites (Kibale, Uganda; Ituri, DR Congo; Kakamega, Kenya; Budongo, Uganda). The results of these studies suggest that Guerezas exhibit impressive dietary flexibility. Guerezas tend towards extreme folivory at Kibale (Oates 1977a, Wasserman & Chapman 2003, Chapman *et al.* 2004) and Ituri (Bocian 1997), while their diets are more evenly balanced between leaves and fruit at Kakamega (Fashing 2001b) and Budongo (Plumptre 2006). Few primates are as folivorous as Guerezas at Kibale where up to 89% of the annual diet consists of leaves (Chapman *et al.* 2004), while at Kakamega, fruit accounts for up to 44% of the annual diet, and up to 81% of the diet in months when fruit is abundant (Fashing 2001a, b).

Unlike other *Colobus* species (McKey 1978, Harrison 1986, Dasilva 1994, Maisels *et al.* 1994), Guerezas consume primarily pulpy fruits rather than seeds (Dunbar & Dunbar 1974a, Fashing 2001b; A. Plumptre pers. comm.). In the case of both leaves and fruits Guerezas tend to focus on abundant species (Oates 1977a, Fashing 2001b). Furthermore, the total number of plant species consumed annually is generally low (Ituri 31 spp. [Bocian 1997]; Kakamega >37 spp. [Fashing 2001b]; Kibale 43 spp. [Oates 1977a]). Often a single species plays a major role in the diet of Guerezas: plant parts (mostly young leaves) of *Celtis gomphophylla* (syn. *C. durandii*) (Ulmaceae) comprised 50% of the annual diet for Guerezas at Kibale (Oates 1977a) and plant parts (mostly mature leaves) of *Prunus africana* (Rosaceae) made up 19% of the annual diet for Guerezas at Kakamega (Fashing 2001b, 2004). In addition to being the most frequently consumed items in the annual diet of Guerezas at Kakamega, *P. africana* mature leaves were also the primary fallback resource for Guerezas at this site, accounting for as much as 50% of the diet during months of fruit scarcity (Fashing 2004).

The chemical basis of food choice has been unusually well studied in Guerezas. Guerezas typically select food items that are high in protein, low in fibre, or both (Bocian 1997, Chapman *et al.* 2004, Fashing *et al.* 2007a). Secondary compounds also sometimes play a role in Guereza food choice, with most items high in condensed tannins tending to be avoided at Kibale (Oates *et al.* 1977) and Kakamega (Fashing *et al.* 2007a), but not at Ituri (Bocian 1997). Most minerals do not appear to strongly influence food choice, though there are several exceptions (Rode *et al.* 2003, Fashing *et al.* 2007a). Guerezas at both Kibale and Kakamega select for food items high in zinc, and engage in long journeys to access rare resources such as herbaceous swamp plants or *Eucalyptus* (Myrtaceae) bark that are rich in sodium (Oates 1978, Rode *et al.* 2003, Fashing *et al.* 2007a, Harris & Chapman 2007).

Guerezas typically engage in several prolonged feeding bouts spaced throughout the day with particularly sharp increases in time spent feeding occurring in the late afternoon at Kibale (Oates 1977a) and Chobe, Uganda (Oates 1977a), and in the mid- to late afternoon at Ituri (Bocian 1997). Feeding bouts are generally

followed immediately by long periods of rest, which are presumed to be necessary if Guerezas are to ferment and extract nutrients from their leafy diets (Oates 1977a).

In forest habitats group daily travel distances are relatively low (Kibale: mean = 535 m, range 288–1004 m, n = 60 days on one group [Oates 1977a]; Kakamega: mean = 588 m, range 166–1360 m, n = 185 days on five groups [Fashing 2001a]; Ituri: mean = 609 m, range 268–1112 m, n = 55 days on one group [Bocian 1997]). Unlike many other primates Guerezas do not appear to substantially alter their daily travel distance in response to temporal fluctuations in food availability (Oates 1977a, Bocian 1997, Fashing 2001a, b). Instead, Guereza ranging patterns may be influenced more by the distribution of the rare, sodium-rich resources, such as herbaceous swamp plants and *Eucalyptus* bark, that they periodically make long journeys to access (Oates 1977a, Fashing 2001a, Fashing *et al.* 2007a, Harris & Chapman 2007). They have also been seen out in freshly burned grassland, apparently eating ash or charcoal (Kingdon 1971). These journeys require some groups to cover much greater distances than others depending on how far a group's usual ranging area is from the high-sodium resources (Harris & Chapman 2007). This disparity among groups in distance to sodium-rich resources may help explain why Guereza daily path lengths and home-range sizes are not typically correlated with group size (Fashing 2001a, Fashing *et al.* 2007a, Harris & Chapman 2007). It is also possible, however, that the lack of a correlation between group size and ranging variables reflects an absence of scramble competition over food within most Guereza groups (Fashing 2001a).

Home-range areas of groups vary widely from 1.5 ha at Murchison Falls, Uganda (n = 1, Leskes & Acheson 1971) to 100 ha at Ituri (n = 1, Bocian 1997). Mean home-range areas at other sites include: Limuru, Kenya: 2.0 ha, n = 1 (Schenkel & Schenkel-Hulliger 1967); Bole, Ethiopia: 2.0 ha, range 1.4–3.6 ha, n = 10 (Dunbar 1987); Kyambura Gorge, Uganda: 3.7 ha, range 1.7–6.2 ha, n = 24 (Krüger *et al.* 1998); L. Naivasha, Kenya: 4.8 ha, n = 1 (Rose 1978); L. Shalla: Ethiopia, 5.6 ha, range not reported, n = 6 (Dunbar 1987); Entebbe, Uganda: 7.5 ha, range 6.4–9.3 ha, n = 3 (Grimes 2000); Kibale: 13.7 ha, range 8.8–18.8 ha, n = 6 (Harris 2005); Budongo, Uganda: 14 ha, range 7.3–21.3, n = 25 (Suzuki 1979); Kakamega: 18 ha, range 16–20 ha, n = 2 (Fashing 2001a); Kibale: 28 ha, n = 1 (Oates 1977a). Even at sites where home-ranges are relatively large (e.g. Kakamega, Kibale, Ituri), groups tend to concentrate their activities within a smaller 'core area' of their range (Oates 1977a, c, Bocian 1997, Fashing 2001a, Harris 2005). At Kibale, Harris (2006a, Harris *et al.* 2010) found that core areas featured a greater abundance of food per unit area than other portions of her groups' home-ranges.

Comparisons across Guereza study sites suggest that home-ranges become compressed into increasingly smaller areas as population density increases (Dunbar 1987, Fashing 2001a). Range overlap between groups is often high in moist forests where densities are intermediate (Kibale: 74% overlap [Oates 1977b], 83% overlap [Harris 2005]; Kakamega: >67% overlap [Fashing 2001a]), but tends to be much less extensive in moist forests where densities are low (Ituri: 22% overlap, Bocian [1997]; Budongo, Uganda: overlap not reported, but can be inferred from ranging and density data to have been minimal [Suzuki 1979]), and in gallery forests where densities are high (Chobe, Uganda: 10% overlap [Oates 1977a]; Bole, Ethiopia:

'relatively little' overlap [Dunbar & Dunbar 1974a]). The extensive range overlap at Kibale and Kakamega may be due in part to the convergence by many groups on small patches of rare resources at these sites (swamp plants and soil at Kibale, and *Eucalyptus* bark and soil at Kakamega) (Oates 1977c, 1978, Fashing 2001a, Fashing *et al.* 2007a, Dierenfeld *et al.* 2007).

Social and Reproductive Behaviour Social. Guerezas live in groups that typically include 1–2 adult ♂♂, 1–6 adult ♀♀ and their dependent offspring (Oates 1994, Fashing 2007). Adult ♂♂ not belonging to bisexual groups appear to travel most often alone or in pairs, though larger all-male groups of up to four animals occur (Oates 1974, P. Fashing pers. obs.). Bisexual groups range in size from two (Marler 1969, Suzuki 1979) to 23 individuals (Fashing 1999). Mean group size tends to be larger in large forest blocks than in small fragments and gallery forests (Dunbar 1987, Onderdonk & Chapman 2000, Fashing 2007). Groups in large forest blocks are more likely to include multiple ♂♂ (Oates 1994, Fashing 2007). The extent to which multimale groups are stable has been debated. Dunbar & Dunbar (1976) and Oates (1994) contend that multimale groups are only the temporary results of immigration and maturation within the group, while von Hippel (1996) argues that multimale groups can be stable over long periods and are, in fact, the typical social unit for Guerezas inhabiting large moist forest blocks.

Long-term, intermittent, longitudinal monitoring of Guereza populations in two large moist forests suggests that the extent to which multimale groups predominate and are long-lasting varies among forests. Over a recent 28-year period at Kakamega, five of six censuses of Guereza group composition indicated that 50% or more of the groups surveyed contained multiple ♂♂ (1980: 50%, $n = 6$ [Cords in Mulhern 1991]; 1990: 100%, $n = 2$ [Mulhern 1991]; 1992: 89%, $n = 18$ [von Hippel 1996]; 1997–98: 40%, $n = 5$ [Fashing 2001a]; 2004: 80%, $n = 5$; 2008: 83%, $n = 6$ [P. Fashing pers. obs.]). Furthermore, P. Fashing (pers. obs.) found that one recognizable adult ♂ at Kakamega remained subordinate in a multimale group for at least seven years, suggesting that the composition of multimale groups sometimes remains stable over long periods. On the other hand, studies over the past three decades at Kibale indicate that multimale groups are consistently less common than uni-male groups (1971–72: 14–29%, $n = 7$ [Oates 1977c]; 1992–93: 43%, $n = 40$ [Teelen 1994]; 2002–03: 17%, $n = 6$ [Harris 2006a]) and do not appear to be stable in composition over time (Oates 1977c).

Affiliative behaviour is common while agonism is rare within Guereza groups (Leskes & Acheson 1971, Dunbar & Dunbar 1976, Oates 1977b, Struhsaker & Leland 1979, Dunbar 1987, Fashing 1999, 2001a, Harris 2005). Grooming is the most frequent affiliative behaviour among Guerezas and they spend up to 15% of their time engaged in this behaviour (Kakamega: 6% [Fashing 2001a]; Kibale: 6% [Oates 1977b], 15% [Harris 2005]). Adult ♀♀ are the primary groomers in most groups at Kibale and Kakamega (Oates 1977b, Fashing 2001a, Harris 2005), although in groups where they are present, juvenile ♀♀ frequently groom others at Kakamega as well (P. Fashing 2001a, pers. obs.). Adult and juvenile ♂♂ groom others only rarely both at Kibale and Kakamega (Oates 1977c, Fashing 2001a, Harris 2005). Adult ♀♀ are typically the primary recipients of grooming (Oates 1977b,

Fashing 2001a), although Harris (2005) found that adult ♂♂ in Kibale often received more grooming than most adult ♀♀. Amongst adult ♀♀ within a group, there is considerable inter-individual variation in the extents to which they groom and are groomed by others (Oates 1977b, Harris 2005, P. Fashing pers. obs.). Oates (1974) noted that the smallest adult ♀♀ in his study group at Kibale received far less grooming than other adult ♀♀. This pattern was also observed in the group for which social relationships were most carefully studied at Kakamega (P. Fashing pers. obs.).

Agonism is typically uncommon within Guereza groups (Kibale: one incident every 8.7 h [Oates in Struhsaker & Leland 1979]; one incident every 9.1 h [Harris 2005]; Kakamega: no incidents during 16,710 scan samples and only occasional incidents outside scan samples [Fashing 2001a]). Still, Harris (2005) found that, at Kibale, displacements amongst adult ♀♀ occurred more often than expected in the context of feeding, and that ♀♀ displacing others fed more often than expected in the immediate aftermath of the displacement. Harris (2005) also noted that some adult ♀♀ had consistently unidirectional dominance relationships with other ♀♀ in their groups. These results suggest that, despite their reliance on a highly folivorous diet, contest competition over food occurs amongst ♀♀ within Guereza groups at Kibale (Harris 2005), albeit at a low rate.

Relationships between Guereza groups are typically antagonistic (Oates 1977a, c, Fashing 1999, 2001c, 2007, Harris 2005, 2006b, 2010). Patterns of home-range defence vary widely across habitat types, across forests of similar habitat type, and even within individual forests over time. Defence of the entire range appears typical of Guerezas in gallery forests where ranges are small (Dunbar 1987), while groups in large moist forests, where ranges are larger, tend to focus on defending only portions of their range (Oates 1977c, Fashing 1999, 2001c, Harris 2005). Guerezas in the large moist forest at Kakamega consistently engage in site-specific home-range defence, most staunchly and successfully defending those portions of their range they occupy most often (Fashing 1999). In the large moist forest at Kibale, Oates (1977c) found that the outcomes of most encounters were also location-specific, though some encounters appeared to be decided by inter-group dominance relationships instead. In another study at Kibale 30 years later, Harris (2006b) found that inter-group dominance relationships were the decisive factor influencing the outcomes of most encounters and that her six study groups could be ordered into a linear transitive dominance hierarchy based on competitive ability during encounters.

Males are the most aggressive group members during inter-group encounters, with ♀♀ only occasionally playing aggressive roles (Oates 1977b, Fashing 2001c, Harris 2010). Male inter-group aggression appears related primarily to the defence of food resources, although in some instances aggression may also be related to mate guarding (i.e. direct defence of mates [Fashing 2001c, Harris 2010]). The occasional ♀ aggression that occurs during encounters is probably related to resource defence, although during most encounters ♀♀ appear to rely on ♂♂ to do the bulk of the resource defence (Fashing 2001c, Harris 2010). Fashing (2001c, 2007) suggests that Guereza ♂♂ may engage in inter-group resource defence as a means of indirect mate defence; ♀♀ may be more likely to mate with, and less likely to transfer away from, ♂♂ who successfully defend food sources for their group.

Western Guereza *Colobus guereza occidentalis*.

One of the most distinctive sounds in the forests of equatorial Africa is the loud-call of the ♂ Guereza. This call, termed a 'roar' (Schenkel & Schenkel-Hulliger 1967), can be heard as far as 1.6 km away from its source (Marler 1969). Males uttering roars often simultaneously engage in a ritualized jumping display. Roars are most often given around dawn, when they are usually contagious, with ♂♂ from across the forest joining in once one ♂ begins roaring (Schel & Zuberbühler 2012). Dawn roars have been postulated to serve as inter-group spacing calls (Marler 1969, Waser 1977b) and/or as a form of male–male competition (Oates & Trocco 1983, Oates *et al.* 2000a, Harris *et al.* 2006). Roars are also sometimes given during the day when they appear to function primarily as predator alarm calls (Marler 1972, Oates 1994, Schel *et al.* 2009, 2010, Schel & Zuberbühler 2009). Kingdon (1971) noted roaring in response to nocturnal earthquakes and found that some groups in western Uganda called at about 03:00h with some frequency. Occasionally given at night, the function of these nocturnal roars is unclear.

In a study of captive ♂ Guerezas, Harris *et al.* (2006) found that the mean formant dispersion (i.e. difference, in Hz, between frequency bands) of the roars uttered by individual ♂♂ was significantly inversely correlated with their body mass. Harris (2006b) also reported that the mean formant dispersion of roars by ♂♂ in the wild at Kibale could be used to predict the outcome of encounters between groups. The lower the mean formant dispersion of a male's roars, the more likely his group was to win encounters with other groups. Guereza roars thus appear to be honest signals of body size, which may reflect ♂ competitive ability (Harris 2006b, Harris *et al.* 2006).

Allomaternal behaviour is common in Guerezas with juvenile ♀♀ and nulliparous adult ♀♀ particularly interested in carrying the infants of other ♀♀. This behaviour has been most thoroughly investigated in captive animals (Wooldridge 1969, Emerson 1973, Horwich & Manski 1975, Horwich & Wurman 1978). At Kibale, infants are handled most by non-mothers in their first 1–2 weeks of life, when they have all-white coats and are still completely dependent on others for all locomotion (Oates 1977c). Rate of infant transfers to allomothers during this stage is ca. 3–5 incidents/h at Kibale. Infants and, to a lesser extent, their mothers sometimes attempt to resist transfers to allomothers, and infants often squeal and flail about under the care of allomothers until their mothers come to retrieve them (Oates 1977c). Adult ♂♂ rarely engage in infant care, with all observed instances resulting from infants approaching ♂♂ and clinging to them (Oates 1977c, P. Fashing pers. obs.). However, individual juvenile ♂♂ occasionally seek out young infants to hold and carry, though much less frequently than ♀♀ (P. Fashing pers. obs.).

Most of what is known about Guereza mating behaviour comes from a recent study at Kibale (Harris & Monfort 2006). During this study, 334 solicitations for copulation were observed, of which 85% were accepted. Females and ♂♂ played the role of solicitor almost equally often. Twenty-three per cent of copulations were harassed by other group members, most commonly subadult ♂♂, though adult ♀♀ and juveniles occasionally harassed copulations as well. When a ♀ is in oestrus, copulatory rate can be high; one ♀ copulated with a particular ♂ 29 times in 64 min (Harris & Monfort 2006). Based on this report and a smaller sample of copulatory events observed

at Kakamega, Guerezas appear to be multiple mounters (Harris & Monfort 2006, Fashing 2007).

The percentage of time Guerezas spend in close proximity with other primate species (i.e. in polyspecific associations) varies across forests, though rarely reaches the frequencies observed among cercopithecines (Waser 1987, Cords 1990, Enstam & Isbell 2007). At Kakamega and Kibale, where polyspecific associations were defined as occasions when members of two species were within 50 m of one another, Guerezas spent 24% (P. Fashing pers. obs.) and 40% (Harris 2005) of their time in these associations, respectively. Guerezas most often formed these associations with Blue Monkeys *Cercopithecus (n.) mitis stuhlmanni* at Kakamega (P. Fashing pers. obs.) and with Uganda Red Colobus *Procolobus rufomitratus tephrosceles* at Kibale (Harris 2005). Polyspecific associations were defined differently at Bole where they were considered to occur only when the two closest members of different species are nearer to one another than are the two most widely separated group members of the same species. By this definition, Guerezas spent 11% of their time in polyspecific associations at Bole, most often with Grivets *Chlorocebus aethiops* (Dunbar & Dunbar 1974a).

Reproduction and Population Structure Unlike the Olive Colobus *Procolobus verus*, red colobus *Procolobus* spp., the Angola Colobus *Colobus angolensis* and the Black Colobus *Colobus satanas*, Guereza ♀♀ lack sexual swellings (Oates 1994, Bocian 1997). Ovarian cycle length, based on hormonal monitoring of three ♀♀ at Kibale, is ca. 24 days (range 15–27 days; Harris 2005). Most copulations at Kibale occurred from five days before to three days after the estimated date of ovulation. In some groups at Kibale multiple ♀♀ are sometimes simultaneously in oestrus (Harris & Monfort 2006). Females in captivity first give birth at 4.5–5.0 years of age after a gestation period of ca. 170 days (Rowell & Richards 1979). Gestation in the wild is ca. 152 days (range 142–161 days) based on hormonal monitoring of three ♀♀ at Kibale (Harris & Monfort 2006). Only singletons have been recorded. Birth-weight averages 445 g (Harvey *et al.* 1987). Inter-birth intervals are ca. 17 months at Kakamega (Fashing 2002), and 22–25 months at Kibale (Oates 1977c, Harris & Monfort 2006). No birth season observed at either Kibale or Kakamega, though there was some synchrony of births within study groups at Kakamega (Oates 1977b, Fashing 1999, 2002). Rowell & Richards (1979) suggest that Guerezas breed rapidly and aseasonally because their specialized digestive system releases them from the selective pressures imposed on other monkeys by seasonal food shortages. Few data are available on ♂ reproductive parameters.

Groups nearly always contain more adult ♀♀ than adult ♂♂ (Oates 1994, Fashing 2007). Average adult ♀ to adult ♂ ratios in groups were 3.4 : 1.4 at Kibale (n = 7 groups; Oates 1977c) and 3.8 : 2.4 at Kakamega (n = 5 groups; Fashing 2007). Immature to adult ♀ ratios in groups were 6.5 : 3.4 at Kibale (n = 7 groups; Oates 1977c) and 6.8 : 3.8 at Kakamega (n = 5 groups; Fashing 2007). Ten of 11 adult ♀♀ in three closely monitored groups gave birth during a 17-month study at Kakamega (Fashing 2002). Only one of these infants disappeared during the study period, suggesting that infant survivorship is high at this site (Fashing 2002). Infant mortality attributed to falls and infanticide (Oates 1977b), though the latter has been observed only at Kibale (Onderdonk 2000, Harris

Mt Kilimanjaro Guereza *Colobus guereza caudatus* adult male.

& Monfort 2003, Chapman & Pavelka 2005). Chapman & Pavelka (2005) suggest that infanticide risk may act as the primary constraint on group size among Guerezas at Kibale. Longevity in the wild is unknown, though Guerezas live to at least 23 years and 9 months in captivity (Jones 1982).

Male Guereza emigrate from their natal groups after adolescence and ♀♀ may occasionally transfer between groups (Harris *et al.* 2009). Bachelor ♂♂ and, to a lesser extent, all-male groups consisting of adult and/or subadult ♂♂ occur at Kibale and Kakamega, indicating that ♂♂ spend considerable periods living outside bisexual groups after dispersing (Oates 1977c, Fashing 1999). An all-male group with four members was regularly observed following one of P. Fashing's (pers. obs.) study groups at Kakamega over several weeks before eventually joining it permanently. An adult ♀ and her small juvenile who did not belong to any of the Kakamega study groups were also observed following and occasionally approaching one of Fashing's groups on several consecutive days but then were not seen again. Two members of another Kakamega study group, an adult ♂ and a large juvenile ♀, became increasingly peripheral to their group over several weeks before disappearing permanently. They are assumed to have transferred. There is also evidence from Kakamega that adult ♀♀ take an active role in expelling other adult ♀♀ from their group (P. Fashing pers. obs.). On several occasions over a 2-day period adult ♀♀ cooperated in holding down an adult ♀ group-mate while biting and hitting her until she fell to the forest floor. After the last instance of aggression from her ♀ group-mates, the victim fled through the undergrowth and was never observed in the group again.

Predators, Parasites and Diseases The primary predator on Guerezas appears to be the African Crowned Eagle *Stephanoaetus coronatus*, though the intensity of Crowned Eagle predation differs widely among sites. For example, Guerezas accounted for 39% of the prey of Crowned Eagles at Kanyawara study site in Kibale Forest (Skorupa 1989). However, just 12 km away at Ngogo, Guerezas comprised only 4% of the Crowned Eagle's diet (Mitani *et al.* 2001). Mitani *et al.* (2001) suggest that this disparity may be the result both of Guereza densities being higher at Kanyawara and inter-individual variation in hunting behaviour between Crowned Eagle pairs at the two sites.

Robust Chimpanzees *Pan troglodytes* prey on Guerezas at both Kibale (Mitani & Watts 1999, Watts & Mitani 2002) and Budongo

(Suzuki 1975). However, the rate of chimpanzee predation at Kibale is low with Guerezas accounting for only 4% of the chimpanzee's mammalian prey items (Watts & Mitani 2002). Leopards *Panthera pardus* probably also prey on Guerezas at low rates: Hart, J.A. *et al.* (1996) found that Guerezas and Angola Colobus combined comprised only 1% of the prey items in Leopard scats at Ituri, DR Congo; such remains could arise from Leopards scavenging African Crowned Eagle kills.

Guerezas appear to use several tactics to avoid predation. For example, adult ♂♂ give loud-calls ('roars') when they detect a predator. These vocalizations may help intimidate the predator and alert group-mates (Marler 1972, Schel *et al.* 2009, 2010). In the case of African Crowned Eagles, ♂ Guerezas may also use physical threats to intimidate them. P. Fashing (pers. obs.) once witnessed a ♂ Guereza chase off an Crowned Eagle perched quietly in the same tree as the ♂ and his group; the ♂ Guereza repeatedly raced to within 1 m of the Crowned Eagle and lunged at it. Another tactic Guerezas may use to avoid predation is to cluster together on moonlit nights, presumably to reduce their chances of being detected. Consistent with this assertion is von Hippel's (1998) finding that the number of sleeping trees occupied on a given night by members of a Guereza group in Kakamega Forest is significantly inversely correlated with the fullness of the moon. Lastly, aside from their loud-calls, most Guereza vocalizations are relatively quiet, a characteristic that reduces their conspicuousness to predators.

Ten species of gastrointestinal parasites were present in 476 faecal samples collected from Guerezas at Kibale: *Trichuris* sp., *Entamoeba coli*, *Entamoeba histolytica*, *Oesophagostomum* sp., *Strongyloides fulleborni*, *Ascaris* sp., *Colobenterobius* sp., *Bertiella* sp., an unidentified Strongyle, and a species in the Dicrocoeliidae. Prevalence (percentage of faecal samples in which a parasite was present) exceeded 10% only for *Trichuris* sp., which was found in 79% of the samples (Gillespie *et al.* 2005b).

A preliminary study of 23 Guereza faecal samples from Kakamega revealed nine species of parasites: *Trichuris* sp., *E. coli*, *E. histolytica*, *Heterophyes* sp., *Fasciola* sp., *Schistosoma* sp., an unidentified Strongyle, an unidentified hookworm and an unidentified worm. Like at Kibale, *Trichuris* sp. was among the most prevalent parasites and was found in 87% of samples from Kakamega. Other parasites present in at least 10% of samples from Kakamega were *E. coli*, *E. histolytica*, *Heterophyes* sp., *Fasciola* sp., the unidentified Strongyle and the unidentified hookworm (P. Fashing, C. Ashira & I. Farah pers. obs.).

Many of the parasites found among Guerezas at Kibale also occur commonly among the human population in W Uganda. However, no differences were found in parasite prevalence between Guerezas living in anthropogenically disturbed (logged) forest and those inhabiting undisturbed forest (Gillespie *et al.* 2005b). Still, when Chapman *et al.* (2005) examined the effects of immigration of Guerezas from a fragment cleared by humans into a second fragment where Guereza parasite loads were already being monitored, they found that, over the next five years, *Trichuris* sp. infection prevalence and intensity increased while Guereza density declined.

Conservation IUCN Category (2012): Least Concern. *C. g. percivali*: Endangered. *C. g. gallarum*, *C. g. dodingae* and *C. g. matschiei*: Data Deficient. All other subspecies: Least Concern. CITES (2012): Appendix II.

Western Guereza *Colobus guereza occidentalis* adult male.

Guerezas have traditionally been hunted for ceremonial purposes by many African peoples, including the Kuria, Chagga, Kikuyu, Samburu and Luhya. Guerezas were also hunted heavily for their skins to supply the European fur market in the nineteenth century, and in the twentieth century to make rugs for the tourist trade (Oates 1977b). The Guereza skin trade was outlawed in Kenya and Ethiopia in the 1970s (Dunbar & Dunbar 1975a, Oates 1977b), though Guereza pelts and rugs were still found on sale illegally in an Addis Ababa souvenir shop as recently as 2003 (P. Fashing pers. obs.). Although primates are not often hunted for their meat in the African savanna zone, or in much of East Africa, Guerezas are hunted as food in the forest zone; in western equatorial forests they are threatened, along with other large forest primates, by the bushmeat trade. For instance, Fay (1985) reported that Guerezas were still abundant in gallery forests in the Manovo–Gounda–St Floris N. P. in the savanna zone of Central African Republic, while they had been nearly extirpated in the southern, forested, portion of the country.

Perhaps the most threatened subspecies is *C. g. percivali*, which is endemic to the Mathews Range F. R. (940 km²) where this subspecies remains widespread from 1400–2000 m. Incidence of loud calls indicates that some sites support at least three groups/km². It appears that the habitat and the primates of the Mathews Range are better protected now than in the recent past (Mwenge 2008, De Jong & Butynski 2010a).

The Guereza is one of the few primate species that generally responds well to some habitat disturbance (Fashing *et al.* 2012), actually attaining higher densities in logged than in undisturbed areas at Kibale (Skorupa 1986, Struhsaker 1997, Chapman *et al.* 2000) and Budongo (Plumptre & Reynolds 1994). However, intensive logging and forest clearance for agriculture are as much a threat to Guerezas as they are to other forest-dependent primates (Chapman *et al.* 2003, 2007).

Measurements

Colobus guereza

HB (♂♂): 615 (543–699) mm, n = 20

HB (♀♀): 576 (521–673) mm, n = 22

T (♂♂): 667 (521–826) mm, n = 20

T (♀♀): 687 (528–797) mm, n = 22

Specimens in BMNH; localities not listed (Napier 1985)

C. g. occidentalis

HB (♂♂): 593 (535–690) mm, n = 16

HB (♀♀): 554 (485–640) mm, n = 13

T (♂♂): 811 (670–885) mm, n = 16

T (♀♀): 773 (715–825) mm, n = 13

HF (♂♂): 191 (175–207) mm, n = 16

HF (♀♀): 179 (165–190) mm, n = 13

E (♂♂): 44 (37–50) mm, n = 16

E (♀♀): 40 (35–43) mm, n = 13

WT (♂♂): 9.3 (6.8–11.3) kg, n = 46

WT (♀♀): 7.4 (5.4–10.9) kg, n = 46

Body measurements: various localities in E DR Congo (Allen 1925)

Weight: numerous localities (Delson *et al.* 2000)

C. g. guereza

WT (♂♂): 13.5 (12.4–14.4) kg, n = 3

WT (♀♀): 9.2 (8.2–10.1) kg, n = 3

Specimens from Ethiopia in MNHN (J. F. Oates pers. obs.).

C. g. matschiei

WT (♂♂): 9.9 (8.2–11.8) kg, n = 15

WT (♀♀): 8.3 (6.4–10.2) kg, n = 15

Several localities (Delson *et al.* 2000)

GENUS *Procolobus*

Olive Colobus Monkey, Red Colobus Monkeys

Procolobus de Rochebrune, 1887. Faune de Sénégal. Suppl. Vert., Mamm. 1: 95.

Tshuapa Red Colobus *Procolobus rufomitratu tholloni* adult male.

Polytypic genus endemic to the forests of tropical Africa. Two subgenera provisionally recognized (*Procolobus* and *Piliocolobus*), one species of Olive Colobus and 18 taxa of red colobus monkeys. The number of species of red colobus monkeys is controversial but six are profiled in this volume. For further details, see profiles for the subgenera *Procolobus* and *Piliocolobus*, and Struhsaker (1981b, 2010), Colyn (1991), Grubb *et al.* (2003), Groves (2001, 2007b), Ting (2008a, b), Cardini & Elton (2009) and Oates (2011).

Recent molecular data indicate that *Procolobus* and *Piliocolobus* diverged prior to the late Miocene (6.9–6.4 mya) (Ting 2008a, b, Roos *et al.* 2011). If the suggested divergent time standard for genera of 6–4 mya is adopted, *Piliocolobus* should be considered a genus based on its divergence from *Procolobus* at least 6 mya (Goodman *et al.* 1998, Groves 2001).

All members of the genus *Procolobus* share the following characters:

- 1 Four-chambered stomach. This differs from the three-chambered stomach of *Colobus*. All Colobinae have cellulolytic bacteria that allow consumption and digestion of large quantities of leaves and seeds.
- 2 A sagittal crest in most adult ♂♂, and a larger nuchal crest in ♂♂.
- 3 Enlarged supraorbital ridges.
- 4 Larynx reduced in size (not enormously enlarged as in *Colobus*), subhyoid sac absent and pterygoid fossa deepened.

- 5 Adult and subadult ♀♀ have perineal swellings that vary in size over time. There is tremendous inter-taxa variation in the maximum size of these swellings, with the largest so far recorded being found in *P. badius temminckii*, *P. badius badius*, *P. preussi*, *P. rufomitratu oustaleti* and *P. gordonorum*, and the smallest in *P. rufomitratu tephrosceles*, *P. r. rufomitratu* and *P. kirkii*.
- 6 Males of all ages have a perineal organ that superficially resembles the very smallest swellings of adult ♀♀.
- 7 Ischial callosities are separate in both sexes.

Pelage colour usually includes varying amounts of reddish-brown or orange, depending on the taxon. Coat colour is often highly variable, even amongst members of the same social group. Cranial differences are considerable, and the two putative subgenera are considered by many authors (Kingdon 1997, Jablonski 1998, Groves 2001, 2005c, 2007b) to be generically distinct. In his monograph on cranial morphology, Verheyen (1962) separated the Olive Colobus *Procolobus verus* as a distinct genus while uniting red colobus with black-and-white colobus in the genus *Colobus*.

Procolobus eat relatively little animal food and rarely drink water (e.g. from tree-holes), obtaining most water from food. They are largely diurnal although some activities, such as copulation, sometimes occur at night. Their forest habitats are highly variable in rainfall and tree species composition, ranging from the dry and seasonal forests (mean annual rainfall of ca. 1050 mm for *P. b. temminckii* at Fathala, S Senegal; Gatnot 1976) to the extremely wet forests of S Bioko I., Equatorial Guinea (ca. 10,000 mm mean annual rainfall) in the case of *P. p. pennantii*. Found from sea level (e.g. *P. p. pennantii* on Bioko I. and *P. kirkii* on Zanzibar [Unguja] I.) to ca. 2200 m (*P. gordonorum* in the Udzungwa Mts, Tanzania).

Ashy Red Colobus *Procolobus rufomitratu tephrosceles* perineal and anal region in adult female (left) and adult male (right).

Subgenus *Procolobus* Olive Colobus Monkey

Procolobus de Rochebrune, 1887. Faune de Sénégalambie. Suppl. Vert., Mamm. 1: 95.

Monotypic subgenus endemic to the moist forests of West Africa. Subgenus *Procolobus* embraces a single species, the Olive Colobus *P. verus*. *Procolobus verus* is restricted mainly to high forest in West Africa, though occurring also in some gallery forests, for example along the Benue R., Nigeria (its easternmost distribution). This is the smallest of all extant African colobines. Pelage dull olive greyish-green or olive-brown comprised of agouti-banded hairs. *Procolobus verus* has a swept-up crest and distinctively cow-licked hair on the crown, hairy ears, and a glans penis covered in minute papillae. Differs from the subgenus for red colobus monkeys, *Piliocolobus*, in numerous cranial features (Verheyen 1962, Groves 2001, Cardini & Elton 2009). Some of these are:

- 1 Facial skeleton not so prognathous, premaxillae vertical; supraorbital ridges thin, curved; margins of pyriform aperture sharp; an incipient anterior nasal spine; posterior palatal canals deeply sunk in fossae; wide choanae and pterygoid fossa, with flat basisphenoid floor.
- 2 Symphyseal foramen present in mandible. This is a rare feature in 'higher primates'.
- 3 Maxillary incisors have a lingual cingulum and tubercle; lateral incisors are rather caniniform. Lower M3 have a tuberculum sextum.

- 4 Second and fourth fingers are remarkably shortened, and the second finger has a peculiarly claw-like nail.

Subgenus *Procolobus* shares the following features with *Colobus*: shallow, wide interpterygoid fossa and other features of the basicranium, and oval orbits with thin supraorbital arches. This subgenus, however, lacks the subhyoid sac and enlarged larynx that characterize the very vocal *Colobus* species. No other colobines, living or fossil, have been allocated to this subgenus.

Of behavioural peculiarities, mothers carrying their young in the mouth or the young clinging to the mother's neck. These are assumed to be primitive or conservative behaviours, although these habits could have been selected through infants being consistently weak or inefficient in their grasp of the mothers' short, slippery hair. Characteristically, *Procolobus* are quiet and inconspicuous, and their groups form long-term associations with those of sympatric *Cercopithecus* spp., especially Diana Monkey *Cercopithecus* (d.) *diana*. Other features of this subgenus are given in the profile for *P. verus*.

Peter Grubb & Colin P. Groves

Procolobus verus OLIVE COLOBUS (VAN BENEDEN'S COLOBUS)

Fr. Colobe de van Beneden; Ger. Grüner Stummelaffe

Procolobus verus (van Beneden, 1838). Bull. Acad. Sci. Belles-Lettres Belg. 5: 347. 'Africa'.

Taxonomy Monotypic species. Sometimes treated as a monotypic genus (see below), but most authors currently recognize the Olive Colobus as a monotypic subgenus within *Procolobus*, a genus that also contains the subgenus *Piliocolobus*, the red colobus monkeys (Grubb *et al.* 2003).

Van Beneden's original description placed the Olive Colobus in the genus *Colobus*, but it was allocated to its own genus, *Procolobus*, by de Rochebrune (1887). Pocock (1935) recognized the close affinities of the red colobus monkeys and the Olive Colobus by 'provisionally'

assigning the red colobus monkeys to *Procolobus*, with *verus* as the type species. This arrangement has been supported by several later authors, including Kuhn (1967), Grubb *et al.* (2003) and Oates (2011). Others, however, see *Procolobus* as a monotypic genus (Dandelot 1974, Corbet & Hill 1980, Kingdon 1997, Groves 2001, 2005c, 2007b). Synonyms: *chrysurus*, *cristatus*, *olivaceus*. Chromosome number: not known.

Description Small, olive-brown, arboreal monkey. Smallest colobine monkey. Adult ♀♀ same colour as adult ♂♂. Adult ♀♀ average about 91% the weight of adult ♂♂. Head small and rounded. Face naked, dark grey. Eyes surrounded by obvious 'spectacles' of bare, puckered, grey skin. Ears large. Crown with short sagittal crest, which is particularly noticeable in adult ♂♂. Thumbs extremely reduced. Hands long. Feet especially long, exceeding in length both the thigh and the crus. Detailed anatomical description given by Hill (1952). Dorsal pelage varies from light reddish-brown to dark greyish-brown, sometimes with a slight olivaceous tinge. Ventrums dull grey to whitish. Testes large, contained in a pendulous scrotum. Glans of the penis unique among anthropoids in bearing small horny spicules. Adult ♀♀ have large cyclical circumvulval swellings, which reach a length of >6 cm. Perineal swellings present in juvenile ♂♂. Infants similar to adults in colour.

Olive Colobus *Procolobus verus* adult male.

Geographic Variation None recorded.

*Procolobus verus*

Similar Species None within geographic range.

Distribution Endemic to West Africa. Rainforest BZ. Restricted to coastal forests from Sierra Leone eastward to just east of the Niger R. in Nigeria. Although most records are south of 08° N (Oates 1981, Wolfheim 1983, Grubb *et al.* 1998), the Olive Colobus occurs as far north as 09° N in the Comoé N. P., Côte d'Ivoire (Fischer *et al.* 2000). Recent records for areas where this monkey had not been recorded previously (Dahomey Gap of S Bénin [Oates 1996b, Campbell *et al.* 2004, Nobime *et al.* 2011]; Niger Delta [Anadu & Oates 1988, Powell 1995]) suggest that the Olive Colobus may be more widespread than has been suspected, and that its apparent rarity may be due in part to its crypticity.

Current distribution probably similar to the historical distribution, but populations are today fragmented within this range as a result of deforestation by humans. The distribution of the Olive Colobus shows remarkable general correspondence to that of another endemic West African mammal, the Pygmy Hippopotamus *Choeropsis liberiensis*.

Habitat Lowland moist forest, swamp forest and forest galleries in the derived savanna/dry forest zone. Most abundant in riverine forest (Oates 1981). Presence in the Niger Delta confirmed only for the seasonally flooded forest of the upper Delta (Powell 1995). In Bénin the habitat in the Lama Forest is seasonally inundated. The sacred forest where the Olive Colobus occurs at Togbota is in the lagoon of the Ouémé R. Annual rainfall (and its distribution) within the species' range is extremely variable, from over 3000 mm with a 4-month dry season at Tiwai I., Sierra Leone, to ca. 2000 mm with a 3–4 month dry season in Tāi N. P., Côte d'Ivoire, to <1200 mm with a 5-month dry season in the Ayangba region of E Nigeria.

Abundance Generally rare, although density in one area of Tāi N. P. was ca. 14–21 ind/km² (Galat & Galat-Luong 1985, Korstjens

Lateral, palatal and dorsal views of skull of Olive Colobus *Procolobus verus* adult male.

2001). On Tiwai I., where Olive Colobus are relatively abundant, the estimated density was 7–8 ind/km² (Oates *et al.* 1990, Whitesides *et al.* 1988). In Kakum, Ghana, 0.06–0.19 groups encountered per km of transect walked (Oates *et al.* 2000a).

Adaptations Diurnal and arboreal. Olive Colobus appear to have a proclivity for areas with thick undergrowth and abundant lianas, such as river margins, secondary forest and canopy gaps (Booth 1957, Kuhn 1964, McGraw & Sciulli 2011). The Olive Colobus is a cryptic animal that is hard to detect because of its small size, its drab colouration, its habit of remaining inactive for long periods in thick growth, its tendency to live in small, dispersed groups and its quietness (most calls are soft, and they are given infrequently). Olive Colobus use their long hind-limbs to leap (20% of locomotor time is spent leaping compared to 18% for red colobus *Piliocolobus* spp., 14% for black-and-white colobus *Colobus* spp., and <11% for *Cercopithecus* spp. in Tāi; McGraw 1998a).

Olive Colobus are almost always seen in close proximity to groups of other monkeys, especially *Cercopithecus* spp., with which they may maintain prolonged association. This has been viewed as an anti-predator strategy (Booth 1957, Whitesides 1989, Oates & Whitesides 1990). The ranging patterns of individuals are strongly

influenced by the movements of the other-species group with which they are travelling.

Like other colobine monkeys, Olive Colobus have a large, sacculated stomach, including a bacterial fermentation chamber. Like red colobus, the stomach has a distinct four-part structure (Kuhn 1964). A study of second-molar anatomy by Kay (1981) found Olive Colobus to have the thinnest enamel and the greatest relative shearing crest development of any catarrhine primate. These anatomical features are correlates of the highly folivorous diet of this species (see below).

One of the most remarkable behavioural features of this unusual monkey is the method of carrying the infant. Unlike any other monkey or ape, infants are carried in the mother's mouth, as first reported by Booth (1957). At Tiwai and Tãi this behaviour continued until infants were at least ten months old, and infants were never seen clinging to the mother's ventrum; the mother typically held the infant by the skin of its flank, with the infant tucked against her neck and its tail wrapped around her neck and upper back (Oates 1994). Booth (1957) suggested that this behaviour occurs because the infant would have difficulty clinging to its mother's belly given its rudimentary thumb and her sparse ventral pelage, and would be in danger of being dislodged as the mother moves through thick vegetation.

Foraging and Food Folivorous. The Olive Colobus appears to be entirely vegetarian, but feeding often occurs in thick, low growth in the forest, where details of what is being ingested are hard to observe. While feeding, members of a social group are frequently highly dispersed, and mingled with monkeys of other species. In Tãi the home-range of two groups was 29 ha and 33 ha (Galat & Galat-Luong 1985), while Korstjens (2001) found the annual home-range of two groups at the same site to be 54 ha and 58 ha (Korstjens *et al.* 2007). At Tiwai I., a group associating with a group of Diana Monkeys *Cercopithecus (d.) diana* had a home-range of 28 ha (Oates 1994).

Olive Colobus travel and activity patterns are strongly influenced by the behaviour of the other monkey species with which they associate, and therefore vary considerably from place to place. As a result of their frequent association with *Cercopithecus* spp., Olive Colobus often travel longer distances each day than do most colobines. Daily mean travel distance in Tãi was 1202 m (± 297 , $n = 12$; Korstjens 2001, Korstjens *et al.* 2007). Annual activity budgets in Tãi (A. H. Korstjens & R. Noë pers. obs.) and Tiwai I. (J. Oates pers. obs.): 16% and 28% feeding, 50% and 39% resting, 30% and 26% moving, and 4% and 7% socializing (mainly grooming). McGraw (1998a) gives for Tãi: 13, 30, 19 and 6, respectively. At Tãi McGraw (1998a) found Olive Colobus to spend 64% of their time in the understorey (between 5 and 15–20 m), while at Tiwai I. 59% of observations were in the middle canopy at 10–19 m (Oates & Whitesides 1990). Both at Tãi and at Tiwai, Olive Colobus used lower heights in the canopy for foraging than travelling; 85% of Tãi foraging records were from the understorey or below, compared to 72% for travel (McGraw 1998a, see also McGraw & Sciulli 2011). At Tiwai 54% of feeding records came from below 15 m compared to 32% for travel (Oates & Whitesides 1990). Occasionally Olive Colobus come to the ground to cross tree gaps, and they sometimes forage on the ground on fallen fruits and on termite hills (Korstjens & McGraw pers. obs.). In Tãi they spend far more time on the ground (6%) than conspecific Western Red Colobus *Procolobus badius badius* (0.1%) or King Colobus *Colobus polykomos* (0.4%) (McGraw 1996,

Olive Colobus *Procolobus verus*.

1998c). There appears to be little variation in activity patterns during the day except for a peak in feeding in the afternoon, especially after 16:00h (Deschner 1996, J. Oates pers. obs.).

Based on 521 observations of feeding at Tiwai I., the composition of the Olive Colobus diet was 59% young leaves, 15% other leaves or leaf parts, 14% seeds, 7% flowers and 4% whole fruits or fruit pulp (Oates 1988a). Of 991 observations on feeding at Tãi, 91% were leaves or leaf parts, and 9% fruit or seeds (Korstjens 2001, Korstjens *et al.* 2007). Most of the leaves and seeds eaten by Olive Colobus at these two sites came from second-growth, riverbank or understorey trees (e.g. *Myrianthus libericus*, *Napoleona leonensis*, *Plagiosiphon emarginatus*, *Rinorea longicuspis*, *Scyttopetalum tieghemii*, *Strephonema pseudocola* and *Terminalia ivorensis*) and from lianas (see Korstjens 2001 for a detailed list of tree species used at Tãi).

Social and Reproductive Behaviour Social. Although Olive Colobus are social, grouping patterns are highly variable and fluid. Across the species' range in West Africa, group sizes range from 2 to 15 individuals. In Tãi, groups ranged in size from 3 to 14, with a mean of 7.1 ($n = 17$, Galat & Galat-Luong 1985; $n = 6$, Korstjens & Schippers 2003, Korstjens & Noë 2004). In the few cases where group composition has been assessed, 1–3 adult ♂♂ were present. Two adult ♂♂ were present in two, and three adult ♂♂ in one of six groups in Tãi (Galat & Galat-Luong 1985, Oates 1994, Korstjens & Schippers 2003, Korstjens & Noë 2004). Groups show frequent changes in composition, especially through ♀♀ transfer and natal dispersal by both sexes. For instance, a group at Tiwai contained two adult ♂♂, five adult ♀♀, one juvenile and three infants in Apr 1983, but by Nov 1985 contained only one adult ♂, one adult ♀ and one juvenile (Oates 1988a). During 4.5 years of observation in Tãi, one adult ♀ transferred into a group every 3.9 adult ♀ observation years; for ♂♂ this value was only one per 6.8 adult ♂ observation years. Of 11 juveniles monitored at Tãi, none matured in their natal group. New groups formed around solitary adult ♂♂ who were associated with a Diana Monkey group (Korstjens & Schippers 2003, Korstjens & Noë 2004, Korstjens *et al.* 2007). Related to the weak group cohesion, Olive Colobus show relatively low levels of intra-group affiliative behaviour; grooming is more common between ♂♂ and ♀♀ (especially around the time of mating activity) than among ♀♀. Overt agonistic behaviour is rare.

It is unclear whether Olive Colobus groups defend territories. However, adult ♂♂ have a distinctive high-pitched 'laughing' call, rendered by Hill & Booth (1957) as 'hoo hoo hoo hoo yow yow wee wee yow', rising in pitch to the penultimate syllable and dying away on the last. Both at Tāi and at Tiwai, Olive Colobus adult ♂♂ accompanying different Diana Monkey groups approach each other and exchange laughing calls, accompanied by much of side-to-side head-bobbing threatening gestures (Korstjens & Noë 2004) while the Diana Monkey groups have territorial encounters. Olive Colobus ♀♀ generally remain hidden in the vegetation and do not get involved in these conflicts. However, Korstjens & Schippers (2003) observed three ♀♀ with swellings giving sexual presents to ♂♂ of neighbouring groups during such encounters. In two of these cases the male(s) who were presented to mated with the proceptive ♀, while in the third case the ♂ chased the ♀ away (Korstjens & Schippers 2003, Korstjens & Noë 2004).

Females with sexual swellings are often followed closely by adult ♂♂, sometimes throughout the long receptive period (median 17 days; see below). Mating is frequent (sometimes >40 times/day) during these consortships. If there is more than one adult ♂ in the group, both may mate with the ♀ within five minutes. In Tāi a group is visited by a solitary ♀ (of unknown origin) with a sexual swelling, on average, once every 57th observation day (Korstjens & Schippers 2003, Korstjens & Noë 2004). These ♀♀ typically mate with male(s) of the group and disappear again within three weeks (Korstjens & Schippers 2003, Korstjens & Noë 2004).

Reproduction and Population Structure The large perineal sexual swellings of Olive Colobus ♀♀, and the large testes and penile spicules of ♂♂, are mentioned above. Female swellings last 14–20 days, median 17 days ($n = 7$), and can recur monthly (Korstjens & Noë 2004). At Tiwai, where the rainy season usually occurs from May to Oct, almost all observed copulations occurred during Mar–Aug, and ♀♀ with large sexual swellings were seen only in Jun–Aug. Very small infants were seen only in Nov–Apr, with the majority estimated to have been born in Jan, during the pronounced Dec–Mar dry season. In Tāi the rainy season occurs during Sep–Oct and the dry season from Dec to Feb. Here, ♀♀ with large swellings occur throughout the year, but births ($n = 13$) are most common during Oct–Feb, and never observed during May–Sep (Korstjens & Noë 2004). These observations suggest a typical colobine gestation of about six months, with births (only singletons observed) primarily during or close to the dry season. Young leaves are most abundant in the Tiwai forest in Feb–Mar (late dry season) and May–Jun (early rains) (Davies *et al.* 1999).

Few data on population structure are available, but social groups usually contain more adult ♀♀ than ♂♂. Six groups in Tāi had a mean of 1.5 adult ♂♂ (range 1–3) and 3.0 adult ♀♀ (range 1–5) per group (Korstjens & Schippers 2003, Korstjens & Noë 2004). In Tāi inter-birth intervals range from 1.2 to 2.0 years (mean 1.6, $n = 6$); juveniles are generally weaned at ca. one year of age, but one juvenile survived the loss of its mother at an age of 8.4 months (Korstjens & Schippers 2003). The only ♂ monitored from birth until attaining secondary sexual characteristics matured at an age of 3.7 years (Korstjens 2001, Korstjens & Schippers 2003).

Predators, Parasites and Diseases The cryptic appearance and behaviour of the Olive Colobus, combined with its strong

tendency to associate with other forest monkeys, are thought to have evolved as devices to lower predation risk. African Crowned Eagles *Stephanoetus coronatus*, Leopards *Panthera pardus* and Robust Chimpanzees *Pan troglodytes* prey on Olive Colobus (Boesch & Boesch 1989, Buzzard 2004, Shultz *et al.* 2004, Shultz & Thomsett 2007, Zuberbüler & Jenny 2007). No Olive Colobus remains were found in an analysis of 215 Leopard scats in Tāi (Hoppe-Dominik 1984). During a 7-year study in Tāi, Boesch & Boesch (1989) recorded only two attempts by chimpanzees to hunt Olive Colobus, compared with 110 attempts to hunt Western Red Colobus. This study occurred where the density of Western Red Colobus is estimated to be about eight times greater than that of Olive Colobus. Korstjens (2001) estimated that, each year, chimpanzees capture 0.9% of the Olive Colobus population, compared with 3.2% of Western Red Colobus, and 1.4% of Western Black-and-white Colobus in the same area. Shultz *et al.* (2004) calculated predation rates in Tāi of 1.0% of the Olive Colobus population per year by Leopards, and 4.8% by African Crowned Eagles.

Conservation IUCN Category (2012): Near-Threatened. CITES (2012): Appendix II.

The main threat to Olive Colobus is loss of habitat. Fortunately, this monkey does well in secondary forest and farm bush. Olive Colobus are shot, but, partly due to their strong smell, small size and cryptic nature, they are not a major target of hunters. Consequently, Olive Colobus are often one of the few remaining species in heavily hunted forests in Côte d'Ivoire and Ghana (Oates *et al.* 2000a, Refisch & Koné 2005, McGraw 2007b). Priority action for the long-term survival of the Olive Colobus is better control of hunting. Important areas for conservation are the larger protected areas, especially Tāi and Sapo, and smaller or interesting ones like Tiwai and Kakum in Ghana. The more eastern populations need attention; for instance, there is no effective conservation area for Olive Colobus within Nigeria.

Measurements

Procolobus verus

HB (♂♂): 458 (430–480) mm, $n = 8$

HB (♀♀): 465 (435–490) mm, $n = 6$

T (♂♂): 594 (570–640) mm, $n = 8$

T (♀♀): 610 (570–640) mm, $n = 6$

HF (♂♂): 136 (130–145) mm, $n = 8$

HF (♀♀): 135 (125–143) mm, $n = 7$

E (♂♂): 28 (26–31) mm, $n = 8$

E (♀♀): 27 (26–29) mm, $n = 7$

WT (♂♂): 3.8 (3.3–4.4) kg, $n = 7$

WT (♀♀): 3.6 (2.9–4.1) kg, $n = 5$

Ghana (Booth 1957)

WT (♂♂): 4.7 (4.0–5.7) kg, $n = 23$

WT (♀♀): 4.3 (3.6–5.4) kg, $n = 11$

Numerous sites. Based on the dataset presented in Delson *et al.* (2000) minus the four specimens taken from Booth (1957)

Subgenus *Piliocolobus*

Red Colobus Monkeys

Piliocolobus de Rochebrune, 1887. Faune de Sénégalie. Suppl. Vert., Mamm. 1: 96.

Some taxa of red colobus:

- (a) Temminck's Red Colobus *Procolobus badius temminckii*.
- (b) Niger Delta Red Colobus *Procolobus (pennantii?) epieni*.
- (c) Tana River Red Colobus *Procolobus rufomitratatus rufomitratatus*.
- (d) Preuss's Red Colobus *Procolobus preussi*.
- (e) Ashy Red Colobus *Procolobus rufomitratatus tephrosceles*.
- (f) Udzungwa Red Colobus *Procolobus gordonorum*.
- (g) Tshuapa Red Colobus *Procolobus rufomitratatus tholloni*.
- (h) Kivu Red Colobus *Procolobus rufomitratatus foai*.
- (i) Zanzibar Red Colobus *Procolobus kirkii*.

Polytypic subgenus endemic to the forests of tropical Africa. The various taxonomies applied to this subgenus are reviewed in Grubb *et al.* (2003) and in Ting (2008b). This volume, very provisionally, recognizes six species of red colobus monkeys and 18 taxa:

- P. badius* Western Red Colobus. Includes *P. b. badius*, *P. b. temminckii* and *P. b. waldroneae*.
- P. preussi* Preuss's Red Colobus.
- P. pennantii* Pennant's Red Colobus. Includes *P. p. pennantii*, *P. p. bouvieri* and possibly *P. p. epieni*.
- P. rufomitratatus* Eastern Red Colobus. Includes *P. r. rufomitratatus*, *P. r. tholloni*, *P. r. oustaleti*, *P. r. langi*, *P. r. ellioti*, *P. r. lulindicus*, *P. r. foai*, *P. r. parmentieri* and *P. r. tephrosceles*.
- P. gordonorum* Udzungwa (or Iringa) Red Colobus.
- P. kirkii* Zanzibar Red Colobus.

The last ancestor for *Procolobus* and *Piliocolobus* is estimated at 9.4–4.4 mya (Roos *et al.* 2011) and 9.1 mya (Perelman *et al.* 2011). *Piliocolobus* differs from nominotypical *Procolobus* in numerous cranial features (Verheyen 1962, Groves 2001, 2007b, Cardini & Elton 2009). These include the following:

- 1 Jaws prognathous; strong straight supraorbital ridges; suborbital fossa present; pyriform aperture margins rounded; no anterior nasal spine; posterior palatal canals shallow; choanae and pterygoid fossa narrow, and basisphenoid crested and bordered laterally by gutters.
- 2 Mandible lacks a symphyseal foramen; upper incisors with no incisor cingulum or tubercle; no tuberculum sextum on posterior lower molar.
- 3 Pelage usually includes varying amounts of reddish-brown or orange, depending on the taxon, and most taxa lack agouti

Ashy Red Colobus *Procolobus rufomitratus tephrosceles*.

banding. The second and fourth fingers are not shortened, and all fingers have flat nails.

Red colobus monkeys have long presented one of the thorniest taxonomic problems among the African primates (Grubb *et al.* 2003, Ting 2008a, b, Cardini & Elton 2009, Struhsaker 2010). There is little doubt that they are a monophyletic group, within which there is a

complex pattern of variation distributed across many allopatric forms (none are sympatric) spread across equatorial Africa from Senegal and Bioko I., Equatorial Guinea, to Zanzibar I., Tanzania. However, these different forms show more variability than would be expected from a single species. In colour pattern, some populations of red colobus differ at least as much as related species of *Colobus* or *Cercopithecus*, and there are probably many different species (Kingdon 1997, Groves

2001, 2005c, 2007b). Regional variation in vocalizations also suggest that there are several species. Struhsaker (1981b, 2010) grouped 12 red colobus taxa on the basis of similarities in 11 calls that are common to one or more of these taxa. An additional six taxa, for which the vocal repertoire remains unknown, were placed in a particular group on the basis of geographical distribution, coat colour, cranial features, and the opinions of others. The resultant seven groups are:

(*temminckii*, *badius*, *waldroneae*) (*preussi*) (*pennantii*) (*bouvieri* ?status) (*epieni*, *tholloni*, *foai*, *langi*, *lulindicus*, *oustaleti*, *elliotti* = *semlikiensis*?, *parmentieri*, *tephrosceles*, *rufomitratu*s) (*gordonorum*) (*kirkii*).

*Procolobus rufomitratu*s is very diverse, because of cranial features and considerable geographic isolation. The nominate form *P. r. rufomitratu*s has itself been treated as a distinct species, yet in vocalizations and colour pattern it is particularly similar to its nearest (but distant) neighbour to the west, *P. r. tephrosceles*. Populations of *P. r. sceles*, *P. r. elliotti* and *P. r. oustaleti* are in close proximity near the border of DR Congo and Uganda, and have suggestive similarities in colour pattern as well as in vocalizations. *Procolobus r. oustaleti* is particularly variable and may be divisible into further races.

The subspecies *P. r. langi*, *P. r. elliotti* (including *semlikiensis*), *P. r. lulindicus* and *P. r. foai* intergrade in a complex pattern (Colyn 1991), and not all are considered valid by some authors (Groves 2001, 2007b, Struhsaker 2010). These four subspecies, together with *P. r. parmentieri*, make up the informal *foai*-Subgroup, whose distribution is constrained by the Aruwimi–Ituri and Lomami Rivers, and Western Rift Valley.

Procolobus r. tholloni is treated as a species by Groves (2001, 2007b) and is unlike other red colobus in the extent of its bright orange colouration. According to Colyn (1991) and Struhsaker (2010), however, *tholloni* is related to the *foai*-Subgroup within the *P. r. (rufomitratu*s) Group.

Procolobus gordonorum is akin to *P. kirkii* in vocalizations (Struhsaker 2010) and some aspects of the pelage and cranium (Cardini & Elton 2009). Molecular data indicate that *P. gordonorum* and *P. kirkii* diverged ca. 0.6 mya (Ting 2008a, b).

Procolobus p. preussi is regarded as a separate species by some authors (Groves 1989, 2001, 2005c, 2007b, Kingdon 1997, Oates 2011) as it is distinctive and separated from the nearest population of *P. pennantii* (i.e. *P. p. pennantii* on S Bioko I.) by ca. 250 km (Oates *et al.* 2004), which includes the ca. 32 km stretch of water (Atlantic Ocean) that separates Bioko I. from Cameroon. The molecular data indicate that *pennantii* and *preussi* diverged ca. 0.3 mya (Ting 2008a, b). *Mammals of Africa* treats *preussi* as a full species (for details, see the *P. preussi* profile). Thus, the number of species of red colobus tentatively recognized in this volume is six.

After the profiles in this volume were prepared for publication, Ting's (2008b) dissertation on *Procolobus* molecular systematics became available. Here are some of the more important findings put forth in this dissertation:

1. The close relationship between *badius* and *temminckii* is further supported by a divergent time estimated to be 0.3 mya.

Tentative phylogenetic tree for extant red colobus *Procolobus* (after Ting 2008a, b).

Red colobus adult male skulls showing short muzzle (Oustalet's Red Colobus *Procolobus rufomitratu oustaleti*) (above) and long muzzle (Tshuapa Red Colobus *Procolobus rufomitratu tholloni*) (below).

2. The form *epieni* (Niger Delta) appears to be much more closely related to the red colobus of central and East Africa (e.g. *rufomitratus*, *kirkii* and *gordonorum*) than to those of West and west-central Africa (e.g. *pennantii* and *preussi*). This supports the relationships as discerned from the data on vocalizations (Struhsaker 2010). Unlike earlier taxonomies, however, Ting (2008b) treats *epieni* as a full species. This is based on the considerable (i.e. species-level) mitochondrial divergence that he observed for *epieni*.
3. The form *waldronae* may represent a relatively ancient and distinct mitochondrial lineage, perhaps with a divergent time of 3 mya. If so, this supports the taxonomies of Dandelot (1974) and Groves

(2007b), which, based on pelage and morphology, give *waldronae* full species status.

4. The available molecular data do not support the designation of either *preussi* or *gordonorum* as presented in this volume.

See Struhsaker (2010) for additional information on the taxonomy, demography, behaviour, ecology and conservation of *Procolobus* spp., particularly *P. t. tephrosceles*.

Peter Grubb, Thomas T. Struhsaker & Kirstin S. Siex

Procolobus badius WESTERN RED COLOBUS (BAY COLOBUS)

Fr. Colobe bai d'Afrique occidentale; Ger. Westafrikanischer Stummelaffe

Procolobus badius (Kerr, 1792). Animal Kingdom, p. 74. Sierra Leone (probably Sherbro I.).

Bay Colobus *Procolobus badius badius* adult male.

Taxonomy Polytypic species. *Procolobus badius* formerly comprising most or all red colobus (Schwarz 1928a, Napier & Napier 1967, Wolfheim 1983, Napier 1985). Here restricted to three West African subspecies: *P. b. temminckii*, *P. b. badius* and *P. b. waldronae* (Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 1998, 2003). Note that 'waldroni' is 'corrected' to 'waldronae'. Relatedness of *temminckii*, *badius* and *waldronae*, supported by studies of Struhsaker (1981b, 2010), Ting (2008a,b) and Cardini & Elton (2009). Dandelot (1974), Groves (2007b) and Oates (2011) consider *waldronae* to be a full species. Rahm (1970) regarded *P. preussi* as a subspecies of *P. badius* but Groves (1989) pointed out that *preussi* is distinct and, subsequently, treated this taxon as a species (Groves 1993, 2001, 2005c, 2007b), as have Kingdon (1997), Cardini & Elton (2009), Struhsaker (2010), Oates (2011) and the present volume. Synonyms: *ferruginea*, *ferruginosus*, *fuliginosus*, *rufo-fuliginosus*, *rufoniger*, *temminckii*, *waldronae*. Chromosome number: $2n = 44$ (Romagno 2001).

Description Medium-size, arboreal monkey with crown and back the same colour, no whorl of hair behind ears, cheeks the same colour as lower limbs, and tail not red. Sexes alike in colour. Only slight sexual dimorphism; mean weight of adult ♀♀ about 92% that of adult ♂♂. Canines of adult ♂ only moderately larger than

those of adult ♀. Face relatively flat, dark bluish-grey to black with pink margins around mouth, eyes and nostrils (although contrast less prominent in some older animals). Area surrounding nostrils appears raised or swollen (although individuals vary in the degree to which nasal margins are raised, particularly in *C. b. waldronae*). Crown glossy black or ashy-grey, with red, if any, confined to small areas above and behind ear or behind brow. Cheeks, sides of neck, lower limbs, inner limbs, flanks, hands and feet orange-ochre to deep mahogany-red. Ventrums orange-ochre, mahogany-red, or whitish, depending on the subspecies. Dorsum, upper arms and upper legs glossy black or ashy-grey. Tail red, reddish-brown, or black. Unlike other *Procolobus* (*Piliocolobus*) species, there is little or no white in the pelage and 'crown whorls' are absent. Infant dorsum grey; tail with reddish tint; ventrum whitish (Groves 2007b).

Geographic Variation

P. b. badius Bay Colobus or Upper Guinea Red Colobus. S Guinea, Sierra Leone and Liberia to W Côte d'Ivoire. Nostrils raised on a swelling of nasal septum. Cheeks, flanks, lower limbs, ventrum, hands and feet mahogany-red. Dorsum and upper limbs glossy black. Tail dark brown over basal half, black distally, or all black. Perineal region and inside of thighs with patch of white hairs. Adult ♀ has large sexual swelling.

P. b. temminckii Temminck's Red Colobus. SW Senegal, Gambia, Guinea-Bissau and Guinea. Much the same pattern as *P. b. badius* but considerably paler or 'washed-out'. Face dusky, grey to grey-black with pinkish circum-orbital patches and muzzle patches from the lower lip to the top of the nostrils (Starin 1991). Cheeks, sides of neck, lower limbs, hands, feet, sides of belly orange-ochre (north-west extreme of range) to russet-brown or red (south part of range). Brow and nape with patches of orange-ochre. Dorsum, upper limbs and thighs slaty to ashy-grey (north-west extreme of range) to charcoal or black (south part of range). Tail rusty or orange-brown. Fingers and toes rufous. Midline of underlimbs and ventrum light orange-red to grey to whitish. Perineal region and insides of thighs with patch of white hairs. Geographically variable; in particular, animals in the relatively dry, open, Fathala Forest, Delta N. P., SW Senegal, at the north-west extreme of the

range are much paler than those from all (wetter) sites farther south (Galat-Luong & Galat 2005, A. Galat-Luong & G. Galat pers. comm.).

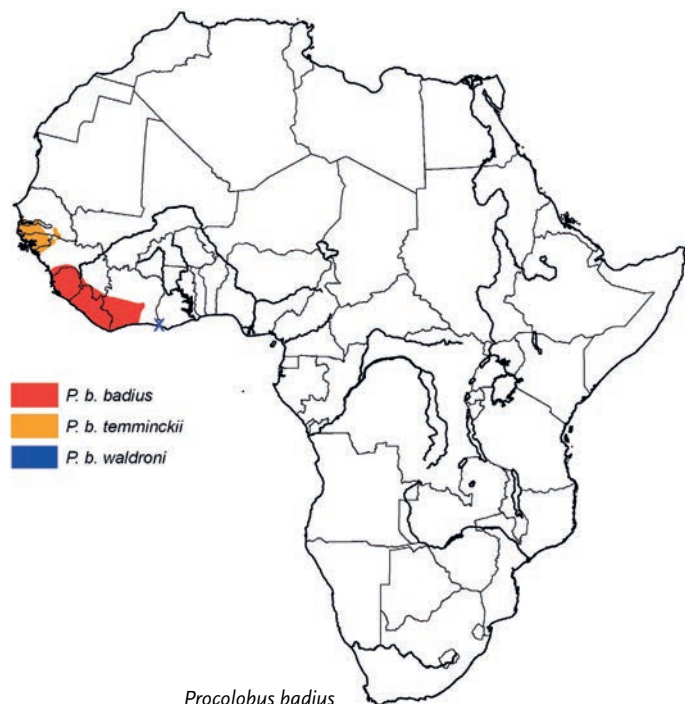

P. b. waldronae Miss Waldron's Red Colobus. SC Côte d'Ivoire to SW Ghana. Similar to *P. b. badius* but (1) nose flatter, without raised fleshy base, (2) tail all black, (3) forehead and outer thighs mahogany-red, (4) ears with reddish tuft above, (5) brow with reddish patch behind, and (6) scrotum white.

Similar Species None within geographic range.

Distribution Endemic to West Africa. Rainforest BZ, including the 'Northern Rainforest-Savanna Mosaic'. From SW Senegal and Gambia southeastwards to SW Ghana (Booth 1956b, 1958b, Rahm 1970, Wolfheim 1983, Lee *et al.* 1988, Groves 2007b). Distribution maps for *P. badius* in Ghana, Sierra Leone and Gambia presented in Grubb *et al.* (1998). Distribution map for *P. badius temminckii* over the northern part of the range (Senegal and Gambia) presented in Galat *et al.* (2009). Known northern limit (SW Senegal) for *P. b. temminckii* is 13° 50' N. Known western limit (SW Senegal) for *P. b. temminckii* is 16° 30' W. Known eastern limit (SC Senegal) for *P. b. temminckii* is 13° 15' W (Gatinot 1974, 1976). In fringing or gallery forests in Gambia, Senegal and Guinea-Bissau.

P. b. badius: Sierra Leone, adjacent parts of SE Guinea and Liberia to Nzi-Bandama R. System, W Côte d'Ivoire. Known limits are from 09° 00' N, 12° 35' W (Rokupr, Sierra Leone) to the Bandama R. (Groves 2007b).

P. b. temminckii: S Senegal, Gambia, E and S Guinea-Bissau, NW Guinea and NW Sierra Leone (Galat *et al.* 2009). In SC Guinea Bissau, present east of the Rio Grande (Rio Corubal) at Catio (Monard 1938), and close to the border with Guinea in the Cantanhez Forest and Cacine Basin (Gippoliti & Dell'Omo 1996).

Mapped from the Fouta Djallon in Guinea (Booth 1958b), from which no other published records are available. Reported from NW Sierra Leone (Harding 1984a) but otherwise geographically isolated from *P. b. badius*.

P. b. waldronae: from Nzi-Bandama R. System SC Côte d'Ivoire eastwards to SW Ghana. Separated from *P. b. badius* by the Nzi-Bandama R. System. Now perhaps extinct (see below).

Habitat *Procolobus b. badius* and *P. b. waldronae* prefer undisturbed, dense, primary, moist lowland forest with tall, emergent trees (Booth 1956b, 1958b, Struhsaker 1975, Wolfheim 1983, Grubb *et al.* 1998, Galat-Luong & Galat 2005). *Procolobus b. temminckii* is unusual among red colobus (with the exception of the Tana River Red Colobus *Procolobus rufomitratus rufomitratus* of Kenya) in that it inhabits relatively dry, 'fringe', deciduous forest and savanna woodland and gallery forest, although also present in moist, dense, lowland forest, mangrove forest (swamp) and perennial gardens (Booth 1958b, Struhsaker 1975, Gatinot 1976, Dupuy & Verschuren 1977, Gunderson 1977, Starin 1981, 1991, Harding 1984a, b, Galat-Luong & Galat 2005, Galat *et al.* 2009, McGraw & Sciulli 2011). At Saloum Delta N. P., SW Senegal (13° 41' N, 16° 30' W, 76 km², 6–16 m asl), on the north-western extreme of the geographic range of *P. b. temminckii* (and of the range for the genus *Procolobus*), groups were encountered 60% of the time in closed habitat and 39% of the time in open habitat (n = 213, Galat-Luong & Galat 2005).

Mean temperature in Fathala Forest is 26.5 °C and mean annual rainfall was 1050 mm during 1950–70 (Gatinot 1976, 1977), 904 mm during 1963–73, and 738 mm during 1987–97 (Galat-Luong & Galat 2005, Galat *et al.* 2009). The wet season is from Jun–Oct. *Procolobus b. temminckii* is present in Abuko Nature Reserve (107 ha, 5–16 m asl, 13° 24' N, 16° 00' W), W Gambia, where the mean daily minimum temperature is ca. 20 °C, mean daily maximum temperature is ca. 30 °C. During the course of one year, the lowest temperature recorded was 11 °C (Jan), and the highest was 41 °C (Mar). Mean annual rainfall was 1181 mm (range 582–1854) from 1946–79, but has declined by >300 mm per year since 1979 (Galat *et al.* 2009). The single wet season is from mid-Jun to mid-Oct, with Aug being the wettest month (Gunderson 1977, Starin 1994, 1999). Mean relative humidity ranges from 51% (Feb) to 87% (Aug) (Gunderson 1977). *Procolobus b. temminckii* also in the Kilimi area (240 km², ca. 200 m asl, 09° 43' N, 12° 32' W), NW Sierra Leone. Here, mean daily temperature is between 21 °C and 27 °C, and temperatures range from 18 to 38 °C. Mean annual rainfall is ca. 2160 mm (Harding 1984a, b). Most populations of *P. b. temminckii* are found <50 m asl (A. Galat-Luong & G. Galat pers. comm.). The highest reported altitude is ca. 200 m asl (Kilimi area, Harding 1984).

Procolobus b. badius occurs in Tai Forest, SW Côte d'Ivoire (4540 km², 125–370 m asl), where mean annual rainfall is ca. 1990 mm, and mean monthly minimum and maximum temperatures are ca. 20 °C and 30 °C, respectively. The wet season here is from Mar through Oct (Galat & Galat-Luong 1985). At Mt Nimba, Guinea, *P. b. badius* known to occur from near sea level to ca. 900 m (Galat-Luong & Galat 1990). During the dry season, mean temperature at high altitude varies between 15 °C and 20 °C, and to below 10 °C during the wet season. Mean annual rainfall is ca. 2500 mm (A. Galat-Luong & G. Galat pers. comm.).

Abundance Density of *P. b. temminckii* 45–480 ind/km² in W Senegal (Gatinot 1975). Gunderson (1977) found 310–880 ind/km² in Abuko Nature Reserve, while a later study by Starin (1991, 1994) found 124 ind/km². Density in Pirang Forest Park (64 ha), W Gambia, was 81 ind/km² (Galat-Luong 1988). Density of *P. b. badius* is 180 ind/km² in Taï N. P., Côte d'Ivoire, and 49–70 ind/km² at Tiwai I., Sierra Leone (Oates *et al.* 1990). Galat & Galat-Luong (1985) recorded a density of 37 ind/km² in Taï Forest. See also Zuberbühler & Jenny (2007) and N'Goran *et al.* (2012). Of the seven species of monkeys in Taï, *P. b. badius* is the most common, comprising about 33% of the monkey population. These densities are not typical of most parts of the range as *P. badius* is intensively hunted in many areas. *Procolobus b. waldronae* has been effectively exterminated by habitat loss and hunting (see Conservation section).

Adaptations Diurnal and arboreal. In Abuko Nature Reserve, during the dry season, there are activity/foraging peaks from 8:00–10:00h and from 16:00–18:00h. The activity peaks were much less prominent during the wet season (Gunderson 1977).

During a 30-year study of *P. b. temminckii* in Fathala Forest, Galat-Luong & Galat (2005) identified five changes in behaviour that enhanced the survivorship of the ca. 560 individuals in that population. In spite of a >50% reduction in the area of forest and a >30% decline in woody species diversity, the size of this populations dropped by only 12% between 1974–76 and 2002. They attributed this survival to five major adaptive shifts, namely: (1) increased frugivory; (2) greater terrestriality; (3) a higher tendency to form polyspecific associations with Green Monkeys *Chlorocebus sebaeus*; (4) increased use of more open habitat; and (5) adoption of mangrove forest as both a refuge and source of food.

'Gloger's Rule' states that colour tones darken with increasingly humid environments. Both *P. b. badius* and *P. b. waldronae* live in relatively tall, dense, dark primary moist forest. The colouring of *P. b. badius* and *P. b. waldronae* represents an extreme among red colobus, being made up of intensely black upperparts and strongly contrasting mahogany-red cheeks, lower limbs and ventrum. The geometry of these contrasts and the intensity of fully saturated black and red pigmentation suggest intra-specific selection for strong visual emphasis of gestures and of positioning of the limbs. The evolution, in many taxa of animals, of bright species-specific colouring is correlated with ritualized positional behaviours and displays. It appears that intra-specific selection for unambiguous postures and gestures (in the relatively dense and dark primary moist forest) has been stronger in *P. b. badius* and *P. b. waldronae* than has selection for crypsis against predators. This cannot be said for *P. b. temminckii*. This subspecies has a pale grey and ochre tinted pelage and occupies much drier, more open, lower canopy forests on the north-western margins of the species' range. Here, far better visibility and selective pressures imposed by visual predators (e.g. African Crowned Eagle *Stephanoaetus coronatus* and Leopard *Panthera pardus*) are likely explanations for the 'faded' tints that show much less colour or tonal contrast.

Foraging and Food Folivorous. *Procolobus b. temminckii* spends ca. 21% of time feeding, although this varies on a monthly basis (range 13.8–34.7%) (Starin 1991). Fruits and seeds comprise the

majority of the diet for *P. b. temminckii* (35.9% in Fathala Forest and 41.6% in Abuko Nature Reserve), followed by young leaves (24.0% and 26.2%, respectively), leaf buds (17.5% and 8.7%, respectively), mature leaves (5.4% and 11.7%, respectively) and floral parts (8.7% and 8.6%, respectively) (n = 1488; Gatinot 1977). In a second study in Fathala Forest, the diet comprised 56.7% young leaves, 18.8% fruits, 13.4% leaf buds, 6.3% mature leaves, 0.8% flowers and 4.0% other items (n = 1875; Diouck 1999). Fruit dominates the diet during the rainy season, young leaves and leaf buds during the dry season in Abuko Nature Reserve (Starin 1991). All three of these studies found that *P. b. temminckii* eats far more fruit and seed than reported for other forms of *Procolobus*. In contrast, one study in Taï Forest, found that leaves comprised the bulk of the diet of *P. b. badius* (83.5%), followed by fruit (10.4%) (n = 230 observations; Galat & Galat-Luong 1985). A second study, however, found that fruit comprised ca. 30% of the diet (Korstjens *et al.* 2007).

In Abuko Nature Reserve, items from 105 plant species are consumed (Starin 1991), but only 39 plant species were reported consumed in Fathala Forest (Gatinot 1977). In Fathala Forest, the top ten, top five and top one food species account for 89.9%, 77.5% and 43.6% of the annual diet, respectively (Gatinot 1977, n = 1 group). Here the most frequently eaten species was *Erythrophleum guineense*, followed by *Pterocarpus erinaceus*, *Ficus glumosa* and *Detarium senegalense*. A second study in Fathala Forest found that leaves are most often eaten from *E. guineense*, *Terminalia macroptera*, *Dichrostachys glomerata*, *P. erinaceus* and *Celtis integrifolia* (Galat-Luong & Galat 2005). In Abuko Nature Reserve, the diet is more diverse, with the top ten, top five and top one food species accounting for 61.2%, 44.1% and 12.6%, respectively (n = 1 group). The most common food species in Abuko Nature Reserve include *Parinari excelsa*, *Ficus trichopoda*, *D. senegalense*, *Parkia biglobosa* and *Pseudospondias microcarpa*. Feeding on soil from termite mounds occurs at Abuko Nature Reserve (Starin 1991).

In Fathala Forest, Gatinot (1975) found *P. b. temminckii* at a mean height of 9.4 m, while Diouck (1999) found the mean height to be 5.1 m during the wet season and 5.8 m during the dry season (n = 7077 records). In Abuko Nature Reserve, 61% of observations (n = 99) in canopy. In Pirang Forest Park, 80% of observations (n = 298) in canopy. In Taï N. P., 92% of observations (n = 1903) in canopy (Galat-Luong 1988). See also McGraw (1998, 2007).

Procolobus b. temminckii in Fathala Forest, Pirang Forest Park and Abuko Nature Reserve live in a much more open habitat (i.e. dry forest, gallery forest and woodland). The amount of time spent on the ground varied from 1 to 4% for Fathala Forest (Diouck 1999), 2.4% for Pirang Forest Park (n = 298) and 15% for Abuko Nature Reserve (n = 99; Galat-Luong 1988, Galat-Luong & Galat 2005). At Fathala Forest, groups sometimes move >2 km across open ground to temporarily occupy small patches of isolated forest (Galat-Luong 1988).

Size of group home-ranges for *P. b. temminckii* was 9.0–19.7 ha (n = 7) in Fathala Forest (Gatinot 1975, Diouck *et al.* 1996, Galat-Luong & Galat 2005) and 4.3–12.8 ha in Abuko Nature Reserve (n = 3; Gunderson 1977). A later, long-term (5.5 years) study in Abuko Nature Reserve found group home-ranges of 11–34 ha (mean = 22 ha, n = 3). The main study group had a home-range of 34 ha, of which >60% was shared with two other groups. A second

group, with a home-range of 11 ha, shared >62% of its home-range with other groups (Starin 1991, 1994). Home-range size for one group of *P. b. badius* in Tai Forest was 100 ha (Galat & Galat-Luong 1985). See also Korstjens *et al.* (2007).

Social and Reproductive Behaviour Social. Live in multimale-multifemale groups. Mean size of *P. b. badius* groups in Tai Forest was 36.8 (8–70, $n=17$); Galat & Galat-Luong 1985), but groups of >90 animals occur (Korstjens *et al.* 2007). Groups of 20–>60 present in Gola F. R., Sierra Leone (Davies 1987). Groups of >100 in Sierra Leone up to the 1950s (Grubb *et al.* 1998). Mean size of *P. b. temminckii* groups in Fathala Forest was 29 (14–62, $n=22$) in 1973 (Gatinot 1975), 18 (9–38, $n=14$) in 1990–94 and 16 in 1996–2002 (Galat-Luong & Galat 2005). In Abuko Nature Reserve, mean group size was 34 (24–40, $n=3$) in one study (Gunderson 1977). A later study found mean group size at Abuko Nature Reserve to be 23 (14–32, $n=5$; Starin 1991, 1994). Mean size of three groups in the Pirang Forest Park was 18 (17–20). All eight groups observed in Cantanhez Forest comprised >25 individuals (Gippoliti & Dell’Omo 1996). Mean size of five groups in Kilimi area was 7.5, with the largest group comprising 20 individuals (Harding 1984a, b). Solitary individuals reported in Abuko Nature Reserve, Fathala Forest, Cantanhez Forest and Kilimi area (Harding 1984, Starin 1994, Gippoliti & Dell’Omo 1996, Galat-Luong & Galat 2005).

In Abuko Nature Reserve, groups of *P. b. temminckii* contain 1–5 adult ♂♂ and 9–14 adult ♀♀ plus young (Starin 1991, 1994). Group adult sex ratio varies from 2.0 to 7.0 ♀ : ♂ ($n=16$; Gatinot 1977, Starin 1991). No apparent bias in infant sex ratio ($n=28$ infants; Starin 1991). In Tai Forest, one group of 32 *P. b. badius* had three adult ♂♂ and 13 adult ♀♀, while a group of 37 had about nine adult ♂♂ and ten adult ♀♀. Mean number of adult ♀♀ per adult ♂ was 3.3 ($n=6$ groups). Mean number of immatures per adult was 0.7 ($n=10$; Galat-Luong & Galat 2005).

Procolobus b. temminckii spend ca. 52% of the time resting, 21% feeding, 13% moving, 7% playing and 6% grooming ($n=1$ group; Starin 1991). Time spent in resting and feeding varies more among individuals than among age-sex classes. Adult ♀♀ are the predominant groomers and adult ♂♂ are the main recipients of grooming. Play is conducted mainly by infants and juveniles, mostly in the trees (only ca. 1% of play occurs on the ground). Infant ♂♂ play more than do infant ♀♀; conversely juvenile, subadult and adult ♀♀ play more than do ♂♂ of the same age categories (Starin 1991). See McGraw (1996, 2007a) and McGraw & Sciulli (2011) for activity budget and positional behaviour of *P. b. badius* in Tai Forest.

Procolobus b. temminckii subadult ♂♂ and (surprisingly) subadult ♀♀ both move between groups. During one long-term (5.5 years) study at Abuko Nature Reserve, 12 subadult ♀♀ permanently emigrated from their natal group, ten subadult ♀♀ permanently immigrated, and six subadult ♀♀ temporarily moved into or out of the focal group (Starin 1991, 1994). Movement of ♀♀ appears to be voluntary and not the result of overt competition and aggression. Their transfer is immediate and with little aggression. Of the 11 subadult ♀♀ who left the focal group, eight travelled in the immediate company of age mates; not spending time as solitary or extra-group ♀♀. Ten of these 11 ♀♀ eventually ended up in a

group with at least one fellow natal group mate. In contrast, six of seven subadult ♂♂ in the focal group were aggressively forced out of the group. All six spent time as ‘adolescent exiles’ and four, perhaps five, returned to their natal group once a resident adult ♂ died or disappeared. Males prefer to rejoin their natal group, probably because joining a ‘strange’ group can be fatal. Two ♂♂ were killed, and another two ♂♂ were probably killed, while attempting to join an alien group. Both of the attacks that led to killings were initiated and maintained by the resident adult ♀♀, and the killings were, in each case, conducted by a single adult ♂ and multiple adult ♀♀. In addition, six solitary ‘alien’ ♂♂ were chased from the focal group. In all instances the initial aggressive response was by immature ♀♀ and immature ♂♂ screaming, or by adult ♀♀ screaming and/or chasing the alien ♂. Exiled ♂♂ lived alone, with an older ♂, with a ♀, or with a natal group ♂ for >1–26 months before joining a group ($n=7$).

The great majority of copulations with fully swollen ♀♀ are performed by one ♂. These ‘chief copulators’, however, usually change from breeding season to breeding season (Starin 1994).

Group composition varies over the short term with the formation, by adult ♀♀, of subunits, indicating a fission-fusion sociality (Gunderson 1977, Starin 1991, 1994, Diouck *et al.* 1996, Galat-Luong & Galat 2005). Territorial behaviour not observed although aggressive encounters between groups occur. Adult ♂♂ and adult ♀♀ both participate in these aggressive inter-group encounters (Starin 1991, 1994, Galat-Luong & Galat 2005). For further detail on social and reproductive behaviour see Gatinot (1977), Starin (1991, 1994, 2001) and Galat-Luong & Galat (2005).

From 1990–2002, Galat-Luong & Galat (2005) found *P. b. temminckii* groups in Fathala Forest to be in polyspecific associations during 35.7% of 171 encounters; 10.5% of these associations were with Patas Monkeys *Erythrocebus patas* and 89.5% were with *C. sabaeus*. All three species were in association on one occasion. Pourrut *et al.* (1996), during 114 encounters with groups of *P. b. temminckii* in Fathala Forest, found *P. b. temminckii* + *C. sabaeus* 39% of the time, and *P. b. temminckii* + *C. sabaeus* + *E. patas* 6% of the time. No observations were made of *P. b. temminckii* + *C. patas* only. Diouck (1999) encountered 64 polyspecific associations at Fathala Forest. Of these, 95% were of *P. b. temminckii* + *C. sabaeus*, 3% were of *P. b. temminckii* + *E. patas* and 2% were of all three species. In Kilimi area, *P. b. temminckii* were consistently associated with King Colobus *Colobus polykomos* (Harding 1984a). In Tai Forest, *P. b. badius* groups in polyspecific associations during 87% of 67 encounters; most frequently with Diana Monkey *Cercopithecus (d.) diana* (55% of encounters), followed by Lesser Spot-nosed Monkey *Cercopithecus (c.) petaurista* (43%) and Campbell’s Monkey *Cercopithecus (m.) campbelli* (31%) (Galat & Galat-Luong 1985). See also McGraw *et al.* (2007).

Procolobus badius has a distinctive vocal repertoire (Struhsaker 1975, 1981b, 2010). *Procolobus b. temminckii* give the following calls: ‘chirp’, ‘nyow (bark)’, ‘yelp’, ‘squeal (scream)’, ‘sneeze (cough)’, ‘sqwack’, ‘rraugh’, ‘whine’, ‘quaver’, ‘wa-ah!’, ‘wa!’, ‘woo’, ‘ack’, ‘eh!’ and ‘copulation quavers’, most of which are shared with *P. b. badius*. The vocal repertoires of *P. b. temminckii* and *P. b. badius* do, however, differ somewhat. For example, the ‘wa-ah’ and ‘whine’ of *P. b. temminckii* are not known to be given by *P. b. badius* (Struhsaker 1975, 2010, Starin 1991, Galat-Luong & Galat 2005). The ‘chist’ and ‘wheet’ are notably absent from the vocal repertoire of *P. badius*. See

Temminck's Red Colobus *Procolobus badius temminckii* adult female (left) and Bay Colobus *Procolobus badius badius* adult male (right).

Struhsaker (1975, 1981b, 2010) and Starin (1991) for information on the circumstances and functions of some of these vocalizations.

Reproduction and Population Structure Male *P. b. temminckii* in Abuko Nature Reserve begin reproducing at ca. 28 months (range 26–30, $n = 4$). Females begin reproducing at ca. 34 months (range 30.8–38.8, $n = 4$), with the first infant born at ca. 50 months (range 24–60, $n = 4$). Mean inter-birth interval is 29.4 months (range 27.8–32.0, $n = 4$). Adult ♀♀ exhibit large sexual (perineal) swellings during which mating and conception occur. Full swelling lasts 4–8 days (mean = 5.4 days, median = 5 days, $n = 23$). Mean length of gestation is about 173 days ($n = 2$). Pregnant ♀♀ do not appear to avoid strenuous exercise or stressful situations. Up until the time of birth they take part in intense inter-group chases, attacks, and fights with alien (intruder) ♂♂. Eight of nine infants at Abuko Nature Reserve were born during the night or early morning (19:00–07:00h), while only one was born during the daylight hours (sometime between 07:45 and 13:00h). Six of seven nulliparous ♀♀ left the group for a period of 1–9 days after giving birth. In contrast, none of the seven multiparous ♀♀ left the group just before or after giving birth. Neonates are licked clean and the placenta is probably eaten by the mother immediately after being expelled (Starin 1988, 1991).

The majority of conceptions in Abuko Nature Reserve take place during times of high precipitation and humidity, rising temperatures, increasing day length, and when diets are rich in fruit and flowers. Births are seasonal, occurring primarily during the dry season. There is considerable intra-group synchrony in the time of births. Infant mortality is high (ca. 21%) during the first five months of life ($n = 28$). After the first five months, mortality for ♂♂ was 0% up until their third or fourth year, and mortality for ♀♀ was 0% well into adulthood. These data agree with data collected elsewhere in Abuko Nature Reserve; of the 13 non-focal group deaths, the majority were young ♂♂. There is strong indirect evidence for infanticide (dead infants with canine puncture wounds). In one group, of six infants below the age of six months that died or disappeared, two (perhaps three) were the victims of infanticide. Live to at least 16 years in the wild (Starin 1991, 1994).

Male *P. b. temminckii* are multiple mounters. Although the majority of ♀♀ mate with many ♂♂, including ♂♂ from other groups, they prefer the dominant ♂ (who receives the most sexual advances and the least rejections). Masturbation uncommon but observed both among ♂♂ and ♀♀ at Abuko Nature Reserve (Starin 2004).

Predators, Parasites and Diseases Four percent of 215 Leopard scats in Tāi N. P. held *P. b. badius* (Hoppe-Dominik 1984). In another study, 10% of 215 scats held *P. b. badius* (Zuberbühler & Jenny 2007). Here, 80% of the prey of Robust Chimpanzees *Pan troglodytes* were *P. b. badius* (Boesch & Boesch-Achermann 2000; see also Bshary 2007). *P. troglodytes* kill ca. 3–4% of this population each year (Shultz *et al.* 2004). Predation by African Crowned Eagles on *P. b. badius* is well documented for Tāi N. P. (Shultz 2001, McGraw *et al.* 2006a, Shultz & Thomsett 2007). Shultz *et al.* (2004) estimate that 8% of the *P. b. badius* in Tāi N. P. are killed each year by the above-mentioned three predators. Humans are, however, the primary predator (Koné & Refisch 2007, McGraw *et al.* 2007; see Conservation section). In Abuko Nature Reserve, from 1978–1983, Nile Crocodile *Crocodylus niloticus* and Central African Rock Python *Python sebae* account for 40% of known deaths of *P. b. temminckii*; two young adult ♂♂ killed by *C. niloticus* and two adult ♀♀ killed by *Python sebae*. In addition, two adult ♀♀ appeared to have died of snakebite. *Python sebae* is thought to be the most important predator for *P. b. temminckii* at this site (Starin, 1989, 1991, 1992).

The following parasites were found in 57 *P. b. temminckii* faecal samples at Fathala Forest: strongyles (present in 38.1% of faecal samples), strongyloides (5.0%) and amoeba (1.4%). There was no evidence for ascaris or trichurus. *Procolobus b. temminckii* living in core gallery forests (where they do not need to move on the ground and where human presence is less frequent) had a much lower incidence of infection (i.e. at least one of the above-listed parasites was present in 4.3% of 24 faecal samples) than those living in more open habitats and where human presence is frequent (e.g. forest boundaries and near camps where at least one of the above-listed parasites was present in 37.5% of 33 faecal samples). Whitish individuals, and individuals with areas lacking hair, observed near the largest neighbouring village. This may be the result of severe parasitism or of inadequate intake of at least one nutrient (A. Galat-Luong & G. Galat pers. comm.).

In Abuko Nature Reserve, ulcers on the penis, scrotum and groin observed on all *P. b. temminckii* breeding ♂♂ (and on some subadult ♂♂), and external mouth ulcers seen on at least five juvenile ♀♀ (Starin 2004). Mouth ulcers also reported for *P. b. temminckii* in Fathala Forest (A. Galat-Luong & G. Galat pers. comm., E. Starin pers. comm.). Mouth ulcers on ♀♀ and genital ulcers on ♂♂ present at Bijilo Forest Park, Kiang West N. P. and River Gambia N. P., Gambia (E. Starin pers. comm.).

Conservation IUCN Category(2012): Endangered as *P. badius*, *P. b. badius* and *P. b. temminckii*. Critically Endangered as *P. b. waldroneae*. CITES (2012): Appendix II.

Numbers of all three subspecies have declined throughout the range in recent decades, but details on population size and extent of decline are lacking for most sites (Wolfheim 1983, Lee *et al.* 1988). Details on the distribution of *P. b. temminckii* at the north end of the range provided by Galat *et al.* (2009), along with the reasons for the decline of this species in this region. Surviving populations are widely scattered and isolated. *Procolobus b. badius* and *P. b. waldroneae* appear to be particularly sensitive to habitat degradation and fragmentation. Like all *Procolobus* spp., *P. badius* is extremely vulnerable to hunting (Davies 1987, Lee *et al.* 1988, Starin 1989, Grubb *et al.* 1998, Struhsaker 1999, 2005, 2010, Oates *et al.* 2000a, McGraw & Oates

2002, 2007, N'Goran *et al.* 2012). This is because *Procolobus* spp. are (1) large and, therefore, provide much meat for the cost of a shotgun shell, (2) conspicuous as they are brightly coloured, noisy and live in large groups, and (3) they are often slow to detect danger or to flee from dangers (Davies 1987).

Survival of the westernmost population of *P. b. temminckii* in the Fathala Forest and Abuko Nature Reserve illustrates that some populations have the capacity to adapt their behaviour to limited levels of habitat change (see Galat-Luong & Galat 2005, Galat *et al.* 2009, and Adaptations section).

The extinction, or near extinction, of *P. b. waldronae* illustrates how vulnerable all red colobus species are in countries that exert little or no control over bushmeat hunting and the destruction of forest (Oates *et al.* 1997, McGraw 1998d, 2005, McGraw *et al.* 1998b). The known range of *P. b. waldronae* in Ghana has been searched since 1993, but no living animals have been found. Although the search continues, the last material evidence for the existence of *P. b. waldronae* in Ghana was obtained in 1972 in the form of a skin (Struhsaker & Oates 1995, Oates *et al.* 1997, Oates 2006). In early 2002, another hunter's skin raised hopes that a population of *P. b. waldronae* might still survive in or near the Ehy (=Tanoé) Forest (300 km²), extreme SE Côte d'Ivoire (McGraw & Oates 2002, 2007). Subsequent surveys, however, failed to find any evidence that *P. b. waldronae* is not extinct (Koné 2004, Koné & Akpatou 2005, McGraw 2005, Koné *et al.* 2007a, b, Oates 2011, Gonedelé Bi *et al.* 2012). The Ehy Forest seems to be the only place where a small population of *P. b. waldronae* might survive, but this forest is being logged, cleared for oil palm plantations, and heavily hunted by Ivorian and Ghanaian hunters. An urgent survey of the Ehy Forest has been called for. If extinct, *P. b. waldronae* is 'the first recorded extinction of a widely recognized primate taxon in the twentieth century, and human hunting rather than habitat loss has almost certainly been the primary cause of the monkey's extinction' (Oates *et al.* 2000a, p. 1530).

At least seven species of threatened primates occur in the same forests as *P. badius*. These include White-thighed Colobus *Colobus vellerosus* (Vulnerable), Roloway Monkey *Cercopithecus (d.) roloway* (Critically Endangered), White-naped Mangabey *Cercocebus lunulatus* (Critically Endangered) and Robust Chimpanzee *Pan troglodytes* (Endangered) (Gonedelé Bi *et al.* 2012). All of these species would benefit from actions taken to ensure the survival of *P. badius*, especially the protection of habitat and the strict enforcement of hunting laws. Development and effective implementation of a 'Red Colobus Action Plan' should have a high conservation priority (Oates 1996a, Oates *et al.* 2000a, McGraw & Oates 2002, 2007).

Some of the most important sites for the survival of *P. badius* are:

P. b. temminckii: Niokolo Koba N. P. (8175 km²), Fathala Forest (76 km²) in Saloum Delta N. P., Forêt Classée de Patako (55.8 km²), Forêt Classée de Sangako (21.4 km²) and Basse Casamance N. P. (5.0 km²), Senegal; Kiang West N. P. (110 km²), Bama Kuno Forest Park (9.3 km²), River Gambia N. P. (= Baboon I.) (5.8 km²), Katilenge (= Kahlenge) Forest Park (3.2 km²), Abuko Nature Reserve (1.1 km²), Pirang Forest Park (0.6 km²) and Bijilo Forest Park (0.5 km²), Gambia; Basin of the Tombali, Cumbija and Cacine Rivers, including the Cantanhez Forest (650 km²), Guinea Bissau. Details on the distribution and conservation status of *P. b. temminckii* in Senegal and Gambia are given in Galat *et al.* (2009), along with the reasons for the decline of the populations of *P. b. temminckii* in this region.

P. b. badius: Taï N. P. (3400 km²) Côte d'Ivoire; Grebo National Forest (2603 km²), Sapo N. P. (1308 km²), North Lorma National Forest (712 km²), Liberia; Gola Forest (748 km²), Loma Mountains Non-hunting Forest Reserve (332 km²; now under consideration for national park status) and Tiwai I. (12 km²), Sierra Leone; Réserve Naturelle Intégrale des Monts Nimba (= Nimba UNESCO Man and Biosphere Reserve) (218 km²), Guinea.

P. b. waldronae: Tanoé Swamps Forest (= 'Ehy Forest and vicinity'; ca. 300 km²), Côte d'Ivoire. This is thought to be the only site in which this subspecies might still exist. The conservation of this site is of particular concern at this time as there are plans to cut this forest in order to establish an oil palm plantation. Important populations of *C. lunulatus* and *C. (d.) roloway* also here. See: <http://www.manifeste-fmt.org/>

Thomas M. Butynski, Peter Grubb & Jonathan Kingdon

Procolobus preussi PREUSS'S RED COLOBUS

Fr. Colobe bai de Preuss; Ger. Preuss-Stummelaffe

Procolobus preussi (Matschie, 1900). Sitzb. Ges. Naturf. Fr. Berlin, p. 183. Barombi, Elephant L., N Cameroon.

Preuss's Red Colobus *Procolobus preussi* adult female.

Taxonomy Monotypic species. Taxonomic history of *P. preussi* summarized by Grubb *et al.* (2003) and Ting (2008b). Cranium distinct (Groves 2001, Cardini & Elton 2009). Based on morphological and phenotypic characters, Schwarz (1928a), Allen (1939), Rahm (1970), Napier (1985) and Grubb (1990) treat *preussi* as a subspecies of *P. badius*. There are, however, some phenotypic characters (e.g. pale inner limbs and ventrum, agouti-speckled dorsum) that suggest affinity to Pennant's Red Colobus *Procolobus pennantii*. In addition, the geographic range of *preussi* is >1000 km from the nearest population of *P. badius* and the region in between holds several well-

recognized geographic barriers to primate distribution (e.g. major rivers). Moreover, the geographic range of *preussi* lies relatively close to, and between, the ranges of the Bioko Red Colobus *P. p. pennantii* and the Niger Delta Red Colobus *P. p. epieni*. As such, Grubb *et al.* (2003) provisionally include *preussi* as a subspecies of *P. pennantii*. This is referred to as the 'Western Assemblage of Red Colobus' or '*Procolobus pennantii*-Subgroup'. This close relationship is supported by molecular data, which place *P. preussi* closest to *P. p. pennantii* with a divergence time of 0.3 mya (Ting 2008a, b). A close relationship between *P. preussi* and *P. pennantii* is, however, not supported by the data on vocalizations. The vocal repertoire of *preussi* is distinct but with closest affinity with *P. badius* (Struhsaker 1981b). Vocal repertoire of *P. preussi* overlaps the vocal repertoires of *P. b. badius* and *P. b. temminckii* by 58%, and that of *P. p. pennantii* by only 32% (Struhsaker 2010). Dandelot (1974) viewed the differences among *preussi*, *badius* and *pennantii* as species-level differences and concluded that *preussi* is a full species. This was followed by Groves (1993, 2001, 2005c, 2007b), Kingdon (1997), Cardini & Elton (2009), Struhsaker (2010) and Oates (2011), and is the taxonomy used here. This very localized form might represent a stabilized hybrid that arose in the contact zone between more westerly and easterly parent populations. Chromosome number: not known.

Description Medium-sized arboreal monkey with orange-rufous cheeks, limbs and tail. As far as is known, colouration of adult ♂ like adult ♀. The few body measurement data available suggest that there is little, if any, sexual dimorphism, except that the adult ♂ appears to be slightly more robust than the adult ♀. Face quite flat, dark grey with pink margins around mouth and nose. Nostrils 'swollen' at base like *P. badius*. Fur dense, more frizzy than other red colobus species. Cheeks and sides of neck orange-rufous. Brow to ears and upper cheeks black. A whorl above brows, but no whorls above ears. Crown and temples with longish pelage that is swept back to cover ears. Crown, nape, shoulders, back, rump and base of tail blackish, blackish-grey, or greyish-brown with fawn or deep red bands or tips to hairs (i.e. agouti-speckled). Dorsum may become greyer posteriorly. Flanks and limbs orange-rufous or sandy, becoming dark brown-black on hands with tendency for digits to be black. Limbs white on inner surface. Ventrums pinkish-buff or pale red-gold, this colour going narrowly up throat to chin. Tail all rusty; sometimes sandy or reddish with brown-black, light grey, or blond over distal ca. 25%. Perineal organ of adult ♂ not

conspicuous. Adult ♀ has prominent clitoris and very large, pink, sexual swelling (Struhsaker 1975). Neonate black above, light grey below. Vocally distinct (Struhsaker 1981b).

Geographic Variation None, but individual variation exists in the intensity and extent of orange and red.

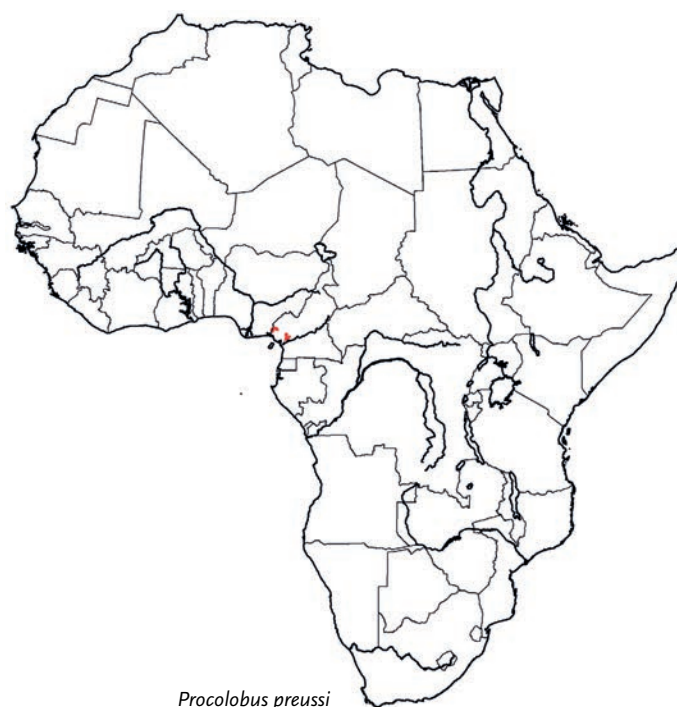

Similar Species Sympatric monkeys are unlikely to be confused with this colobine species.

Cercopithecus (c.) *erythrotis*. Sympatric. Reddish nose and ears. No red, rufous or orange on limbs.

Distribution Endemic to a small region between Cross R. in extreme SE Nigeria south-eastward to Sanaga R. in SW Cameroon (Eisentraut 1973, Napier 1985, Lee *et al.* 1988, Oates 1996a, Grubb *et al.* 2000, Dowsett-Lemaire & Dowsett 2001, Oates *et al.* 2004). Rainforest BZ. In 1988 and 1999 observed north-east of Ekonganaku (05°04'N, 08°39'E) in the Ikpan Block of the Oban Division (2800 km²) of Cross River N. P., Nigeria (Oates 1996a, Grubb & Powell 1999, Grubb *et al.* 2000). In 1977 thought to be confined in Cameroon to the region along the border with Nigeria; south of the Ikon-Mamfe Road (04°24' to 05°36'N, 08°48' to 09°20'E) in an area of ca. 7200 km² (S. Gartlan pers. comm. to Lee *et al.* 1988). Within this area, confirmed only for Korup N. P. (04°53' to 05°28'N, 08°42' to 09°16'E; 1260 km²) at this time but in 1977 present in Ejagham Council F. R. (749 km²) off the north boundary of Korup N. P. (S. Gartlan pers. comm. to Lee *et al.* 1988). *Procolobus preussi* last reported in this forest in 1996 (Usongo 1996). About 80 specimens collected in Yabassi District and Ndokfass District, S Cameroon, by P. C. M. Merfield in 1939 (Napier 1985). In 2001 observed in the Ndokbou Forest (>1000 km²) and Ebo Forest (1400 km²; 04°30'N, 10°30'E), Yabassi region, just to the north of the Sanaga R. South-east limit probably near Ebo (04°10'N, 10°16'E. Also near Toubassala, south-east of Mt Nlonako (Dowsett-Lemaire & Dowsett 2001, F. Dowsett-Lemaire pers. comm.). Reported to be in the Bakossi Mts and in Banyang Mbo during the 1990s (I. Faucher pers. comm. to F. Dowsett-Lemaire). This species probably widespread from the Cross R. to Ebo in the recent past. It is somewhat surprising that *P. preussi* does not occur on the foothills of Mt Cameroon, especially given the proximity of *C. pennantii* on Bioko I. to the west.

Habitat Coastal lowland forest and mid-altitude forest (Lee *et al.* 1988, Dowsett-Lemaire & Dowsett 2001, Oates *et al.* 2004). Appears to prefer primary forest and old secondary forest (Usongo & Amubode 2001, Linder 2008). Lowest known altitude is roughly 50 m (J. Linder pers. comm.). Maximum altitude reported for *P. preussi* is ca. 1000 m (Ebo Forest at southern end of range; F. Dowsett-Lemaire pers. comm.). Although Korup N. P. ranges from near sea level to 1079 m (Mt Yuhun), *P. preussi* not known to occur below 50 m or above 300 m (in north-east Korup N. P.; J. Linder pers. comm.).

Dominant plant family at Korup N. P. is Leguminosae (especially the subfamily Caesalpiniaceae). Other major families are Annonaceae, Euphorbiaceae, Rubiaceae, Scytopetalaceae, Myristicaceae, Olacaceae, Verbenaceae and Sterculiaceae (Gartlan *et al.* 1986, Linder 2008). One major refuge for *P. preussi* is Korup N. P. where 1700 plant species have been recorded. Nearly 500 tree

Procolobus preussi

species have been recorded for south Korup N. P. The structure of the tree community at some sites in Korup N. P. that are occupied by *P. preussi* is described in detail by Linder (2008). *Procolobus preussi* lives in one of the wettest areas of Africa; rainfall >500 mm during most months at some sites (Gartlan & Struhsaker 1972, Struhsaker 1975, Sarmiento & Oates 2000). Mean annual rainfall at south end of Korup N. P. is ca. 5460 mm and mean annual rainfall at north end of Korup N. P. is ca. 2700 mm, about one-third of which falls in Jul and Aug (Gartlan *et al.* 1986, Linder 2008). Over the historic range of *P. preussi* there is a short dry season during Dec–Feb. In this region humidity is usually above 90% and temperatures range from 15 to 33°C. In south Korup N. P., monthly temperature ranges from a mean minimum of 23.7°C to a mean maximum of 30.2°C (Gartlan *et al.* 1986). August is the coolest month and Feb is the hottest month.

Abundance Gartlan & Agland (1980) estimated that fewer than 8000 *P. preussi* survived in 1980. Oates (1996a) estimated that 10,000–15,000 were present in Korup N. P. in 1996. No estimates exist for the Yabassi region, but it is said to be 'widespread' (Dowsett-Lemaire & Dowsett 2001: 5). British museums hold at least 80 *P. preussi* specimens collected from the Yabassi region in 1939 alone. This strongly suggests that *P. preussi* was once common in this region (Napier 1985).

In 1970, T. Struhsaker (pers. comm. in Linder 2008) encountered 0.15 groups of *P. preussi*/h in south Korup N. P., making this one of the most frequently recorded species of primate in this region. In Korup N. P., in 2004–05, Linder (2008) encountered 0.04 groups/km during 352 km of census. In south Korup N. P., Dunn & Okon (2003) encountered 0.06 groups/km in 2001–03 during 420 km of census, while Linder (2008) encountered 0.05 groups/km during 243 km of census here in 2004–05. In north Korup N. P., Edwards (1992) encountered 0.07 groups/km in 1990 during 74 km of census. She estimated 0.52 groups/km² (quadrat method) and 0.56 groups/km² (line transect method), or 26–28 individuals/

km². In this same region, Linder (2008) encountered 0.05 groups/km during 74 km of census in 2004–05 and estimated 0.46 groups/km² and 23 individuals/km² (line transect method).

Adaptations Diurnal and arboreal. The colouring of *P. b. badius*, which has some resemblances with that of *P. preussi*, is discussed in the profile of that species and the point is made that strong colour contrasts can serve intra-specific communication. Red, especially, acts as a strong contrast with green vegetation (Sumner & Mollon 2003). It is interesting, therefore, that the most conspicuous feature of *P. preussi* is its bright orange-rufous tail. *Procolobus preussi* is not the only cercopithecoid monkey to evolve such a brightly coloured tail; members of the *Cercopithecus (cephus)* group, including the sympatric *C. erythrotis*, also have bright orange-rufous tails. In the latter there are behaviour patterns to suggest that tail postures and movements provide information about dominance ranking. Whether this is also the case for *P. preussi* is not known. Orange-rufous limbs presumably help enhance the visibility of limb postures and gestures.

Of 13 groups of *P. preussi* encountered during surveys in Korup N. P., 92% were in association with groups of at least one other species of monkey (Struhsaker 2000a). These large associations are believed to enhance predator detection and avoidance, and to provide foraging advantages (Gartlan & Struhsaker 1972, Struhsaker 2000a).

Foraging and Food Folivorous, dependent on emergent trees for food (S. Gartlan pers. comm. to Lee *et al.* 1988). Prefers the upper strata (Linder 2008). Seventeen species of plants belonging to nine families observed eaten by *P. preussi* in Korup N. P. (Usongo & Amubode 2001). Species and plant part most eaten were young leaves of *Lecomtedoxa klaineana* (27%) and *Xylopia aethiopica* (22%). Families Sapotaceae and Annonaceae constituted about 50% of total food items. Information on the nutritive values (e.g. crude protein, crude fibre, ether extract, nitrogen-free-extractable and total ash) of some of the food items is presented in Usongo & Amubode (2001).

Social and Reproductive Behaviour Social. Little-studied. Struhsaker (1975, 2000a) reports mean group size in Korup N. P. >47 (range >24–80). All of his 36 encounters with *P. preussi* in Korup N. P. were with groups (i.e. no solitary individuals were encountered). More recently (2001–03) Dunn & Okon (2003) observed groups of >100 individuals in south Korup N. P. and found a mean group size of 35 (range = 10–130, n = 23). Has the most complex vocal repertoire of all *Procolobus* spp., including several calls not found amongst other red colobus taxa. The calls given by *P. preussi* include the 'nyow', 'yowl' and 'copulation quaver' (Struhsaker 1975, 1981b, 2010).

Reproduction and Population Structure Few data. Females probably have largest sexual swelling of any species of *Procolobus*, reaching an estimated 25–33% of the female's body volume (Struhsaker 1975) and measuring at least 33 cm lengthwise and 45 cm in circumference (F. G. Merfield pers. comm. in Napier 1985). Sexual swelling of ♀ pink. Females give a quavering copulation call before, during and after mating (Struhsaker 1981b, Oates 1994).

Predators, Parasites and Diseases No information, but likely predators include Leopards *Panthera pardus*, African Golden Cats

Profelis aurata, Robust Chimpanzees *Pan troglodytes*, Central African Rock Pythons *Python sebae* and Nile Crocodiles *Crocodylus niloticus*. The African Crowned Eagle *Stephanoaetus coronatus* is probably the most significant natural predator of *Procolobus* spp. (Struhsaker 2000a, 2010), but any such predation has long been dwarfed by heavy hunting by humans.

Conservation IUCN Category (2012): Critically Endangered. CITES (2012): Appendix II.

Procolobus preussi still present in one protected area in Nigeria, the Oban Division of Cross River N. P., which is contiguous with Korup N. P. (J. Oates pers. comm.). The largest known population occurs in Korup N. P. A second population (of unknown distribution and size) is present in Ndokbou Forest and Ebo Forest but this population is not protected. The bushmeat trade, logging and habitat loss have reduced and extirpated populations over the past 40 years (Lee *et al.* 1988, Oates 1996a, Linder 2008, Linder & Oates 2011). Hunting of critical populations of *P. preussi* continues at a high level in Oban Division of Cross River N. P. (J. Oates pers. comm.), in Korup N. P. (Oates 1996a, Linder 2008) and in the Yabassi region (Dowsett-Lemaire & Dowsett 2001). *Procolobus preussi* is one of the most common monkeys for sale in the bushmeat markets in the vicinity of Korup N. P. (Linder 2008). As a result of hunting, *P. preussi* is now extirpated from many areas, including most, if not all of the Korup Support Zone, of which the Ejagham Council F. R. is a part (Waltert *et al.* 2002, Steiner *et al.* 2003). Although there remains considerable habitat for *P. preussi*, national and international conservation bodies have proved helpless to protect *P. preussi* from the pressures of the bushmeat trade (Bowen-Jones & Pendry 1999, Oates 1999, Linder 2008). The main recommendations for the long-term conservation of *P. preussi* are (1) to stop hunting at all sites and to successfully implement the current human resettlement projects for Korup N. P., (2) to conduct surveys to better determine the distribution and abundance of *P. preussi*, especially in Cross River N. P., Ejagham Council F. R. and Yabassi region, and (3) to up-grade the conservation status of Ebo Forest, Ndokbou Forest and Nlonako Forest and provide them with high levels of protection against hunters.

Measurements

Procolobus preussi

HB (♂ ♂): 560, 630 mm, n = 2

HB (♀): 620 mm, n = 1

***Procolobus pennantii* PENNANT'S RED COLOBUS (BIOKO RED COLOBUS)**

Fr. Colobe bai de Pennant; Ger. Pennant-Stummelaffe

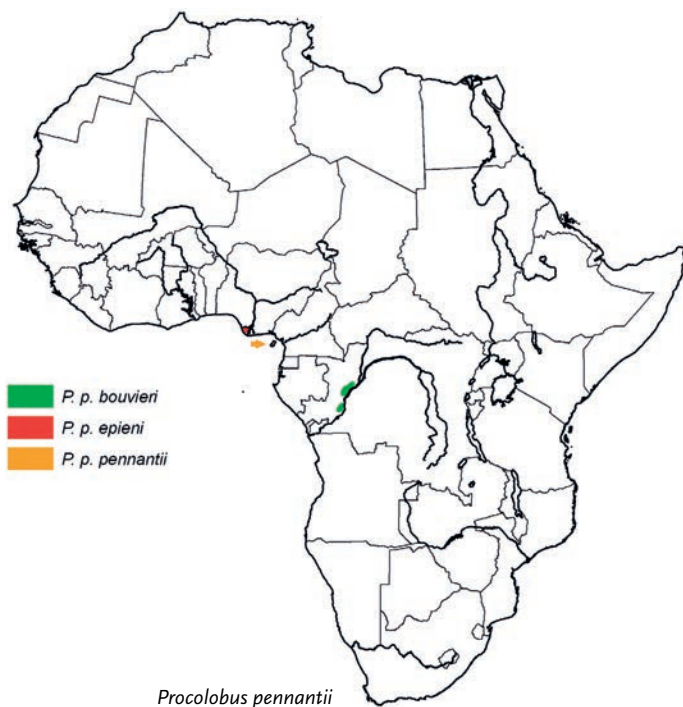

Colobus pennantii (Waterhouse, 1838). Proc. Zool. Soc. Lond. 1838: 57. Fernando Po (= Bioko I.), Equatorial Guinea.

Taxonomy Polytypic species, here taken to include three subspecies, *pennantii*, *bouvieri*, *epieni*. See taxonomic reviews in Grubb *et al.* (2003) and Ting (2008a, b). Dorst & Dandelot (1970) took *P. pennantii* to encompass all red colobus other than *badius* and *temminckii*. Groves (1993) followed a similar course but excepted *preussi* and *rufomitratus* (and restored *waldroneae* to *badius*). Dandelot (1974), Napier (1985) and Grubb (1990) restricted *P. pennantii* to include *bouvieri*. Kingdon (1997) and Groves (2001, 2005c) took *P. pennantii* to include both *bouvieri* and, provisionally, *epieni*. This is the taxonomy adopted here. Grubb *et al.* (2003) placed *preussi*, *bouvieri* and *epieni* in *P. pennantii*. Vocal repertoire (Struhsaker 2010) and molecular data (Ting 2008b) suggest that *epieni* is more closely related to the red colobus of East Africa than to *P. pennantii*. Groves (2007b) and Oates (2011) treat *pennantii*, *preussi*, *bouvieri* and *epieni* as full species. Polymorphic in *epieni* and *pennantii*, less certain in *bouvieri* – but likely (Colyn 1993). Synonyms: *bouvieri*, *epieni*, *likualae*. Chromosome number: not known.

Description Medium-size, arboreal, reddish and black monkey with white cheeks. A highly variable species. For *P. p. pennantii*, adult

♀ ♀ have, on average, slightly greater body linear measurements than adult ♂ ♂. Adult ♀ ♀ are, however, more gracile than adult ♂ ♂, as indicated by their body weight, which is about 94% that of the adult ♂ ♂. Canines of adult ♂ ♂ more than twice as long as for adult ♀ ♀ (see measurements below). Muzzle relatively short (Verheyen 1962). Facial skin black with contrasting pink eyelids, nostrils and lips (most visible in younger animals). Cheeks and throat whitish, dirty white, or pale grey. Crown black or deep brown. Back and tail variable in extent of black, red or brown, but sometimes entirely black. Flanks and limbs predominantly orange or reddish. Ventrums whitish, dirty white, or faint peach. Hands and feet black. Unusual for red colobus in that *P. p. epieni* exhibits traces of agouti freckling on the crown and back. One infant *P. p. pennantii* estimated to be <1 month of age had body and tail black (with some slight mixing of white hairs), except for whitish fringe around face and some white on shoulders and thighs. Face bare, black (no pink skin). Ears, inner limbs, top of hands and top of feet bare, pink. Ventrums thinly covered with whitish hairs (T. Butynski pers. obs.). *Procolobus p. pennantii* is the only taxa of *Procolobus* in which newborns have an entirely black face (T. Struhsaker pers. comm.).

Pennant's Red Colobus *Procolobus pennantii pennantii* adult male.

Geographic Variation Subspecies are very isolated geographically (Colyn 1991, Grubb & Powell 1999, Oates *et al.* 2004, Groves 2007b). Few specimens for each of the three subspecies. As such, the full range of variation within each subspecies is not known.

P. p. pennantii Bioko Red Colobus. Bioko I., Equatorial Guinea. Face with black skin (no pink skin). Pelage around eyes and over bridge of nose sooty. Cheek whiskers long, white, dirty white, or grey. Temples and ears blackish. Crown blackish; no whorls. Hairs of mantle black with orange bands. In the field, the human eye is drawn to the white cheeks and their strong contrast with the blackish temples, ears and crown. Shoulders, upper back, sides, outer limbs variable; orange-brown to blackish-brown. Lower back, hips, lower arms, lower legs and upper-side of tail blackish or blackish-brown, sometimes with infusion of orange. Whitish on outer side of arm restricted to a fringe extending from chest; rest of front and outside of arm orange-brown. Flanks and front of legs orange-brown. Throat, chest, belly, upper outer arms and inner arms and legs dirty white, pale-grey, to faint peach. Black of hands and feet extends somewhat up outside of limbs. Tail varies from all black to black over proximal 50–70%, and deep reddish-brown over the distal 50–30%, becoming increasingly reddish towards tip. Preliminary field observations (T. Butynski pers. obs.) suggest some sexual dimorphism in colour of pelage; most noticeably, adult ♂♂ have a faint peach ventrum, and extensive bright orange-brown (chestnut) on sides and dorsum, while adult ♀♀ have a dirty white ventrum, less extensive, paler orange-brown on sides, and dorsum blackish-brown.

P. p. bouvieri Bouvier's Red Colobus. Between lower Léfini R. and lower Sangha R., Congo, at ca. 00–1° S. Stiff, black superciliary band extends to ears. Crown deep brown or reddish without whorls. Ears with a small tuft behind. Mantle hairs blackish and unbanded. Blackish zone down neck, shoulders and back, becoming greyer and broadening on the rump and extending onto the tail. Rest of

upperparts, outer arms and outer legs russet. Inside of lower legs black. Tail mostly golden-brown.

P. p. epieni Niger Delta Red Colobus. West sector of Niger Delta. Facial skin black to pinkish-grey; some pink skin sometimes on muzzle. Eyelids pinkish (J. L. R. Werre pers. comm.). Crown black with conspicuous hair-whorls behind and over ears. Hairs of mantle black with orange bands. Whitish of underparts extends to outer side of arms, limiting orange-brown to the back of the outer arms. Front of forearms white. Black of hands and feet not extending up limbs. Dorsal pelage agouti-speckled in part (Grubb & Powell 1999, Werre 2000).

Similar Species No similar sympatric species, but two similar subspecies parapatric with *P. p. bouvieri*.

Procolobus rufomitratatus oustaleti. North and east of the Sangha R. Back dark smoky-brown to olive-brown to coppery red. Ventrums paler than dorsum (but not white or dirty-white).

Procolobus rufomitratatus tholloni. East and south of the Congo R. Circumfacial hair short, black, except on lower cheeks where whitish. Back orange-russet all over. Feet dark brown. Tail red for proximal ca. 70%, then brown with blackish tuft.

Distribution Endemic to west-central Africa. Rainforest BZ. Discontinuously small distributions in Bioko I., Nigeria and Congo (Oates *et al.* 2004). See details above under Geographic Variation.

Habitat Moist forest. *Procolobus p. pennantii* in primary lowland, mid-altitude and montane forest from sea level to at least 1500 m in montane forest on the southern one-third of Bioko I. (on Pico Biao). Hunters claim that this species is found to >1800 m in *Schefflera*-dominant forest on Pico Basile (Butynski & Koster 1994, T. Butynski pers. obs.). González-Kirchner (1997b: 99) states that 'The Pennant's Red Colobus was always observed under 2000 m above sea level' but he does not actually state the highest level at which he observed this species. He also states that *P. p. pennantii* prefer primary montane forest. *Procolobus p. pennantii* is largely absent from degraded or secondary forest, but this is likely due entirely to heavy hunting of this monkey in such habitats. *Procolobus p. bouvieri* on the margins of major rivers, but habitat-use poorly known. *Procolobus p. epieni* in mangrove swamps of Niger Delta (Werre & Powell 1997). Annual mean rainfall ranges from ca. 2000 to >10,000 mm.

Abundance In 1986, the highest density (0.6 groups/km) of *P. p. pennantii* occurred in the Gran Caldera de Luba, SW Bioko (T. Butynski pers. obs.). Other encounter rates are 0.18 groups/km in 2008 along 44 km of transect in the Gran Caldera de Luba, and 0.31 groups/km in 2009 along 48 km of transect and 0.34 groups/km in 2010 along 50 km of transect at Badja North, SW Bioko (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. obs.). The Gran Caldera de Luba and Badja North are remote sites where hunting is relatively uncommon and there are no other anthropogenic impacts. As such, the encounter rates at these two sites are likely close to what is expected for an undisturbed population of *P. p. pennantii*. This species has been extirpated from much of Bioko as a result of unsustainable hunting with shotguns (Hearn *et al.* 2006). Large

Niger Delta Red Colobus *Procolobus pennantii epieni* adult male.

groups of colobus, presumed to be *P. p. bouvieri*, have been seen on the right bank of the Congo R. in recent years (R. O'Hanlon pers. comm.). Museum specimens indicate that the range of *P. p. bouvieri* covers a linear distance of at least 200 km. Thus, even if *P. p. bouvieri* is primarily a riverine species, which is uncertain, it seems likely that there are still substantial numbers along the western bank of the Congo and its tributaries (e.g. Sangha R. and Léfini R.).

Adaptations Diurnal and arboreal. This species poses puzzling questions as to what adaptive or maladaptive features restrict the

distinctive subspecies to two or three widely separated geographic locations. Their situation contrasts strongly with their eastern neighbour, *P. r. oustaleti*, which is well distributed across a vast range. Likewise, their western neighbour, the Western Red Colobus *Procolobus badius*, was highly successful and until the twentieth century had a more or less continuous distribution from Senegal to Ghana. The present very restricted populations of *P. pennantii* imply that the species has suffered some biological inhibition that has prevented it from expanding out of its current enclaves. Understanding that adaptive shortcoming is highly relevant to

ensuring the future conservation of this red colobus monkey. Some measure of its relictual status is the distance of ca. 1200 km between the range of *P. p. epieni* in the Niger Delta and that of *P. p. bouvieri* on the right bank of the Congo R. There are no known populations of *Procolobus* over these 1200 km. The presence of *P. p. pennantii* on Bioko I. is puzzling since the population on the mainland opposite Bioko I. is that of Preuss's Red Colobus *Procolobus preussi* – which appears to have a different affinity, being morphologically closer to *P. badius*. Furthermore (assuming that *P. p. epieni* belongs in *pennantii*) *P. preussi* is interposed between it and *P. p. bouvieri*; how did it get there? (Possible explanations for this anomalous distribution are discussed in the profile of *P. preussi*.) Is *P. pennantii* an early form of red colobus that has been widely displaced by later, more adaptable species? Could competition from *Colobus satanas* have displaced *P. pennantii* throughout the intervening area? Perhaps, but the diets of these two species probably differ considerably, and the two species are sympatric on Bioko I. – so why not on the mainland? On Bioko I. González-Kirchner (1997b) found that these two species use the various levels of the forest strata to different extents. On present evidence, *P. pennantii* would appear to be a particularly poor disperser but the cause of its inability to 'regain lost ground' remains unknown. Kingdon (1997) noted the exceptional floristic and faunal richness of the Bight of Bénin, particularly the diversity of primates, and he listed competition with other primates, climate change, past hunting and species-specific disease pandemics as possible influences. Whatever the causes, they are not likely to have been recent.

While it is obvious that all red colobus species have a common ancestor, the timing of their dispersal across equatorial Africa, and the details of their speciation pattern, await a comprehensive molecular study. When molecular trees of the red colobus group are eventually constructed, it seems likely that *P. pennantii* will be seen to belong to an early, possibly conservative, lineage. While all living species of red colobus, under current conditions, appear to be slow dispersers, *P. pennantii* seems to be the poorest colonist of them all. This conclusion is reinforced by their survival close to the focal centre of primate evolution in Africa, presumably the area where they might be expected to have had the longest tenancy. This suggests that their occupation of Bioko I. was the result of an early colonization that took place before the species' decline on the mainland.

Foraging and Food Folivorous. No detailed studies have been made of *P. pennantii*. This species is unlikely, however, to differ from other red colobus species in the broader outlines of its diet. See the profiles for the other *Procolobus* spp. However, the three subspecies of *P. pennantii* live under quite different ecological regimes (especially rainfall), with likely implications for their diet and feeding habits. The main tree species in their diets are likely to differ considerably.

Procolobus p. pennantii covers the altitudinal range from sea level to at least 800 m on Bioko I., and the range may be as much as 1800 m. On Bioko this species is present in coastal forest, 'monsoon forest' (rainfall >10,000 mm/year), mid-altitude (transition) forest and montane forest (Butynski & Koster 1994). Over this range, the composition of the tree community differs greatly, meaning that the diet of *P. pennantii* must also differ greatly over a horizontal distance of ca. 10 km. Therefore, *P. p. pennantii* is likely to have a more diversified diet than *P. p. bouvieri* or *P. p. epieni*, both of which live

at relatively low altitude on relatively flat ground. Sightings of *P. p. bouvieri* have been mostly along the margins of major rivers but it should be remembered that the pre-eminence of river transport in the Congo Basin could give a false idea of the ecological limits of *P. p. bouvieri*. *Procolobus p. epieni* is likely to have the most localized and peculiar diet, living, as it does, in a lowland delta close to the sea. From what is known of seasonal phenology in such littoral habitats it is possible that green fruit is taken more during the wet season while leaves and buds are the staple food during the dry season.

Procolobus p. pennantii spends most of its time in the mid-canopy at ca. 15–30 m above the ground, but does forage in the upper canopy to >45 m (González-Kirchner 1997b) and, at least occasionally, on the ground (Struhsaker 2000a, T. Butynski pers. obs.). Observed feeding on flower buds of *Allophylus africanus* (T. Butynski pers. obs.).

Social and Reproductive Behaviour Social. *P. p. pennantii* groups seem to typically have >20 individuals and some have >30 individuals (Butynski & Koster 1994). Counts of 14 groups by Struhsaker (2000a) yielded a mean size of ca. 14 individuals (range = 5–<30). Groups have 1–3 adult ♂♂ (Struhsaker 2000a) but the majority of groups probably have but one adult ♂ (T. Butynski pers. obs.).

Of 17 encounters with *P. p. pennantii*, 24% were with solitary individuals (Struhsaker 2000a). In another study, none of the ten encounters were with solitary individuals (Butynski & Koster 1994). Group spread sometimes >100 m but usually much less than this (T. Butynski pers. obs.).

Procolobus p. pennantii observed in polyspecific associations with Bioko Black Colobus *Colobus satanas satanas*, Bioko Red-eared Monkey *Cercopithecus (c.) erythrotis erythrotis* and Golden-bellied Crowned Monkey *Cercopithecus (m.) pogonias pogonias*. Of ten encounters during censuses conducted in 1986, *P. p. pennantii* in association with groups of other species of primate 40% of the time. Similarly, of 13 encounters in SW Bioko in 1992, Struhsaker (2000a) found that 38% of the *P. p. pennantii* groups were in a polyspecific association. During surveys conducted on Bioko in the Gran Caldera de Luba in 2008, two (25%) of the eight *P. p. pennantii* groups encountered were in a polyspecific association (Butynski & Owens 2008). Polyspecific associations are thought to confer anti-predator and foraging advantages to the participants (Struhsaker 2000a).

The vocal repertoire of *P. p. pennantii* has the least overlap with other taxa of *Procolobus*. The calls given include: 'chist', 'nyow', 'copulation quaver' and 'convex'. The '2-unit honk', '2-unit chist', 'nasal scream' and 'nasal sqwack' are very distinctive calls unique to *P. p. pennantii*. *Procolobus p. epieni* gives the 'wheet', a call which is absent from the vocal repertoire of *P. p. pennantii* (Struhsaker 1981b, 2010).

The loud, squeaky 'eeeyak' and loud 'honk' calls of *P. p. pennantii* are highly variable in length and intensity. Both calls appear to be given only by adult ♂♂. The 'eeeyak' can be heard to >250 m and the 'honk' to >400 m. The 'honk' may be the loudest call given by any *Procolobus* spp. and probably serves some of the same functions as the loud calls of adult ♂♂ of other primate taxa (e.g. *Colobus* spp., *Lophocebus* spp., *Cercopithecus* spp.). These calls are given in times of excitement (e.g. intra-group aggression, loud noise from a falling tree, detection of a human). Adult ♀♀ give sharp 'ik' and soft 'honk'

warning calls. Soft 'whistles' also given; these may be analogous to the 'wheats' of mainland *Procolobus* spp. (T. Butynski pers. obs.).

Reproduction and Population Structure Few data available. Adult ♀♀ exhibit large perineal swellings, sometimes protruding to >6 cm (T. Butynski pers. obs.).

Predators, Parasites and Diseases The Central African Rock Python *Python sebae* is a likely predator of all three subspecies of *P. pennantii*, perhaps particularly of *P. p. pennantii*, which frequently moves on the ground, as Leopards *Panthera pardus*, African Golden Cats *Profelis aurata* and Nile Crocodiles *Crocodylus niloticus* are all absent from Bioko I. These are all, however, likely predators of *P. p. epieni* and *P. p. bouvieri*. Likewise, the African 'monkey-eating eagle', the African Crowned Eagle *Stephanoaetus coronatus*, is absent from Bioko I. but is expected to be second only to humans as the primary predator of *P. p. epieni* and *P. p. bouvieri*.

Conservation IUCN Category (2012): Critically Endangered as *P. pennantii*, *P. p. epieni* and *P. p. bouvieri*, and Endangered as *P. p. pennantii*. CITES (2012): Appendix II.

Procolobus p. epieni listed as one of the world's 25 most threatened primates in 2008 (Oates & Werre 2009). *Procolobus p. pennantii* previously (2004–08) listed as one of the world's 25 most threatened primates (Butynski *et al.* 2007). *Procolobus p. pennantii* probably has the most restricted range of all of Bioko's 11 species of primates, and is now only known for certain from an area of <400 km² on the south-west of the island, within the Gran Caldera and Southern Highlands Scientific Reserve (510 km²). *Procolobus p. pennantii* is extremely threatened by bushmeat hunting, most notably since the early 1980s when a commercial bushmeat market appeared in the capital city of Malabo (Butynski & Koster 1994). Hearn *et al.* (2006) estimated numbers killed for bushmeat at 550 and 350 in the years 2004 and 2005, respectively, and a decline of more than 40% in the population over the 20 years from 1986 to 2006. The average price paid in the Malabo market for an adult *P. p. pennantii* in 2006 was about US\$42. This is well over twice as much as the cost of the readily available, high-quality, whole chicken, pork and beef at the same market. Similar high prices are paid on Bioko for all seven species of monkeys and for both species of duikers. Bushmeat on Bioko is, obviously, now a 'luxury food' (Hearn *et al.* 2006). Probably all of the *P. p. pennantii* killed on Bioko at this time are coming from within the Gran Caldera and Southern Highlands Scientific Reserve, but small numbers may persist in the most remote and rugged parts of Bioko's other protected area, the Pico Basile N. P. (330 km²). The continued high flow of primates, duikers and other wildlife into the Malabo Bushmeat Market indicates that neither 'protected area' is receiving adequate protection from the government of Equatorial Guinea.

The red colobus monkeys of West Africa and west-central Africa are probably more threatened than any other taxonomic group of primates in Africa. This is partly due to the fact that red colobus are especially sensitive to habitat degradation and vulnerable to hunters (Oates 1996a, Oates *et al.* 2000a, Waltert *et al.* 2002, Struhsaker 2005). None of the few protected areas in which *P. pennantii* occurs is well protected. Of very high priority for the conservation of *P. pennantii* is (1) immediate field surveys to determine the current distributions and abundance of *P. p. epieni* and *P. p. bouvieri* and, at

the same time, (2) rigorous protection of all of those populations that are known to exist.

Providing adequate protection to viable populations of these three subspecies of red colobus would greatly assist the conservation of numerous sympatric threatened taxa. Among primates, these include: Bioko Preuss's Monkey *Allochrocebus preussi insularis*; *C. e. erythrotis*; *C. p. pogonias*; Bioko Stampfli's Putty-nosed Monkey *Cercopithecus (n.) nictitans martini*; Bioko Black Colobus *Colobus satanas satanas*; Bioko Drill *Mandrillus leucophaeus poensis*; Western Chimpanzee *Pan troglodytes verus*; and Nigeria Chimpanzee *P. t. vellerosus*. If a concerted effort is to be made to save all of the diversity present within the red colobus, then the major international conservation NGOs will need to focus their efforts on this taxonomic group and work closely with national conservation NGOs and national protected area authorities.

Procolobus rufomitrat EASTERN RED COLOBUS

Fr. Colobe bai à tête roussee; Ger. Ostafrikanischer Stummelaffe

Procolobus rufomitrat (Peters, 1879). Monatsb. K. Preuss. Akad. Wiss. Berlin 1879: 829. Muniuni, Tana R., Kenya.

Taxonomy Polytypic species. Taxonomy extremely complex and much debated (Thorington & Groves 1970, Rahm 1970, Dandelot 1974, Napier 1985, Groves 1989, 2000a, 2001, 2007b, Colyn 1991, Kingdon 1997, Gautier-Hion *et al.* 1999, Grubb & Powell 1999, Grubb *et al.* 2003, Struhsaker 2010). As treated here, includes at least eight subspecies: Tana River Red Colobus *P. r. rufomitrat*; Ashy (or Uganda) Red Colobus *P. r. tephrosceles* (synonym: *gudoviusi*); Tshuapa (or Thollon's) Red Colobus *P. r. tholloni*; Oustalet's Red Colobus *P. r. oustaleti* (synonyms: *brunneus*, *nigrimanus*, *powelli*, *schubotzi*); Kisangani Red Colobus *P. r. langi*; Lulindi River Red Colobus *P. r. lulindicus*; Kivu Red Colobus *P. r. foai* (synonym: *graueri*); and Lomami River Red Colobus *P. r. parmentieri*. A ninth, Semliki Red Colobus *P. r. ellioti* (synonym: *semlikiensis*), may represent a very large hybrid swarm between the latter five taxa (Verheyen 1962). Most early authorities considered all to be subspecies of a single species of red colobus *Colobus badius* (e.g. Schwarz 1928a, Rahm 1970, Haltenorth & Diller 1980). Dorst & Dandelot (1970) confined *badius* to a single western species while a second species, *pennanti*, embraced all the rest of the red colobus forms. Groves (1989) regarded the nominate population, *P. rufomitrat*, from the lower Tana R., Kenya, to be a species in its own right and most of the forms listed above as subspecies of a single 'Central species', *P. pennantii*, ranging from the Bight of Bénin to Zanzibar I. Groves (2001) again kept *Tana rufomitrat* as a separate species, one of nine in the following red colobus subgroup; *tholloni*, *foai* and *tephrosceles* were also given specific status. Groves (2001) placed, *ellioti*, *langi*, *lulindicus*, *oustaleti*, *parmentieri* and *semlikiensis* as subspecies or synonyms of *Piliocolobus* (*Procolobus*) *foai*. Kingdon 1997 had followed a similar course but provisionally allied *tephrosceles* with *oustaleti* and other populations from north and east of the Congo R. (DR Congo), clustering them as subspecies of a Central African Red Colobus *P. oustaleti*. Gautier-Hion *et al.* (1999) divided *P. r. oustaleti* into six subspecies, and placed *foai*, *langi*, *lulindicus*, *parmentieri*, *powelli*, *nigrimanus*, *oustaleti*, *semlikiensis* and *tholloni* as subspecies of Pennant's Red Colobus *Procolobus pennantii*. See authors listed above and Napier (1985), Colyn (1991), Grubb *et al.* (2003), Groves (2007b) and Struhsaker (2010) for reviews and additional details. Synonyms: see above. Chromosome number: unknown.

Description A medium-sized, arboreal monkey with variable amounts of reddish-brown or orange-brown on top of the head, back, tail and lateral surface of the arms and legs, and paler ventrum. Males generally same or similar colour as ♀♀. Adult ♂♂ of some subspecies up to ca. 25% heavier than adult ♀♀ (e.g. 9–12.5 kg vs. 7–9 kg for *P. r. tephrosceles*; Kingdon 1971, Struhsaker 1975), but this size difference is not present in all subspecies (e.g. *P. r. rufomitrat*; T. Struhsaker pers. obs.). In all subspecies, ♂♂ have larger canines, and nuchal and sagittal crests (Verheyen 1962, P. Grubb pers. obs.).

Colour and patterning highly variable among subspecies and often so within a subspecies, such as *tephrosceles*, *oustaleti* and particularly in the *ellioti*/*semlikiensis* hybrid swarm. See Geographic Variation for information on extent of phenotypic variation. Back and tail often dark-grey, lacking any red or brown depending on subspecies. Tail typically

tufted, especially in adult ♂♂. *Procolobus r. tholloni* is the most brightly coloured subspecies with bright orange or reddish over most of the dorsum. Hair usually of medium length. Face dark grey or blackish in most subspecies, but *tholloni* distinct from the others by having light skin around the eyes, nose and mouth, but not as contrasting as in the Udzungwa Red Colobus *Procolobus gordonorum* or Zanzibar Red Colobus *Procolobus kirkii*. *Procolobus r. tholloni* is also distinguished by its more prognathous skull. See Verheyen (1962), Napier (1985), Colyn (1991), Kingdon (1971, 1997), Gautier-Hion *et al.* (1999), Groves (2001) and Grubb *et al.* (2003) for detailed descriptions, illustrations and discussions of the complex of subspecies here recognized within *P. rufomitrat*.

Newborns differ in colour from adults, are all dark grey to blackish on the dorsum and top of head, and light grey below. All newborns so far described for the subspecies within *P. rufomitrat* (*tephrosceles*, *oustaleti*, *tholloni*) have distinct pink lips and noses that are joined by a pink stripe. These pink parts of the face contrast sharply with the otherwise dark face. This facial pattern is lost in *P. r. tephrosceles* at about 3–4 months of age, but not lost in *P. r. oustaleti* until about 2–3 years. Red and brown colours do not appear in the pelage until about two months of age in *P. r. tephrosceles*, but may appear earlier in *P. r. tholloni*. Adult colouration in *P. r. tephrosceles* occurs at about 3.5 months (Struhsaker 1975 and unpub. data).

There is tremendous variation in colour and other phenotypic characters between and within the subspecies of this subgroup (see above). For example, *P. r. tephrosceles* in the Mbisi Forest of S Tanzania has longer hair than in Kibale, Uganda, and a much higher incidence of stump tails. Fifteen per cent of the Mbisi adults and subadults in a sample of 35 had stump tails, whereas none was seen amongst juveniles (Rodgers *et al.* 1984). These characters are attributed to the high altitude (2400 m) and southerly latitude (07° 40' S) that result in much colder temperatures at Mbisi. Sexual dimorphism, particularly in body size, is most pronounced in *P. r. tephrosceles* and least in *P. r. rufomitrat*.

Geographic Variation

P. r. rufomitrat Tana River Red Colobus. Lower Tana R. forests, Kenya.

Predominantly greyish-brown dorsum. Darker on shoulders and

Tana River Red Colobus *Procolobus rufomitrat rufomitrat* adult male.

Oustalet's Red Colobus *Procolobus rufomitrat oustaleti* adult male.

tail, but paler on rump and lateral surface of limbs. Crown and nape dull orange contrasting with black brow and dark greyish-black face. 'Cow-lick' (whorl) of stiff hairs behind each ear. Dorsum dull greyish-brown to charcoal grey. Ventrums greyish-white.

P. r. tephrosceles Ashy or Uganda Red Colobus. Border of Western Rift in SW Uganda and W Tanzania from Kibale N. P., SW Uganda, to Mbisi F. R., SW Tanzania (ca. 00° 41' N to 07° 55' S; Davenport *et al.* 2007). Resembles *rufomitrat* but much more robust; back and tail dark grey to black; lighter grey sides and ventrum; arms and legs grey with varying amounts of brown on lateral surface especially on the upper or proximal part of the arm; brown usually absent from hindlegs; facial whiskers grey. Face greyish; cap rusty-red with whorled hair above/behind ear (sometimes edged with a black tuft) conspicuous in some individuals. Black on brow extends to ears, sometimes up onto crown. Some ♂ develop conspicuous cape on shoulders. Considerable variation in colour.

Tshuapa Red Colobus *Procolobus rufomitrat tholloni* adult male.

P. r. tholloni Tshuapa or Thollon's Red Colobus. South of the Congo R. east to Lomami R., and south to the Kasai-Sankuru R., DR Congo. Circumfacial hair short, black, except on lower cheeks where hair is whitish. Muzzle square and prominent. Crown deep brown or chestnut, upperparts and outer surfaces of limbs orange-russet. Ventrums whitish with yellowish tone. Upper surfaces of hands and feet dark brown. Tail red for about 70% of its length, terminal tuft black.

P. r. oustaleti Oustalet's Red Colobus. North of Congo R. from Sangha R. in west across the Oubangui R. east to L. Albert. Northern limit is the gallery forests north of the Uele R. and Congo/Nile watershed in S Sudan. South-east limit is the Aruwimi-Ituri R., DR Congo. Medium sized. Highly variable colouration, but predominantly reddish-brown. Crown reddish-brown; face dark. Dorsum varies from dark smoky-brown to olive-brown to coppery-red to dark mahogany. Ventrums paler than dorsum. Hands and feet often black. Tail light brown to black.

P. r. langi Kisangani Red Colobus. Lowland forest east of Congo R. from about Bumba to Boyoma Falls. North of Maiko R. to valley of Aruwimi R., east to piedmont of Western Rift Highlands. Crown, shoulders and front legs deep orange, reddish or chestnut. Dorsum, hindlegs and tail blackish. Ventrums grey.

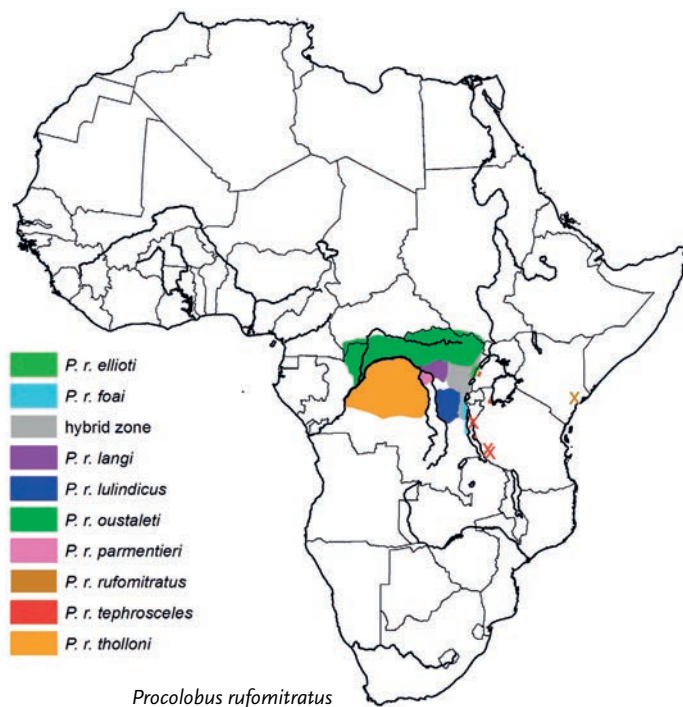

P. r. lulindicus Lulindi River Red Colobus. Riverine (lowland) forest subspecies. Western limit is the Lualaba R. Between Lova-Oso R. in north and Elila R. in south, DR Congo. Crown reddish. Crest poorly developed. Brow-band black. Ears with prominent tufts at base. Proximal dorsum blackish. Distal dorsum and legs reddish. Ventrums greyish. Hands, feet and tail blackish. Pelage short.

P. r. foai Kivu Red Colobus. Montane forest species. Between Lova R. on west side of L. Kivu and ca. 6° S on west shore of L. Tanganyika, E DR Congo. Pelage long, with 'ragged' appearance. Ears with prominent tufts at base. Cheeks often streaked with dark brown freckles. Brows black beneath red tuft on forehead; crown reddish. Proximal dorsum blackish. Distal dorsum reddish. Ventrums greyish. Limbs, hands and feet unicolour, light reddish, paler than distal dorsum. Tail reddish.

P. r. parmentieri Lomami River Red Colobus. Between Lomami R. and Lualaba R., south to Ruiki R. and Lutanga R. Face black with pinkish lips, chin and base of nose. Ears with prominent tufts at base. Frontal band black. Crown brownish-red without crest. Mid-back, shoulders and upper arms black, rest of dorsum and lateral side of arms and legs brick red. Ventrums and throat whitish. Feet and hands black.

P. r. ellioti Semliki Red Colobus. From Congo-Lualaba R. east to Semliki Valley, and west shore of L. Edward. Northern limit the Aruwimi-Ituri R. Southern limit the Maiko R. Highly variable subspecies and probably represents a large hybrid swarm involving *langi* and *semlikiensis* (Colyn 1993). Apart from an orange cap there is no consistent coat colour or pattern (Lorenz von Libernau, L. 1917, Colyn 1993, T. Struhsaker pers. observ.). Predominantly reddish-brown. Crown orange-red. Proximal dorsum and shoulders generally reddish. Saddle grey or reddish tones, hindlegs and tail dark brown, grey or black. Arms rusty orange or grey. Forearms orange-red or charcoal grey.

Similar Species None within geographic range.

Distribution Endemic to central and East Africa. Rainforest, Afromontane–Afroalpine and Coastal Forest Mosaic BZs. From the Sangha R. in W Central African Republic, east to the lower Tana R. in E Kenya, north to S Central African Republic and S Sudan, and south to N Zambia and SW Tanzania (Kingdon 1971, Rodgers 1981, Colyn 1991, 1993, Gautier-Hion *et al.* 1999, Groves 2001, 2007b, Struhsaker 2010). Subspecies distributions given above under Geographic Variation.

Habitat In a variety of forest types, including gallery forest, forest-miombo mosaic, old-growth lowland, mid-altitude and montane moist forest, degraded secondary forests, and raphia palm swamps (Struhsaker 1975, Marsh 1978, 1981, Rodgers *et al.* 1984, Maisels *et al.* 1994, Chapman & Chapman 2000). Present at altitudes from ca. 20 m (lower Tana R., Kenya; Butynski & Mwangi 1994) to 2420 m (Mbizi Forest, SW Tanzania; T. Davenport pers. comm.). Most of the research on *P. rufomitratus* has focused on *P. r. tephrosceles* in Kibale Forest, W Uganda, and on *P. r. rufomitratus* in floodplain/ground water forests along the lower Tana R., E Kenya. In Kibale they are most abundant in moist, old-growth, evergreen forest with emergent trees reaching 50 m in height. Prominent trees in this habitat include: *Parinari excelsa*, *Aningeria altissima*, *Celtis durandii*, *C. africana*, *Markhamia platycalyx*, *Uvariopsis congensis*, *Funtumia latifolia*, *Lovoa swynnertonii*, *Mimusops bagshawei*, *Albizia grandibracteata*, *Newtonia buchananii* and *Piptadeniastrum africanum* (Struhsaker 1975, Chapman & Chapman 2000, Isbell 2012). Common trees in the Tana R. forests include *Sorindeia madagascariensis*, *Ficus sycomorus*, *Diospyros mespiloformis*, *Albizia gummifera* and *A. glaberrima*. Except for the drier lower Tana R. site, *Procolobus rufomitratus* usually occurs where annual rainfall is >1000 mm.

Abundance Extremely common at some sites and rare at others. Population densities of *P. r. tephrosceles* in Kibale range from about 25 to 300 ind/km² (Struhsaker 1975, 1997, Skorupa 1988, Chapman & Chapman 1999, Chapman & Lambert 2000, Teelen 2005). Densities of *P. r. rufomitratus* along the Tana R. range from 33 to 253 ind/km²

(Marsh 1978, Decker 1994a, Mbora 2003). Moderate to heavy levels of selective logging result in very reduced population densities in Kibale (Struhsaker 1975, 1997, Skorupa 1986) that persist for at least several decades (Chapman *et al.* 2000, Struhsaker 2005). Unusually high rates of predation by Robust Chimpanzees *Pan troglodytes* in Kibale, and at Gombe, Tanzania, have also led to major reductions in *P. r. tephrosceles* populations (Wrangham & Bergmann-Riss 1990, Stanford 1998, Mitani & Watts 1999, Mitani *et al.* 2000b, Struhsaker 2005, Teelen 2005). Struhsaker (2005) estimates that there are at least 17,000 *P. r. tephrosceles* in Kibale alone, plus a few thousand more in the small and isolated forests of W Tanzania.

Forest destruction and fragmentation along the lower Tana R. has led to very significant population declines of *P. r. rufomitratus*, which may now number fewer than 1500 individuals (Butynski & Mwangi 1994, 1995, Decker 1994a, Wieczkowski & Mbora 2000, Mbora 2003, Struhsaker 2005). There are no population estimates for other subspecies of *P. rufomitratus*, but *P. r. oustaleti* and *P. r. tholloni* are likely the most numerous because of their vast geographic ranges and large amount of habitat remaining.

Adaptations Diurnal and arboreal. See the subgenus and genus *Procolobus* profiles, as well as the Subfamily Colobinae profile for anatomical and physiological adaptations.

Foraging and Food Folivorous. Daily travel distance for *P. r. tephrosceles* in Kibale is highly variable within and between groups, ranging from ca. 180 to 1185 m. During a 15-month sample period, the daily travel distance of one group of 22 individuals ranged from 222 to 1185 m. Average daily travel distance among five groups in Kibale was between 500 m and 600 m (Struhsaker 1975, Struhsaker & Leland 1987). Daily distances are similar amongst the smaller groups living in the drier and more seasonal riparian forests of the Tana R., Kenya (Decker 1994a). There is disagreement as to whether or not group size affects travel distance (Struhsaker & Leland 1987, Gillespie & Chapman 2001, Struhsaker 2010, Isbell 2012).

Mean annual home-range size varies from ca. 35 ha (Kibale) to 100 ha (Gombe) for *P. r. tephrosceles* (Clutton-Brock 1975, Struhsaker 1975, Struhsaker & Leland 1987), whereas they are only 4–19 ha for *P. r. rufomitratus* in the riverine forest patches along the Tana R. (Decker 1994a). Territoriality is absent amongst the populations studied and groups often have extensive, if not complete, overlap in home-ranges (Struhsaker 2000b). Exceptions exist in heavily logged areas of Kibale where there is little overlap in home-ranges and inter-group encounters are rare (Skorupa 1988, Struhsaker 2000b).

Feeding occurs throughout the day, but is frequently alternated with periods of rest and travel (Struhsaker 1975, Marsh 1981). Time spent feeding during the daylight hours is ca. 23–30% for *P. r. rufomitratus* (Decker 1994a) and ca. 45% for *P. r. tephrosceles* (Struhsaker 1975). Young leaves dominate (ca. 30–50%) the diets of all three subspecies for which there are data, i.e. *P. r. tephrosceles* at Kibale (Struhsaker 1975, 1978b, Clutton-Brock 1975, Chapman & Chapman 2000, Isbell 2012), *P. r. rufomitratus* at Tana R. (Marsh 1981, Decker 1994a) and *P. r. tholloni* at Salonga N. P., DR Congo (Maisels *et al.* 1994). Mature leaves are eaten to a much lesser extent and even then it is usually the petioles and not the lamina that are consumed (Struhsaker 1975, 1978b). In the Salonga N. P., DR Congo, *P. r. tholloni* eats large quantities of seeds (31% of diet). Seeds sometimes dominate the diet

of *P. r. tephrosceles* in Kibale for periods of several weeks (T. Struhsaker pers. obs.). Hundreds of tree and liana species are fed upon. Some of the common food species are: (1) *P. r. tephrosceles*: *C. africana*, *C. durandii*, *N. buchananii*, *M. platycalex*, *Aningeria altissima*, *Milletia dura*, *L. swynnertonii*, *P. excelsa* and *A. grandibracteata*; (2) *P. r. rufomitratu*: *F. sycomorus*, *Sorindeia obtusifoliolata*, *Acacia robusta*, *A. gummifera* and *Pachystela brevipes*; and (3) *P. r. tholloni*: *Guibourtia demeusei*, *Dialium* sp., *Symphonia globulifera*, *Cynometra pedicellata*, *Gilbertiodendron dewevrei* and *Daniella pynaertii*. *Procolobus r. tephrosceles* of Kibale occasionally eats soil from the castings of subterranean termites (T. Struhsaker pers. obs.).

Social and Reproductive Behaviour Social. Groups of *P. r. tephrosceles* average about 45–50 individuals (range 8–80) in Kibale, and 55–59 individuals (range 30–82) in Gombe (Struhsaker 1975, 2000a, b). Groups smaller in the high-altitude and disturbed Mbisi Forest with means of ca. 25 (range <14–30; Rodgers *et al.* 1984) and 40.6 (30–56; Davenport *et al.* 2007). One group of *P. r. tholloni* numbered at least 60 individuals (Maisels *et al.* 1994). Groups of *P. r. rufomitratu* are much smaller, averaging 18 individuals in the 1970s (Marsh 1979), 11 in the late 1980s and early 1990s (Decker 1994a) and 10 (4–31) in 1999–2000 (Mbora 2003). Fission–fusion occurred in a *P. r. tephrosceles* group in a heavily logged area (Skorupa 1988, Struhsaker 1997, 2000a), and for another group in an unlogged part of Kibale (Chapman & Chapman 2000).

Groups of *P. r. tephrosceles* in Kibale and Gombe usually contain several adult ♂♂ (mean = 7–8, range 1–13), but the smaller groups in Mbisi appear to have fewer adult ♂♂ (Struhsaker 2000a, b). Similarly, the large groups of *P. r. oustaleti* in the Ituri Forest, DR Congo, have several adult ♂♂ (T. Struhsaker pers. obs.). *Procolobus r. rufomitratu* at Tana R. is exceptional in that most groups have only one adult ♂ and never more than two (Marsh 1979, Decker 1994a).

Groups of *P. rufomitratu* in Kibale and Gombe contain many adult ♀♀ (mean = 18, range 2–32) and the adult sex ratio (♀ : ♂) averages 2.1 : 1 in Kibale and 1.9 : 1 in Gombe (range 0.6–34, *n* = 16; Struhsaker 2000a, b, 2010). Adult sex ratios are much higher in the one-male groups of *P. r. rufomitratu* at Tana R., averaging 7.3 : 1 in the 1970s (Marsh 1979) and 5.1 : 1 in the late 1980s and early 1990s (Decker 1994a). In general, about 35–50% of group members are immature. Solitary adult and subadult ♂♂ are uncommon. Temporary all-male parties have been seen only in *P. r. rufomitratu* (Marsh 1979).

Amongst *P. r. tephrosceles* in Kibale and *P. r. rufomitratu* at Tana R., all ♀♀ leave their natal groups. Parous ♀♀ transfer between groups and this can occur several times in a lifetime. Even ♀♀ with 1–2-year-old juveniles occasionally transfer between groups. Female transfers appear to be immediate without any aggression (Marsh 1979, Struhsaker & Leland 1979, 1985, Struhsaker & Pope 1991). In contrast, although about half of the *P. r. tephrosceles* ♂♂ in Kibale leave their natal groups, they are rarely able to join other groups. Most of them disappear and presumably die. Males remaining in their natal groups form a coalition among themselves. There is a dominance hierarchy within these ♂ coalitions, which is expressed through displays, and priority of access to food and space. The highest-ranking ♂ undertakes most, but not all, of the copulations. Females sometimes mate with more than one ♂. Red colobus are multiple mounters, i.e. a complete copulation with ejaculation is preceded by a series of incomplete mounts by the same ♂ on the same ♀. No vocalizations are given during copulation, but ♀ *P. r. tephrosceles* often shake their heads and forequarters back

and forth near the end of a complete copulation, perhaps indicating orgasm. Among *P. r. tephrosceles*, copulating pairs are often harassed by other adult ♂♂ and juveniles.

Male dominance ranks and mating success change over time. In Kibale no ♂ has been dominant and the main copulator for more than ca. 3–4 years, but some ♂♂ were reproductively active for nearly 12 years (Struhsaker 1975, 2000b, Struhsaker & Pope 1991). Coalitions of ♂♂ in neighbouring groups fight one another and the outcome of these encounters may be important in determining patterns of ♀ transfer. Females do not usually participate in these fights nor those within groups (Struhsaker 1975). In contrast, *P. r. rufomitratu* along the Tana R. is exceptional in that adult ♂♂ are much less tolerant of one another and groups usually contain only one or, occasionally, two adult ♂♂. On the Tana ♂♂ are able to immigrate and take over groups from incumbent ♂♂. All-male groups are uncommon and unstable in the Tana population (Marsh 1979).

Allogrooming is common and adult ♀♀ are the primary groomers. In contrast, allomothering is extremely rare (Struhsaker 1975). Only once was a *P. r. tephrosceles* ♀ seen carrying another female's infant. She carried this infant along with her own infant for several days until one of the infants disappeared (T. Struhsaker pers. obs.). Play amongst immatures is common during their first two years. The vocal repertoire size of *P. r. tephrosceles* is complex and may contain more than 25 different calls, many of which are components of a graded system (Marler 1970, Struhsaker 1975, 2010). The repertoires of *P. r. oustaleti*, *P. r. ellioti* and *P. r. rufomitratu* are less well studied, but they appear identical to *P. r. tephrosceles* (T. Struhsaker pers. obs.). It appears that *P. r. rufomitratu* on the Tana vocalize much less than the other subspecies of *P. rufomitratu* (Struhsaker 1975). This may be a consequence of their smaller, one-male, social groups.

Polyspecific associations are common for *P. rufomitratu* and have been particularly well documented for the *P. r. tephrosceles* of Kibale. During line transects 72% of all encounters with red colobus groups in unlogged forest were with other monkey species (Struhsaker 2000a). Although they associated with five other monkey species in Kibale, they most typically associated with Red-tailed Monkeys *Cercopithecus (c.) ascanius*. It appears that these associations are formed primarily in response to predation pressure from African Crowned Eagles *Stephanoaetus coronatus* and secondarily to habitat quality, the cost to benefit ratio of foraging together, convergence at common foods and by chance alone (Struhsaker 1981a, 2000b, Chapman & Chapman 2000).

Reproduction and Population Structure Adult ♀♀ have perineal swellings, which are very large (ca. 7–10 × 7–10 cm) in *P. r. oustaleti* (T. Struhsaker pers. obs.) and much smaller (ca. one-third this size) in *P. r. tephrosceles* and *P. r. rufomitratu* (Struhsaker 1975). These swellings appear to occur during oestrus and ovulation, but also occur at other times, such as during pregnancy (Struhsaker & Leland 1985, T. Struhsaker pers. obs.). Oestrous *P. r. tephrosceles* may give off olfactory cues because ♂♂ often nuzzle a female's perineum before mounting her (Struhsaker 1975).

Gestation length is ca. 6–7 months (Struhsaker & Leland 1985). Copulations and births occur in all months, but at Kibale most *P. r. tephrosceles* births occurred during three relatively wet months (Apr, May and Nov) and one dry month (Jun) (Struhsaker 1997). Likewise, no seasonality in births was observed during an 18-month study of *P. r. rufomitratu* (Marsh 1978). Single births are the rule and no twins have

been recorded. Weight at birth unknown, but an infant *P. r. tephrosceles* estimated to be <4 months old weighed 0.5 kg (Struhsaker 1975). The average inter-birth interval for 16 recognizable *P. r. tephrosceles* in Kibale over 18 years was 24.4 months ($n = 73$ births to 16 ♀♀) and 27.5 months when cases of neonatal mortality were excluded (Struhsaker & Pope 1991). A similar inter-birth interval appears to occur among the *rufomitratus* of the Tana R. based on ratios of infants per adult ♀ (Marsh 1979, Decker 1994a, Struhsaker *et al.* 2004). Weaning is a gradual process and is usually complete in *P. r. tephrosceles* by about 12–18 months. Reproductive and physical maturity are reached in about 5.0–5.5 years both in ♂ and ♀ *P. r. tephrosceles* (Struhsaker & Leland 1985, Struhsaker & Pope 1991).

Infanticide by one ♂ was observed during a long-term study of a multimale group of *P. r. tephrosceles* (Struhsaker & Leland 1985) and suspected in *P. r. rufomitratus* when a ♂ replaced the resident ♂ (Marsh 1979). In both cases the evidence supported the hypothesis that infanticide is a reproductive strategy. Mowry (1995) observed possible infanticidal behaviour by a ♂ *P. r. rufomitratus*, but the infant survived the attack.

Population structure is essentially the same as that given for group composition because solitaries are uncommon. Maximum longevity is unknown, but one adult ♀ *P. r. tephrosceles* was observed for nearly 15 years. Because she was fully adult at the initiation of observations, she was probably at least 20 years old when she died (Struhsaker & Pope 1991). Mean annual birth rate in *P. r. tephrosceles* is 0.49 (Struhsaker & Pope 1991). Mean survivorship to adulthood is estimated as 39%. Assuming a 1 : 1 sex ratio at birth, survivorship to adulthood was 47% for ♀♀ and 34% for ♂♂ (Struhsaker & Pope 1991).

Predators, Parasites and Diseases Major predators on *P. r. tephrosceles* are African Crowned Eagles (Struhsaker & Leakey 1990, Mitani *et al.* 2001) and Robust Chimpanzees (Wrangham & Bergmann-Riss 1990, Stanford 1998, Mitani & Watts 1999, Mitani *et al.* 2000b, Struhsaker 2005, 2010, Teelen 2005, Lwanga *et al.* 2011). A herpes-like disease afflicted some *P. r. tephrosceles* in Kibale and apparently killed five out of ten adult ♂♂ in one group over a 2.5 year period (Struhsaker 2000b). Predation by humans is particularly important in DR Congo, e.g. *P. r. tholloni* (Thompson 2000, Struhsaker 2010).

Conservation IUCN Category (2012): Least Concern as *P. rufomitratus*. Endangered as *P. r. rufomitratus* and *P. r. tephrosceles*. Other subspecies Near Threatened, Least Concern or Not Evaluated. CITES (2012): Appendix I for *P. r. rufomitratus*. Other subspecies Appendix II.

Procolobus r. rufomitratus listed as one of the world's 25 most threatened primates since 2002 (Mbora & Butynski 2007, 2009). The main threat to *P. r. rufomitratus* is habitat loss due primarily to agricultural clearing and extraction of forest products by local communities (Butynski & Mwangi 1994, 1995, Wiczowski & Mbora 2000, Decker 1994a, Mbora 2003, Moinde-Fockler *et al.* 2007) and secondarily to alteration of river flow volume and cycles by five hydroelectric power dams upriver (Hughes 1985, Butynski 1995b). Less than 35% of the *P. r. rufomitratus* population is legally protected within the Tana River Primate National Reserve, but even there the habitat is insecure because of inadequate law enforcement (Butynski & Mwangi 1994, 1995, Wiczowski & Mbora 2000). Given the small size, grave threats, and presence of another endemic, Endangered, primate (Tana River Mangabey *Cercocebus galerritus*), the

forests of the lower Tana R. represent the most important site in East Africa for primate conservation actions (De Jong & Butynski 2012). A small subpopulation of *P. r. rufomitratus* was discovered in 2009 at the north end of the Tana Delta (Hamerlynck *et al.* 2012).

The largest population of *P. r. tephrosceles* is in the Kibale N. P. where the habitat is well protected. In Kibale and Gombe, however, the greatest threat to *P. r. tephrosceles* is predation by Robust Chimpanzees, where it is estimated that they kill between 6% and 40% of these monkeys annually (Stanford 1998, Watts & Mitani 2002, Teelen 2005). As a result, *P. r. tephrosceles* populations have declined in both of these national parks in the last 20–25 years (Struhsaker 2005). The Kibale population should be monitored on an annual or semi-annual basis. Status surveys should be done of smaller populations of *P. r. tephrosceles* in areas such as Mahale Mountains N. P., Mbisi F. R. and the Biharamulo region of Tanzania.

Nothing is known of the population status of the other subspecies of *P. rufomitratus*. The very extensive range of some, such as *P. r. oustaleti* and *P. r. tholloni*, suggests their conservation status might not be as dire as those taxa living farther east. Thompson (2000), however, describes the very extensive and intensive hunting pressure on *P. r. tholloni*, which has likely increased with continuous expansion of the bushmeat trade and its extension into rapidly growing urban centres, with the proliferation of weapons and ammunition, all associated with the long-standing conflicts and insecurity in DR Congo. The same problem likely applies to other subspecies of *P. rufomitratus* living in DR Congo. Obvious conservation actions include: more conservation areas; greater law enforcement, conservation education and surveys to better understand the status and conservation problems facing the *P. rufomitratus* of DR Congo.

Measurements

Procolobus rufomitratus

P. r. tholloni

HB (♀♀): 580, 600 mm, $n = 2$

T (♀): 690 mm, $n = 1$

HF (♀♀): 150, 170 mm, $n = 2$

E (♀): 35 mm, $n = 1$

WT estimated to be in lower range for red colobus at 7–10 kg (average WT estimate for red colobus at 8–12 kg)

From Allen (1925) and BMNH

P. r. oustaleti (cf. *powelli*)

HB (♂♂): 540 (455–590) mm, $n = 17$

HB (♀♀): 524 (480–565) mm, $n = 12$

T (♂♂): 726 (650–800) mm, $n = 17$

T (♀♀): 713 (645–790) mm, $n = 12$

HF (♂♂): 186 (170–198) mm, $n = 17$

HF (♀♀): 182 (170–202) mm, $n = 12$

E (♂♂): 39 (35–42) mm, $n = 17$

E (♀♀): 37 (35–40) mm, $n = 12$

WT estimated to be in mid to low range for red colobus at 8–11 kg

From Allen (1925) and BMNH

P. r. oustaleti (cf. *brunneus*)

HB (♂♂): 550, 560 mm, $n = 2$

HB (♀♀): 490 (450–520) mm, $n = 5$

T (♂♂): 630, 770 mm, $n = 2$

T (♀♀): 580 (430–650) mm, $n = 5$

HF (♂♂): 160, 195 mm, n = 2
 HF (♀♀): 163 (154–172) mm, n = 5

Procolobus gordonorum UDZUNGWA RED COLOBUS (IRINGA / UHEHE / GORDON'S RED COLOBUS)

Fr. Colobe bai d'Udzungwa; Ger. Udzungwa-Stummelaffe

Procolobus gordonorum (Matschie, 1900). Sitzb. Ges. Naturf. Fr. Berlin, p. 186. Udzungwa Mts, Iringa, Tanzania.Udzungwa Red Colobus *Procolobus gordonorum* adult male.*Procolobus gordonorum*

Taxonomy Monotypic species. The Udzungwa (= Uzungwa) Red Colobus has been considered a subspecies of Western Red Colobus *Procolobus badius*, Pennant's Red Colobus *Procolobus pennantii*, Tana River Red Colobus *Procolobus rufomitratus* or Zanzibar Red Colobus *Procolobus kirkii*, or as a full species, *P. gordonorum* (Groves 2001, 2005c, 2007b, Grubb *et al.* 2003). Molecular (Ting 2008a, b) and craniometric (Cardini & Elton 2009) data indicate a close relationship with *P. kirkii*. Synonyms: none. Chromosome number: unknown.

Description Medium-sized arboreal monkey with a tricolour pattern of contrasting blackish, whitish and reddish. Sexual dimorphism not pronounced, although adult ♂ has longer canines, slightly larger, more robust and broader head, and thicker tail than adult ♀. Female has a prominent clitoris. Nose and lips pinkish. Cheeks white. Face dark grey to black. Crown cap extensive like an inverted bowl or toupee varying in colour from bright orange-red, brilliant rufous, to red-brown; this colour sometimes extending down the neck, separated from white cheeks by thick black band along brow and temples. Body hair of moderate length, somewhat longer on shoulders. Upper parts, including limbs and most of tail, predominantly glossy black to charcoal grey, with silver-white hairs invading the lower hindlimbs. Anterior edge of shoulders and underparts, including insides of limbs, throat and underside of first 20 cm of tail, whitish. Feet black. In one sample 2% of the monkeys had reddish lumbar-sacral patch. Top of the head of one adult or subadult ♀ entirely grey without any orange-red. Entire back of one adult ♀ orange-red like top of head. Some tails entirely orange-red, while others only partly orange-red or white (Struhsaker & Leland 1980, Ehardt *et al.* 1999, A. R. Marshall pers. comm., T. Struhsaker pers. obs.). Infants up to ca. 3–4 months of age have face dark grey

or blackish while nose and mouth are pale pink like adults. Head and back black. Ventrums grey.

Geographic Variation No pattern of geographic variation observed over the small geographic range of this species, but much intra-specific variation present (see Description).

Similar Species None within geographic range.

Distribution Endemic to south-central Tanzania. Afroalpine BZ and moist evergreen and semi-deciduous forests and miombo woodland adjacent to these forests. Populations occur throughout the Udzungwa Mts, including the following forests in the Udzungwa Mountains N. P.: Mwanihana (probably largest population), Iwonde, Mlale, Matundu and Luhombero; and in the following Forest Reserves: W Kilombero (including Ndundulu, Nyumbanitu, Ukami, Iyondo), Matundu, Udzungwa Scarp, Nyanganje, Kiranzi-Kitungulu and New Dabaga/Ulangambi. Also collected or reported from the non-reserved forests of Muhanga/Boma la Mzinga and Mbongolo that are south of Dabaga. Also in the Kilombero Valley at the eastern base of the Udzungwa Mts in the following forest patches: Magombera, Kiwanga and Kalunga (this forest is now gone). Also in gallery forest along the Msolwa R. south of the railway to its confluence with the Kilombero R., including the Ibiki and Msitu ya Kinjugu Forests (Struhsaker & Leland 1980, Rodgers 1981, Rodgers & Homewood 1982, Decker 1994b, Ehardt *et al.* 1999, Dinesen *et al.* 2001, Struhsaker *et al.* 2004, Marshall *et al.* 2005, P. Grubb pers. obs.). Probably now

extinct in the Lukoga Forest as this forest was essentially destroyed in 1998 (Ehardt *et al.* 1999).

Habitat *Procolobus gordonorum* occurs in a wide variety of forest types ranging in altitude from ca. 250 to 2200 m (Struhsaker & Leland 1980, Rodgers & Homewood 1982, Ehardt *et al.* 1999, Dinesen *et al.* 2001, Struhsaker *et al.* 2004, Marshall *et al.* 2005), including lowland old-growth, secondary and montane forests of the Udzungwa Mts and miombo *Brachystegia* spp. woodland adjacent to old-growth or secondary forest in the lower parts of the Mwanihana forest and elsewhere. Most abundant in low to medium altitude mixed evergreen and semi-deciduous forests (ca. 300–700 m) of the Mwanihana Forest where the canopy attains heights of 30–40 m and annual precipitation is 2000–2500 mm. Prominent tree species in this habitat include: *Parinari excelsa*, *Albizia gummifera*, *Erythrophleum suaveolens*, *Afrosersalia cerasifera*, *Parkia filicoidea*, *Bequartiodendron natalensis*, *Lettowianthus stellatus*, *Chlorophora excelsa*, *Anthocleista grandiflora* and several *Ficus* spp. (F. Rovero & A. R. Marshall pers. comm.). Also in drier, more seasonal forest types (i.e. semi-deciduous, gallery and ground-water forests in the Kilombero Valley).

Abundance Common at some sites. Most recently, Rovero *et al.* (2009) estimated 25,000–35,000 animals. Group encountered rates 0.11/km and 0.46/km at two sites in Udzungwa Mts (Rovero *et al.* 2012) and 1.28/km in Magombera Forest (Rovero *et al.* 2009). Population density varies widely and may be lower at higher altitudes (Dinesen *et al.* 2001, Marshall *et al.* 2005). Rovero *et al.* (2006) estimate 180–245 ind/km² in the low to medium altitude forests of Mwanihana. This means that the largest interbreeding population is likely greater than 2000 individuals. Preliminary estimates indicate at least 1000 in the 10 km² Magombera Forest (A. R. Marshall pers. comm., T. Struhsaker pers. obs.). Uncommon in the more seasonal, lowland gallery forest along the Msolwa R.

Adaptations Diurnal and arboreal. *Procolobus gordonorum* eat soil from the ground and from arboreal termite tunnels in the Mwanihana Forest (A. R. Marshall & A. Pucci pers. comm., T. Struhsaker pers. obs.), presumably for minerals and/or to adsorb anti-feedants and toxins, thereby assisting digestion and nutrient absorption. The daily activity pattern consists of several periods of feeding, travel and social behaviour that alternate with periods of rest.

Foraging and Food Folivorous. Feeding occurs off and on throughout the day and constitutes ca. 34–41% of the diurnal time budget (Rovero 2003). In a preliminary study groups moved 200–600 m/day (F. Rovero pers. comm.). Tree leaves are the most common foods. In Magombera Forest (270 m) foods included: young leaves of *Ochna* sp., mature leaf petioles of *Parkia filicoidea* and unripe, medium-sized fruit of *Treculia africana* (Struhsaker & Leland 1980). In Mwanihana Forest (ca. 700 m) Wasser (1993) recorded 45 plant food species, with the most commonly eaten being: *A. cerasifera*, *A. gummifera*, *Tabernaemontana pachysiphon*, *Uapaca paludosa*, *P. filicoidea*, *E. suaveolens*, *Lagynias pallidiflora* and *Entada pursaetha*. Leaf petioles constituted more than 60% of the feeding observations and 99% of these were mature petioles. Young leaves were the second most common food items (ca. 17%). Rovero (2003) studied two groups

in the Mwanihana Forest, one at ca. 700 m and one at ca. 300 m, and found that leaf lamina (mainly young leaves) were the most frequently items eaten (71% of feeding observations). Leaf petioles constituted only 13% of the diet. He recorded at least 52 plant food species. The most common were: *Parinari excelsa*, *Saba comorensis*, *Antiaris toxicaria* and *Sorindeia madagascariensis*. There are no data on seasonal changes in diet, age and sex differences in diet, on food availability, or on home-range size.

Social and Reproductive Behaviour Social. *Procolobus gordonorum* lives in groups of 7–83 animals (mean = 36.3, S.D. \pm 15.1, n = 60). Solitary individuals, including adult ♂♂ and adult ♀♀ with clinging infants, are uncommon (Struhsaker *et al.* 2004). No all-male associations observed. Group size is largest in large blocks of moist, old-growth, mixed evergreen and semi-deciduous forest, and smallest in small patches of drier, more seasonal, semi-deciduous and degraded forests (Struhsaker *et al.* 2004). Groups in highly degraded forests appear to have fission–fusion societies (Struhsaker *et al.* 2004). Social groups in Mwanihana Forest (large, moist, mature, mixed evergreen and semi-deciduous) have more adult ♀♀ per adult ♂♂ than those in the smaller, highly degraded and semi-deciduous Kalunga Forest (4.1 vs. 3.1), but this difference is not statistically significant (Struhsaker *et al.* 2004). Adults and subadults constitute ca. 65–69% of the group, and juveniles and infants ca. 31–35% (Struhsaker *et al.* 2004).

Little is known about the social behaviour of this species (Struhsaker & Leland 1980), but T. T. Struhsaker's unpublished observations are summarized here. Adult ♂♂ give 'leaping-about' displays while vocalizing. Adult ♂♂ give stylized presentations of their hindquarters to one another and the presenter sometimes squeals. Immatures also present their hindquarters to adult ♂♂, and sometimes adult ♂♂ present to adult ♀♀. These stylized presentations are like those of the Uganda Red Colobus *P. rufomitratus tephrosceles* (Struhsaker 1975). Adult ♂♂ within a group are tolerant of one another and often sit together. Fighting between ♂♂ of a group not seen, but supplantations over potential mates do occur. Preliminary evidence indicates that adult ♂♂ form the stable core of the group – like the groups of *P. r. tephrosceles*. Aggression between adult ♀♀ is rare. Social grooming is common and adult ♀♀ are the primary groomers.

Copulation occurs as a series of mounts with thrusting (up to at least ten mounts). The final mount of the series is terminated with a pause when ejaculation is assumed to occur. The male's feet remain on the substrate and do not grasp the female's ankles. He grasps the female's body with his hands along her sides near her back and hips. Often the ♀ shudders during the thrusting or when the ♂ is pausing (ejaculating?). This shudder may indicate orgasm. No vocalizations have been heard before, during or after copulation. Before mounting, the ♂ sometimes muzzles the female's perineum and/or briefly handles her swelling and/or clitoris with his fingers. Females being mounted usually have large perineal swellings (see below) (Struhsaker & Leland 1980). Small juveniles sometimes harass copulating pairs of adults and will even grab the adult ♂ while he is mounted. Harassed ♂♂ sometimes slap toward and supplant these juveniles. Once an adult ♀ slapped twice toward a young adult ♀ with perineal swelling who was being repeatedly mounted by an adult ♂. Eventually, the ♂ left the young ♀ and suckled from the

aggressive adult ♀. Adult ♂♂ supplant one another for priority of copulation with swollen ♀♀.

Allomothering is not observed. Mothers seem to be the only ones that carry and groom infants. Play is common among small and medium-sized juveniles.

Group ranges overlap extensively, with no indication of territoriality (T. Struhsaker pers. obs.). Groups of *P. gordonorum* associate with other primate species up to 90% of the time. Most associations are with Peters's Angola Colobus *Colobus angolensis palliatus* and Sykes's Monkey *Cercopithecus (n.) mitis* (Struhsaker & Leland 1980, Wasser 1993, Ehardt *et al.* 1999). Juvenile *P. gordonorum* play with juvenile baboons *Papio cynocephalus* on the ground. Young baboons mount and thrust adult ♀ and juvenile *P. gordonorum*. Juvenile *P. gordonorum* also groom juvenile baboons. Once, a juvenile baboon approached and tried to touch an infant *P. gordonorum* that was clinging to its mother, but the mother turned away and soon left with her infant (A. R. Marshall pers. comm., T. Struhsaker pers. obs.).

At least eight types of vocalizations are recognized in *P. gordonorum* (Struhsaker & Leland 1980, Struhsaker 2010). The longest, most complex and variable calls are those given by adult ♂♂ (nasal 'shriek-squawks' and 'quavers'). No detailed systematic study has been done on the context and probable function of these vocalizations, but the long calls of ♂♂ often seem to be associated with the initiation of group progressions. The vocal repertoire of *P. gordonorum* is most like that of *P. kirkii*.

Reproduction and Population Structure Adult ♀♀ have very large pink perineal swellings (ca. 10 × 10 cm, T. Struhsaker pers. obs.). This is apparently related to ovulation because swollen ♀♀ have complete copulations with adult ♂♂. These swellings are larger than those of any of the other East African red colobus taxa, but like those of adult ♀ Temminck's Red Colobus *Procolobus badus temminckii* in Gambia and Senegal, Upper Guinea Red Colobus *Procolobus badius badius* in Taï Forest, Côte d'Ivoire, and Preuss's Red Colobus *Procolobus preussi* in Korup N. P., Cameroon (Struhsaker 1975). Gestation length is not known. There is no pronounced birth season. Young infants, swollen adult ♀♀ and copulations occurred during all study months, i.e. Feb, Jul, Aug, Sep and Oct (Struhsaker & Leland 1980, T. T. Struhsaker pers. obs.).

Single births are the rule. No twins observed. Inter-birth intervals are not known, but ratios of infants to adult ♀ are lower in the small, semi-deciduous and heavily degraded Kalunga Forest (mean = 0.19 infants/adult ♀, n = 5 groups) than in the larger and more mature Mwanihana Forest (mean = 0.41 infants/adult ♀, n = 12 groups, or in the ground-water, and more evergreen, Magombera Forest (mean = 0.53 infants/adult ♀, n = 6 groups (Struhsaker *et al.* 2004). These ratios suggest that fecundity is adversely affected by forest degradation and loss of food trees.

Growth rates and age of physical and sexual maturity are unknown. However, long-term studies of *P. r. tephrosceles* in Kibale show that most juveniles stop nursing by 18–24 months of age, corresponding to the 2-year inter-birth interval in that population. Although older ♂♂, including adults, do suckle from adult ♀♀ in Kibale, this was extremely rare (T. Struhsaker pers. obs.). In contrast, nursing by large juvenile ♂♂ and adult ♂♂ was observed at least six times among *P. gordonorum* during relatively few hours of observation (T. Struhsaker

pers. obs.). All these observations were in degraded forest and may reflect nutritional stress resulting in a longer period of suckling and longer inter-birth intervals. No large juvenile or subadult ♀♀ were observed suckling, suggesting greater investment by mothers in their sons than in their daughters.

Population structure is probably the same as that of social groups. Mortality rates are unknown, but, unless the sex ratio is very skewed at birth, mortality must be higher among ♂♂ than ♀♀ because the adult sex ratio is 3–4 ♀♀ per ♂ in social groups. Solitary adult ♂♂ are not common enough to account for this difference. Group composition and ratios of juveniles to adult ♀♀ indicate that mortality rates among medium-sized juveniles and subadult ♂♂ are slightly higher in small, semi-deciduous and degraded forests than in larger, more mature, evergreen forests (Struhsaker *et al.* 2004). There is no information on longevity.

Predators, Parasites and Diseases The African Crowned Eagle *Stephanoaetus coronatus* is common throughout the range of *P. gordonorum* and is likely its most important predator. Although no cases of predation have been observed, *P. gordonorum* and all other species of primate in the Udzungwa Mts and Kilombero Valley give strong vocal responses to these eagles whenever they are nearby. Leopards *Panthera pardus* are common in many areas of the Udzungwas and they too may prey upon *P. gordonorum*. The local Wahehe people reportedly hunt *P. gordonorum*, particularly in the western and south-western parts of the range. There is no published information on diseases and parasites.

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix II.

Owing to its highly fragmented habitat, the largest population of *P. gordonorum* may number no more than 2000 individuals (Rodgers & Homewood 1982), but more recent estimates (Rovero *et al.* 2006) indicate that the Mwanihana population may be much larger than that. Forest fragments (and separation of *P. gordonorum* populations) within the Udzungwa Mts are maintained largely by fires. These fires prevent forest regeneration and the rejoining of forest patches (Ehardt *et al.* 1999, Dinesen *et al.* 2001, Marshall *et al.* 2001, Struhsaker *et al.* 2004). The majority of these fires are probably started by poachers. *Procolobus gordonorum* is adversely affected by logging, farming and other human activities that degrade and destroy forests (Struhsaker *et al.* 2004). Populations of *P. gordonorum* within the Udzungwa Mountains N. P. are reasonably secure, while those in Forest Reserves and on public land are not. The small forest remnants in the Kilombero Valley are particularly vulnerable. Here the local people are degrading and destroying forest through the removal of trees for timber, firewood, charcoal, building poles and farmland. For example, the Lukoga and Kalunga Forest Reserves have been destroyed over the past decade (Ehardt *et al.* 1999, T. Struhsaker pers. obs.). The Magombera Forest Reserve was officially reduced from ca. 11–15 km² to 6 km² in 1980 to provide land to settlers. However, Landsat images taken in 1999 indicated the size of Magombera to be ca. 10–11 km². In 2002 the remainder of this important forest (that holds more than 1000 *P. gordonorum* and several endemic species of plants) was almost destroyed when the government of Tanzania agreed to relocate squatters there from the nearby Kilombero Sugar Estate. Fortunately the international

conservation community launched a successful appeal that averted this destruction. None the less, Magombera remains under serious threat, as do all Forest Reserves where there is ineffective protection (e.g. Udzungwa Scarp, West Kilombero and Matundu). Hunting of *P. gordonorum* by humans is reported to occur, but there are no data on its extent.

Conservation priorities for *P. gordonorum* are: (1) annexation of the following Forest Reserves to the Udzungwa Mountains N. P.: W. Kilombero (including: Ndundulu, Nyumbanitu, Ukami, Iyondo), Udzungwa Scarp, Matundu and Nyanganje; (2) annexation of the following forests to the Selous G. R.: Magombera, Ibiki and all other forest remnants along the Msolwa R.; (3) prevention of fire to allow forest expansion and establishment of corridors between forest blocks, thereby facilitating the dispersal and increase of forest-dependent species, including *P. gordonorum*; (4) more effective law enforcement to prevent fires, illegal logging and poaching. Research priorities for *P. gordonorum*: (1) demographic and ecological studies to determine densities, natality and recruitment, demographic trends, and correlates with various ecological conditions and forest types; (2) long-term monitoring of populations to determine population

trends at various sites under various ecological conditions; (3) studies to determine ecological requirements and to facilitate forest regeneration and expansion.

Measurements

Procolobus gordonorum

HB (♀ ♀): 600, 655 mm, n = 2

T (♀ ♀): 640, 685 mm, n = 2

HF (♀ ♀): 170, 180 mm, n = 2

E (♀ ♀): 35, 35 mm, n = 2

WT: n. d.

GLS: 101, 105 mm, n = 2

GWS: 75, 80 mm, n = 2

Field measurements for two adult ♀ ♀ at MCZ (C. P. Groves pers. comm.).

Procolobus kirkii ZANZIBAR RED COLOBUS (KIRK'S RED COLOBUS)

Fr. Colobe bai de Zanzibar; Ger. Sansibar-Stummelaffe

Procolobus kirkii (Gray, 1868). Proc. Zool. Soc. Lond. 1868: 180. Zanzibar I., Tanzania.

Zanzibar Red Colobus *Procolobus kirkii* adult female.

Taxonomy Monotypic. Originally named *Colobus kirkii*. Once considered a subspecies of Western Red Colobus *Procolobus badius* and of Pennant's Red Colobus *Procolobus pennantii* (e.g. Schwarz 1928a). Now widely recognized as a full species (Groves 2001, 2005c, 2007b, Grubb *et al.* 2003). Species designation supported by craniometric (Cardini & Elton 2009) and molecular data (Ting 2008a, b), as well as by differences in the vocal repertoire (Struhsaker 2010). Synonyms: none. Chromosome number: not known.

Description Medium-sized, long-tailed monkey with striking tricoloured coat pattern. Smallest of the *Procolobus* spp. and relatively

paedomorphic (Cardini & Elton 2009). Sexes similar in colour and size but adult ♀ ♀ have slightly greater body linear measurements than adult ♂ ♂. Adult ♀ ♀ are, however, more gracile than adult ♂ ♂, as indicated by their slightly lower body weight and much smaller skull. Face and ears black with varying degrees of pink on nose and lips. Fringe around face of long white hairs, sometimes mixed with straw-coloured hairs; fringe usually longer above eyes, shorter on cheeks and chin. Crown and lower back dark brown, rufous, or reddish-brown to orange. Shoulders and upper back black, although in some individuals entire back red-brown. Throat and ventrum white or pale grey sprinkled with black hairs. Legs black with some grey on lateral surface, white or grey on medial surface. Lower hindlimbs grey and black on lateral surface. Hands and feet black. Tail ventral surface white or grey mixed with blond, dorsal surface rufous sometimes blond over distal one-third. Colour variation often pronounced among adults of same social group. No sexual dichromatism. Relative to adult ♀ ♀, adult ♂ ♂ have broader shoulders, much larger skulls, longer canines, more robust muzzle and well developed sagittal and nuchal crests (which are lacking in adult ♀ ♀). Infants: nose and lips pink; face black fringed with long white hairs; top of head, back and lateral surface of limbs black; ventrum white. Red and brown colours appear at ca. 3 months of age.

Geographic Variation None recorded.

Similar Species None within geographic range.

Distribution

Historical Distribution Endemic to Zanzibar (Unguja) I., Tanzania. Probably once occurred throughout Zanzibar I. Presumably at higher

densities on the west and central portions of the island, where deeper, more fertile soils supported higher forest, and at lower densities in the coral thicket forests of the east coast (Pakenham 1984).

Current Distribution Mainly confined to the south-central portion of Zanzibar I. in Jozani-Chwaka Bay N. P. (JCBNP), the adjacent agricultural areas to the south, and the coral thickets and mangrove swamps of Uzi I. 10 km to the south-west. At very low densities in isolated populations in the coral thickets along Zanzibar's eastern coast from Kiwengwa in the north to Mnyambiji in the south. On the west coast there is a small isolated group in the mangrove swamps of Maji Mekundu, and a translocated population of ca. 56 individuals in Masingini F. R. (Struhsaker & Siex 1998a, b). Fifteen *P. kirkii* (5 ♂♂, 10 ♀♀) introduced to Ngezi-Vumawimbi Nature F. R., NW Pemba I., Tanzania, in 1973. Here there were ca. 15–30 *P. kirkii* in 2000 (Camperio Ciani *et al.* 2001b) and 35–40 in 2011 (Butynski & De Jong 2011).

Habitat The core of the *P. kirkii* population is in the 5 km² of evergreen ground-water and seasonally flooded forest in JCBNP and a ca. 40 ha area of perennial gardens and fallow land adjacent to Jozani. Lower numbers occur in the dry coral thickets east and west of the ground-water forest and in the mangrove swamps to the north and south. *Procolobus kirkii* lives at 0–110 m. Temperatures range between 18 and 34°C. Annual rainfall is bimodal and averages 1600 mm (range 1000–2500 mm; Pakenham 1984). Each of these habitats is dominated by two to three tree species (Hall *et al.* 1992, Mturi 1993, Siex & Struhsaker 1999b). The ground-water forest is dominated by *Calophyllum inophyllum*, *Pandanus rabaiensis* and *Polysphaeria parvifolia*; the coral thickets by *Elaeodendron schlechteranum*, *Encephalartos hildebrandtii* and *Mystroxydon aethiopicum*; the perennial gardens by *Terminalia catappa* and *Cocos nucifera* (Hall *et al.* 1992, Siex 2003). There is little overlap in tree species composition among these distinct habitats.

Abundance Total population size is ca. 1500–2000 individuals, concentrated in and around JCBNP (Struhsaker & Siex 1998b). Highest densities occur in ca. 40 ha of agricultural lands adjacent to the southern border of JCBNP (784 ind/km², range 418–1209 in 1999). These high densities are due to population compression following destruction of adjacent habitat rather than to intrinsic growth (Siex 2003). *Procolobus kirkii* are rarely found in gardens located more than 2 km from Jozani Forest. In the southern portion of Jozani Forest the density of *P. kirkii* is 176 ind/km² (range 153–199; Siex & Struhsaker 1999b, Siex 2003). Density in the coral thickets adjacent to Jozani Forest is probably less than 50 ind/km² (Siex & Struhsaker 1999b). Densities appear to decrease with increasing distance from Jozani Forest.

Adaptations Diurnal and arboreal. *Procolobus kirkii* in groups in Jozani Forest and adjacent agricultural areas spend ca. 45% of the day resting (range 39–48%, *n* = 7 groups) and 29% of the day feeding (range 25–32%, *n* = 7 groups) regardless of population density. However, in agricultural areas where *P. kirkii* densities are highest, groups spend less time moving (mean = 6%, range 6–6%, *n* = 4 groups) than in Jozani Forest (mean = 12%, range 11–14%, *n* = 3 groups), and more time involved in social activities (mean = 15%, range 12–17%, *n* = 4 groups vs. 7%, range 6–8, *n* = 3 groups), and in intra-group aggression (mean = 2%, range 0.5–2.2, *n* = 4 groups vs. 0.3%, range 0.1–0.5, *n* = 3 groups; Siex 2003).

Unlike mainland species of *Procolobus*, or *P. kirkii* groups living in forest habitats (which are almost exclusively arboreal), *P. kirkii* groups living in agricultural areas spend ca. 10% of time on the ground (range 6–15%, *n* = 4 groups). In agricultural areas groups spend ca. 23% of total feeding time on the ground (range 14–32%, *n* = 4 groups). Time spent feeding on herbs on the ground varies monthly (range 0–69%, *n* = 4 groups) and peaks during the long dry season (May–Sep) when young leaves in trees are scarce (Siex 2003).

Procolobus kirkii living in perennial gardens (Cooney & Struhsaker 1997, Struhsaker *et al.* 1997, Siex 2003) and Guerezas *Colobus guereza* living in forest fragments around Kibale Forest, W Uganda (C. A. Chapman pers. comm.) are the only non-human primates known to eat charcoal in the wild. The charcoal is possibly to adsorb compounds, such as phenolics, which can be toxic and/or interfere with digestion. This behaviour in *P. kirkii* using agricultural areas may allow this species to feed more extensively on foods that are nutritious but high in phenolic content. In turn, this may partly account for its high population density in this habitat (Cooney & Struhsaker 1997, Struhsaker *et al.* 1997). Water consumption is extremely rare in *P. kirkii* groups in ground-water forest, agricultural areas and coral thickets. Drinking is, however, common (almost daily) in *P. kirkii* groups that utilize mangrove forests. Sources of water include dew and rain on leaves and tree trunks, and in holes of trees and coral stones. Frequency of drinking is directly related to time spent feeding in mangrove forests (K. Nowak pers. comm., K.S. Siex pers. obs.).

Foraging and Food Folivorous. Majority of feeding occurs in two bouts, early morning and late afternoon. Home-ranges in densely populated agricultural areas south of Jozani Forest are smaller (mean = 12.6 ha, range 7.5–16.5 ha, *n* = 4 groups) than

in the ground-water forest of Jozani (mean = 25.3 ha, range 23.3–26.8 ha, $n = 3$ groups). Average daily travel distances moved in the agricultural area are shorter (mean = 310 m, range 280–358 m, $n = 4$ groups) than in Jozani (mean = 565 m, range 507–614 m, $n = 3$ groups; Siex 2003). Young leaves and leaf buds comprise 50–60% of the annual diet (Mturi 1991, 1993, $n = 3$ groups; Siex 2003, $n = 7$ groups), but this varies from 7 to 96% on a monthly basis. In Jozani unripe fruit (predominantly *Ficus sycomorus*) accounts for 24% of the monthly diet (range 0–88%, $n = 3$ groups), but for only 5% (range 0–27%, $n = 4$ groups) in the adjacent agricultural areas. In the agricultural areas herbs comprise 15% (range 0–47%, $n = 4$ groups) of the monthly diet and are important in the May–Sep dry season when food from trees is less abundant (Siex 2003).

Food plants include 63 tree species (Mturi 1993, Siex 2003) and eight herbaceous species (Siex 2003). A few species dominate the diet. The top ten, top three and top one food species account for 85–99%, 43–85% and 17–53% of the annual diet, respectively (Mturi 1991, 1993, $n = 3$ groups; Siex 2003, $n = 7$ groups). The most common food species in the ground-water forest include *Casuarina equisetifolia*, *F. sycomorus*, *Bridelia micrantha* and *Vitex doniana*, whereas in the agricultural areas they are *Terminalia catappa*, *C. nucifera*, *Mangifera indica*, *Flueggia virosa*, *Bridelia micrantha* and *Ficus sur* (Siex 2003). A large portion of the diet, particularly in the agricultural areas, comes from exotic and crop species, mainly *C. equisetifolia*, *T. catappa*, *C. nucifera* and *M. indica*. Many food trees in the agricultural areas appear overbrowsed, probably a consequence of the *P. kirkii* population being compressed (Siex 2003, 2005).

Social and Reproductive Behaviour Social. Mean size of groups in ground-water forest and the adjacent agricultural areas is ca. 30 individuals (range 7–85, $n = 15$). Groups in coral thickets and mangrove forests are smaller (mean = 16, range 5–30, $n = 11$; K. Nowak pers. comm., K. S. Siex pers. obs.). Groups contain 1–10 adult ♂♂ (mean = 2.5, $n = 15$), 3–40 adult ♀♀ (mean = 10.6, $n = 15$) and 2–40 young (mean = 12.0, $n = 15$) (Mturi 1991, Siex & Struhsaker 1999b, Siex 2003, K. S. Siex pers. obs.). In contrast to the Ugandan Red Colobus *Procolobus rufomitratus tephrosceles* in Kibale Forest, where ♀♀ are the primary dispersers between groups, ♂ and ♀ *P. kirkii* both transfer.

Groups are not territorial and overlap in home-ranges is greater in the agricultural areas than in the ground-water forest. Almost complete overlap by multiple groups occurs in the agricultural areas (some areas shared by up to seven groups), whereas groups in the forest have exclusive use of up to 69% of their range (range 35–69%, $n = 3$; Siex 2003). Inter-group encounters in the agricultural areas range from complete tolerance to intense aggression by individuals of all ages and both sexes. Two groups may tolerate one another on one day and then behave aggressively towards one another on the next. In contrast, inter-group encounters in Jozani are less frequent, usually consisting of one group quietly supplanting another. Aggressive encounters between groups in Jozani are rare and only involve adult ♂♂, who give vocal and branch-shake displays (Siex 2003). Groups in Jozani divide into two or more foraging parties ca. 50% of the time, whereas groups in the agricultural areas are very cohesive. These differences may be due to contrasts in resource distribution and population densities. Larger, more cohesive groups may have competitive advantages in

the agricultural areas where food is more uniformly distributed, and where population densities and inter-group competition are higher (Siex & Struhsaker 1999b).

Social activities consist mainly of grooming and play. Adult ♀♀ are the predominant groomers (82% of grooming). Dependent juveniles and infants are the main groomees (55%), followed by adult ♀♀ (24%) and adult ♂♂ (16%). Play involves mainly infants and young juveniles. When older juveniles or adults participate, play is usually focused on these individuals, i.e. younger individual(s) play-attack the older one (Siex 2003). Females often copulate with several ♂♂. All adult ♂♂ in a group copulate, but dominant ♂♂ have a higher frequency of copulation. Aggression between ♂♂ over a ♀ is infrequent. Infants and juveniles often harass copulating adults (Siex 2003). Alloparenting, not reported for other taxa of red colobus, occurs rarely in the agricultural subpopulation of *P. kirkii* (Siex 2003).

Six distinct vocalizations are recognized. Long (>11 sec) spectrographically complex and variable bouts of 'warble' calls are given by adult ♂♂. The warble is distinct from the calls of other species of red colobus and are among the most complex vocalizations of any non-human primate. Sonograms of warble calls indicate two resonators operating simultaneously, a rare phenomenon among vertebrates. These long bouts of calling are typically given by adult ♂♂ prior to the onset of group progressions, among ♂♂ within groups and among ♂♂ of different groups during inter-group encounters (Struhsaker & Leland 1980, Struhsaker 1981b, 2010).

Procolobus kirkii associates with the Zanzibar Sykes's Monkey *Cercopithecus mitis albogularis* ca. 25% of the time (Struhsaker 2000a). These two species groom one another and play together. In Ngezi, preliminary observations suggest *P. kirkii* are frequently, if not almost always, in association with 'forest-living' Pemba Vervet Monkeys *Chlorocebus pygerythrus nesiotus* (Y. de Jong & T. Butynski pers. comm.).

Reproduction and Population Structure Females exhibit perineal swellings that may indicate oestrus and/or pregnancy. Both swollen and unswollen ♀♀ copulate. Length of gestation unknown. Births occur throughout the year, but most (84%) are Jul–Dec, with a birth peak in Oct in Jozani Forest (33% of births in Jozani Forest) and in Dec in the agricultural areas (24% of births in agricultural areas). This overlaps the end of the long dry season and the short wet season (Oct–Dec), the period of maximum food availability (Siex & Struhsaker 1999b, Siex 2003). Single births are the norm, but in 1999 three sets of twins were observed in the agricultural subpopulation. An unconfirmed fourth set of twins was reported in 1998. An estimated 2% of all recorded births ($n = 150$ births) between 1992 and 1999 were twins (K. S. Siex pers. obs.). There are no records of twins for other red colobus taxa. Birth-weight and size unknown. Inter-birth intervals range from ca. 32–35 months in the agricultural areas (mean = 34, $n = 5$ groups, ca. 100 adult ♀♀ over two 1-year periods), and 26–55 months in Jozani (mean = 41, $n = 5$ groups, ca. 85 adult ♀♀ over two 1-year periods) (Siex & Struhsaker 1999b, Siex 2003). Although the majority of ♀ young are weaned by two years, some ♂♂ suckle until they are sexually mature at ca. 4–5 years. Group adult sex ratio varies between habitats and over time (range 2 : 13.7, ♀ : ♂, $n = 15$), as does the ratio of young (infants and pre-dispersal juveniles) per adult ♀ (1.0 in the agricultural areas and 0.73 in Jozani) (Siex & Struhsaker 1999b, Siex

2003). Survivorship of infants and small juveniles varies between habitats and over time. Based on data from 1992–96 and 1999, ca. 35% and 43% of infants ($n = 15$ groups, $n = 150$ infants) survived the first 26 months in the agricultural areas and Jozani, respectively (Siex & Struhsaker 1999b, Siex 2003).

Predators, Parasites and Diseases Historically *P. kirkii* was most likely preyed upon by the Zanzibar Leopard *Panthera pardus adersi*, now probably extinct. There are no large eagles on Zanzibar. Occasionally *P. kirkii* are killed by humans, vehicles and dogs. No obvious external parasites were found on 69 anaesthetized *P. kirkii*. Faecal samples from approximately 55% of these individuals were infected by at least one of three helminths: *Strongyloides* in 52% of the individuals, and *Trichostrongyle* and *Trichuris* each infected 17% of the individuals. Some had secondary and tertiary infections (17% and 2%, respectively) of these three helminths (M. Eberhard & K. Glander pers. comm., K. S. Siex pers. obs.). In a second study of faecal samples from 38 individuals 26% were infected by *Trichuris*, 13% by *Trichostrongyle*, 50% by *Entamoeba* and 3% by *Giardia*. Secondary and tertiary infections were found in 21% and 3% of the individuals, respectively (J. R. Broderon & A. K. Prestwood pers. comm., T. Struhsaker pers. obs.).

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix I. *Procolobus kirkii* is one of Africa's most threatened primates because less than 2000 individuals remain in a very restricted area (Struhsaker & Siex 1998b). The main threat is habitat destruction due to cutting for building poles, fuel, charcoal production and conversion to agriculture. *Procolobus kirkii* is sometimes killed as a perceived agricultural pest. As Zanzibar's human population grows at ca. 5% per year due to intrinsic growth and immigration, these threats will intensify. Approximately half of the remaining *P. kirkii* population is outside of JCBNP where their habitats are unprotected. Of particular importance are the groups in the agricultural areas directly south of JCBNP. These groups are important both to the survival of the species and as a significant economic resource (Siex & Struhsaker 1999a, Siex 2005). In 2002 tourists paid ca. \$100,000 in fees to visit *P. kirkii* in these agricultural

areas. This revenue is shared with the local community. As *P. kirkii* population densities increase in this area due to population compression resulting from habitat destruction elsewhere, human–wildlife conflicts are likely to increase. Consequently, it is recommended that this parcel of 100 ha be purchased and annexed to JCBNP. In addition, legal protection should be given to Kiwengwa Forest, the coral thickets and mangrove forests of Uzi I. and other isolated forest patches inhabited by *P. kirkii*, and habitat corridors established between these patches and JCBNP. Recommendations for the management of *P. kirkii* on Pemba I. are presented in Butynski & De Jong (2011).

Measurements

Procolobus kirkii

HB (♂ ♂): 494 (415–555) mm, $n = 25^*$

HB (♀ ♀): 513 (448–555) mm, $n = 23^*$

T (♂ ♂): 624 (550–670) mm, $n = 25^*$

T (♀ ♀): 655 (564–745) mm, $n = 23^*$

HF (♂ ♂): 158 (140–170) mm, $n = 26$

HF (♀ ♀): 161 (146–171) mm, $n = 25$

E: n. d.

WT (♂ ♂): 7.0 (5.5–9.4) kg, $n = 26$

This subfamily (formerly family) embraces all the non-colobine African monkeys (as well as the mainly Asian macaques, *Macaca*, with one African species, the Barbary Macaque *Macaca sylvanus*). Cercopithecinae is comprised of two tribes, 13 genera with 56 species in Africa. Cercopithecinae vary greatly in size, colour and shape, ranging from the miniature, round-headed talapoin *Miopithecus* spp. to heavily built, long-faced baboons *Papio* spp., drills *Mandrillus* spp. and the Gelada *Theropithecus gelada*. Cercopithecinae embraces 13 African genera, of which the largest number of species belongs to the tribe Cercopithecini: forest guenons *Cercopithecus* spp., savanna monkeys *Chlorocebus* spp., mountain monkeys *Allochrocebus* spp., talapoin monkeys *Miopithecus* spp., the Patas Monkey *Erythrocebus patas* and the Allen's Swamp Monkey *Allenopithecus nigroviridis*. The larger, more terrestrial, large-muzzled baboons (*Papio* spp., *Mandrillus* spp. *T. gelada*) and the baboon-like monkeys (*Macaca* spp., drill-mangabeys *Cercocebus* spp., baboon-mangabeys *Lophocebus* spp. and Kipunji *Rungwecebus kipunji*) are grouped in the tribe Papionini (formerly subfamily Papioninae). The macaques are thought to be of African origin and to have emigrated to Asia about 5 mya ago (late Miocene; Stewart & Disotell 1998).

The divergence between Cercopithecinae and Colobinae occurred ca. 17.9–14.1 mya (mid-Miocene), and the split between cercopithecins and papionins at 11.6 (12.9–10.3) mya (Raum *et al.* 2005, Perelman *et al.* 2011, Roos *et al.* 2011). The earliest fossil documenting the Cercopithecinae–Colobinae split, the colobine *Microcolobus*, dates to 10–11 mya. As *Microcolobus* is a morphologically very primitive colobine, it suggests that the lower limit of the dates put forth for the divergence between Cercopithecinae and Colobinae is the more likely. That both divergences took place within Africa, raises questions as to what geographic, climatic and ecological factors were involved. In spite of the early Miocene record being relatively sparse and localized, it is sufficient to show that Victoriapithecine monkeys were diverse and relatively generalized, surviving as a recognizable entity from about 20 to 14 mya (early to mid-Miocene). The common cercopithecine–colobine lineage probably arose from some south-eastern Africa population of omnivorous/frugivorous Victoria monkeys.

Schematic map showing the possible role of Equatorial Realm and South-eastern Realm in the differentiation of Colobinae and Cercopithecinae.

The likelihood of a cercopithecine origin in southern Africa receives some implicit support from the fossil record. Seven endemic species have been recorded from the Plio-Pleistocene in the far south of Africa in spite of temperate regions normally being not greatly favoured by primates. While it might be expected that eastern Africa would be a preferred region for cercopithecines, fossil sites there remain poor in species, even during the later Pliocene, and fossil colobines, which are almost absent in the south, number six species in Plio-Pleistocene East Africa (Benefit 1999). The distribution and frequency of cercepithecoid fossils in Ethiopia shows that Cercopithecinae only overtook Colobinae as late as 3.3 mya (mid-Pliocene; Benefit 1999).

Kingdon (this volume, pp. 92–3) thinks that physical and ecological separation between a previously common cercopithecoid population in south-eastern Africa and a pre-colobine population that successfully expanded into the equatorial region was the most likely mechanism initiating the divergence between cercopithecins and colobins. The estimated timing is significant because it corresponds to tectonic events combined with major climatic shifts. Very warm, wet conditions were widespread at about 16 mya (see Volume I, Chapter 4). An expansion of forests, and with them, the broadly continuous spread of a common parental population would have been facilitated by such a humid climate. Interruption by tectonic uplift in central-eastern Africa and the drying out of formerly moist forest areas could have re-isolated the populations living in the south-east and exerted new selective pressures on the proto-cercopithecine ancestor. The likelihood that such an ancestor tended to be centred in

the south-east is heightened by still earlier and sustained drying-out of the south-west due to the circumpolar current having a cooling, drying effect from about 20 mya onwards (Barker & Burrell 1977 and see Volume I, Chapter 4).

The fact that contemporary cercopithecins and colobins differ most in dietary and digestive physiology suggests that these differences began with and might be explained by the nature of their physical separation. The biggest differences, apart from the obvious ones connected with latitude, seasonality and temperatures, would have concerned competition and disease (Elton 2007). For equatorial monkeys, the co-existence and competition of abundant, often larger-bodied and well-established ape-like primates would have defined the newcomers' niche (see Colobinae). Isolated south-eastern monkeys, by contrast, would have had less, perhaps no, competition from apes as well as less exposure to primate-specific diseases. Omnivorous diets would have been favoured by the strong seasonality of fruiting in the south-east.

Cheek-pouches have given this group their vernacular name, and their possession is the single most diagnostic feature that distinguishes Cercopithecinae from their sister subfamily, Colobinae. These exceptionally elastic buccal sacs (see illustration below) represent an adaptation whereby rapidly gathered food items can be

stored for later processing. Partly because there is scant need for cheek-pouches when food is dispersed through the forest canopy this feature has been explained as the legacy of a semi-terrestrial stage in their ancestry (Napier & Napier 1967). Exposed to greater risk from predators but also subject to more intense intra-group competition for scarcer food items, selection for the development of inaccessible 'shopping baskets' was an ingenious solution to both pressures. Cheek-pouches gave advantages to animals that could harvest rapidly and then chew and swallow in trees and at leisure. Likewise, a tighter social structure, possibly induced by sustained predation, would have favoured individuals able to rapidly ingest food items without having them snatched away by necessarily competitive conspecifics.

Cercopithecine ancestors would seem to have developed differences in size and skull structure between ♂♂ and ♀♀, both living in polygynous social groups. Among ♂♂, large, impressive and well-armed fighters would have been favoured, leading to strong sexual selection (which was only reversed among late derivative lineages, such as the arboreal guenons).

The hands of cercopithecins are less modified than those of colobines. The lower incisors lack lingual enamel, and the face and nasal bones tend to be elongated (Strasser & Delson 1987). Strasser (1988, 1994) has noted that the feet are 'mesaxonic'. That is, the central digit is the longest and extreme flexibility at the ankle is made possible by a convex distal astragalocalcaneal facet that is acutely angled to the navicula (Kingdon 1988a) and the entire plantar border of the astragalus is occupied by the medial malleolar facet.

Schematic myology of Blue Monkey *Cercopithecus mitis stuhlmanni* showing distended cheek-pouches.

Hand skeleton of a cercopithecine (Mona Monkey *Cercopithecus mona*) (left) compared with that of a colobine (Eastern Red Colobus *Procolobus rufomitratu*) (right).

Tribe PAPIONINI

Papionins: Macaques, Drill-mangabeys, Mandrills, Baboon-mangabeys, Kipunji, Baboons, Gelada

Papionini Burnett, 1828. Q. J. Lit. Sci. Arts Lond. 4.

Olive Baboon *Papio anubis*.

The papionins are medium to large-sized monkeys. They include the macaques *Macaca* spp. of Eurasia and North Africa, and the Gelada *Theropithecus gelada*, Kipunji *Rungwecebus kipunji*, drill-mangabeys *Cercocebus* spp., mandrills *Mandrillus* spp., baboon-mangabeys *Lophocebus* spp. and baboons *Papio* spp. of tropical and temperate Africa. The number of genera is seven and the number of species in Africa is 23. All are quadrupedal, with well-developed thumbs, and with forelimbs and hindlimbs more equal in length than in most other cercopithecids. Tails range from absent to long. Unlike their sister taxa in the tribe Cercopithecini, all studied papionins have the diploid complement of $2n = 42$ chromosomes. Also, unlike cercopithecins, papionine fossils are frequently found in deposits from the mid-Miocene onwards, and include at least three, and probably more, genera that are now extinct (Freedman 1957, Delson 1988, Frost 2001). *Macaca* and *Papio*/*Theropithecus* diverged ca. 5.1 mya according to Perelman *et al.* (2011), but 10.0–5.1 mya according to Roos *et al.* (2011).

A prominent ♀ sexual swelling localized in the genital region is probably ancestral for papionins (and for cercopithecins), and is retained in most tropical and sub-tropical papionine species. Of all non-human primate tribes, Papionini is most heavily weighted towards species that conduct much of their activity on the ground. This has enabled *Macaca* spp. and *Papio* spp. to occupy, and diversify in, the widespread, seasonally dry woodland and savanna habitats of tropical and temperate Africa and Eurasia. A few genera (*Cercocebus*,

Two interpretations of papionin relationships. *Top*: Earlier morphological tree (Strasser & Delson 1987). *Bottom*: Later molecular tree (Harris & Disotell 1998).

Tentative phylogenetic tree for Papionini (partly after Tosi *et al.* 2005). Arrows suggest directions of cranial extension or contraction.

Mandrillus, *Lophocebus*, *Rungwecebus*), however, are committed to tropical rainforest habitats, and some of these species are highly arboreal (*Lophocebus*, *Rungwecebus*).

All Papionini are diurnal, and most live in large, perennial social groups that include multiple adults of both sexes. In some species, groups have a complex, multi-layered internal social structure. In most papionine species the great majority of ♂♂ disperse from their natal group before breeding, while ♀ philopatry results in a group structure based on persistent, ranked, matrilineages.

Of the seven extant papionine genera that are currently recognized, all but *Macaca* are confined to the Ethiopian Faunal Realm, and of these ‘afro-papionins’ (Jolly 2007), only *Papio* currently extends beyond sub-Saharan Africa (into SW Arabia).

The afro-papionins range in size and build from the massive *Mandrillus* spp. and *Papio* spp. to the smaller and more lightly built *Lophocebus* spp., *Cercocebus* spp. and *R. kipunji*. Diverse as they are, the afro-papionins share features of cranial and genital structure, and molecular evidence confirms that they form a single clade that is the sister-group of the Eurasian macaques. These two groups are sometimes named as subtribes (Macacina and Papionina). That the macaques have no particular relatives in sub-Saharan Africa suggests that their ancestral stock left that region before its papionine fauna diversified extensively. Fossil evidence suggests that a macaque-like common ancestor of the afro-papionins, inhabited woodlands rather than equatorial forest, adapted to foraging both on the ground and in the trees, and rapidly diversified into an array of larger (and, therefore, longer-faced), more terrestrially committed, somewhat baboon-like, species.

The living afro-papionins comprise two distinct stocks that survived from this diversity – one branch includes only *Cercocebus* and *Mandrillus*, the other includes *Papio*, *Theropithecus*, *Lophocebus* and *Rungwecebus* (Davenport *et al.* 2006, Zinner *et al.* 2009a). These relationships – now supported by some details of morphology, as well as strong molecular evidence – mandate the splitting of two long-accepted groups, *Papio* + *Theropithecus* + *Mandrillus* (‘baboons’ *sensu lato*, occasionally lumped into a single genus, *Papio*), and *Cercocebus* + *Lophocebus* (‘mangabeys’, traditionally combined as genus *Cercocebus*). To complicate matters further, initial molecular evidence suggests that *Rungwecebus*, which morphologically is a mangabey similar to *Lophocebus*, is a sister-taxon of *Papio* (Davenport *et al.* 2006) that apparently occasionally hybridized with *Papio* long after the two genera diverged (Zinner *et al.* 2009a, Burrell *et al.* 2009)!

Since each branch of the afro-papionins includes both large, long-faced, ground-foraging ‘baboons’, and smaller, short-faced, more arboreal ‘mangabeys’, some convergent evolution must have occurred. Kingdon (1997, and see above) suggests that the ancestral afro-papionin was large and long-faced, in which case the features shared by mangabeys evolved at least twice, and three times if *Rungwecebus* is descended from a *Papio*-like ancestor. If, on the other hand, the ancestral afro-papionin was mangabey-like (Jolly 2007), then large body size (along with long faces, which follow automatically by processes of allometric growth) evolved at least twice, in *Papio* + *Theropithecus*, and in *Mandrillus*. Detailed study of the genetic basis of body mass variation in the different lineages holds the best promise of solving this puzzle.

Clifford J. Jolly

GENUS *Macaca*

Macaques

Macaca Lacépède, 1799. Tableau des Divisions, Sous-Divisions, Ordres et Genres des Mammifères 4.

The genus *Macaca* embraces a large number of Asiatic forms and a single African species, the Barbary Macaque *Macaca sylvanus*. Because the group is so varied and widespread in Asia it was long assumed that *M. sylvanus* was a late immigrant into Africa. Molecular analysis suggests, instead, that *M. sylvanus* arose directly from an African parental population from which the entire Asiatic radiation derives (Stewart & Disotell 1998). *Macaca sylvanus* is, therefore, likely to inhabit part of the range of the genetic founders of this genus, implying that *Macaca* may have originally arisen as a specifically trans-Saharan population of an otherwise typically tropical African monkey population. A fossil

genus with (symplesiomorphic) resemblances to *Macaca* is known from Pliocene (5.3–1.8 mya) sites in East and South Africa – *Parapapio*. Although there is now no doubt that the genus *Macaca* is indeed monophyletic, undoubted synapomorphic conditions for the genus are hard to find. The most convincing one is the presence of maxillary sinuses; as all other Old World monkeys lack these sinuses, their presence in *Macaca* most parsimoniously interpreted as a uniquely derived condition, developed convergently with the Hominoidea.

Colin P. Groves & Jonathan Kingdon

Macaca sylvanus BARBARY MACAQUE (BARBARY APE)

Fr. Magot; Ger. Berberaffe

Macaca sylvanus (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 25. 'Barbary coast', North Africa.

Barbary Macaque *Macaca sylvanus* adult male.

Taxonomy Monotypic species. Known and named by ancient Phoenicians, Etruscans, Egyptians and Greeks, including Aristotle. *Macaca sylvanus* is the only species of macaque found outside Asia, and the only representative of this group in Africa. Fossils found throughout Europe establish *M. sylvanus* as an important component of the fauna during glacial and inter-glacial periods. Genetically, *M. sylvanus* is recognized as a sister-group of Asian macaque species (Morales & Melnick 1998). Intra-specific genetic variation in the species indicates that Algerian mtDNA haplotypes are more divergent than Moroccan ones (Modolo *et al.* 2005), and that the present disjunct clustering of haplotypes may be a product of Pleistocene and Holocene climate changes that resulted in periodic forest fragmentations and interconnections. Haplotype evidence also indicates that the Gibraltar population is a result of artificial introduction of monkeys from the Rif and Akfadou (Algeria) regions.

Lateral, palatal and dorsal views of skull of Barbary Macaque *Macaca sylvanus* adult male.

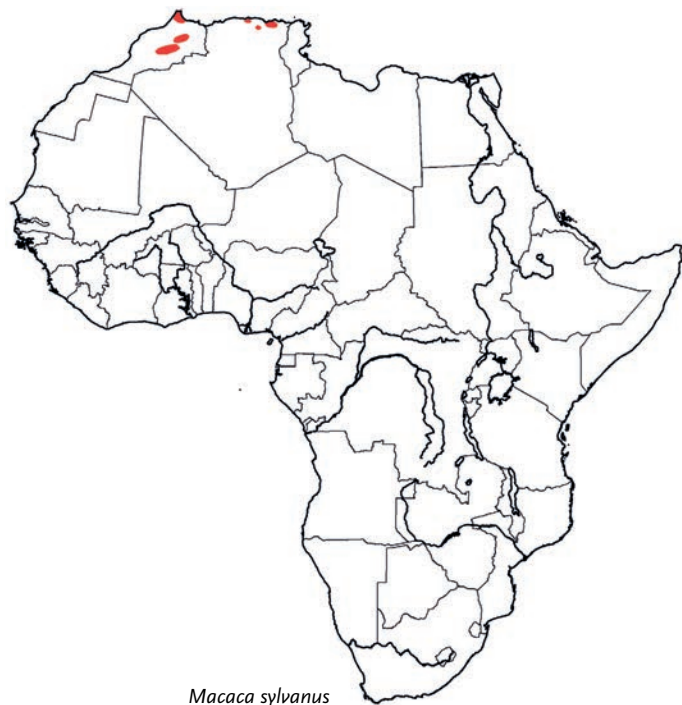

Synonyms: *ecaudatus*, *inuus*, *pithecus*, *pygmaeus*. Chromosome number: $2n = 42$ (Dutrillaux *et al.* 1982a, Romagno 2001).

Description Medium-sized, heavy-set, semi-terrestrial monkey. Sexes alike in colour. Adult ♀ about 68% as heavy as adult ♂. Sides of the face bounded by streaks of dark brown hair, while the face is thinly haired and lightly pigmented. Crown variegated as on the back, but tends to be more brightly coloured. Tail vestigial and inconspicuous; may be absent. Dorsum of subadults and adults typically strongly variegated, pale (buffy to golden-brown to burnt orange) and dark (blackish). Ventrums and legs thinly haired, pale buff to whitish. At birth, dorsum blackish, and ventrum pelage thin and slightly paler (Deag & Crook 1971, Fa 1984e). The gradual transition from blackish infantile pelage to variegated brownish juvenile pelage begins at ca. 45 days of age and is completed by ca. 145 days of age. Pelage length in juveniles is less than in subadults and adults, but the colouration is generally similar. *Macaca sylvanus* is the only macaque in which the ischial callosities of the ♂ meet in the midline, a presumably symplesiomorphic feature with the sub-Saharan African Papionini.

Geographic Variation Erythristic forms reported in Morocco (Panouse 1957, Aulagnier & Thevenot 1986), but geographic patterns in pelage have not been studied. No body mass differences detected between Algerian and Moroccan forms (Fooden, 2007).

Similar Species None within geographic range.

Distribution Endemic to extreme North Africa. Mediterranean Coastal BZ. Extant natural populations of *M. sylvanus* are disjunctly distributed in the Atlas and Rif Mountains in Morocco and Algeria from ca. 31°15'N to 36°45'N, and ca. 07°45'W to 05°35'E. Moroccan and Algerian populations separated by a gap of ca. 700 km, and narrower gaps separate populations within Morocco and Algeria. Holocene extinction records ($n = 28$ populations) indicate that

distributional gaps were narrower within historic times, and that the range recently extended east of Algeria to ca. 10° E into Tunisia (Joleaud 1931). This pattern is not a result of habitat selection as presumed by Taub (1977), but a consequence of range restriction and isolation in the higher altitude habitats as demonstrated by Fa (1984d). No non-human primate is sympatric with *M. sylvanus* (Aulagnier & Thevenot 1986, Kowalski & Rzebik-Kowalska 1991, Majolo *et al.* 2013).

The population on Gibraltar is not native. There is no mention of *M. sylvanus* in ancient commentaries on Gibraltar (Joleaud 1931, McDermott 1938). The oldest known reference to monkeys on Gibraltar is in an eighteenth century document preserved in the British Museum (Sayre 1862, cf. Buffon 1789) that indicates that 'a great quantity' of Barbary Macaques were introduced into the British garrison in 1740 (Busk 1877, Trouessart 1905, Fa 1981). Additional introductions occurred in 1813 and 1860 (Fa & Lind 1996). In 1925 the population was reduced to three individuals (Kenyon 1938), and in 1938–45 major restocking occurred (Fa 1984d). A recent study of mtDNA variation in the existing Gibraltar population indicates that this population includes individuals of both Moroccan and Algerian ancestry (Modolo *et al.* 2005).

Lydekker (1893–1894) and Forbes (1894) indicated that, during the nineteenth century, *M. sylvanus* inhabited southern Spain in the vicinity of Gibraltar. This appears to have been an error (Joleaud 1931, cf. Kelaart in Newman 1846). In a subsequent publication, Lydekker (1916) omitted Spain from the species' distribution. *Macaca sylvanus* from European parks were deliberately released at three localities in Morocco during the 1980s (de Turckheim & Merz 1984, Fa, 1986a). The most successful re-introduction was in 1985, when more than 40 formerly captive individuals were deliberately released near Nador, a northern coastal town at ca. 35°00'N, 03°00'W (Chivers 1984, Aulagnier & Thevenot 1986, Anonymous 1988).

Habitat Habitats occupied by *M. sylvanus* include Atlas Cedar *Cedrus atlantica* forest, Moroccan Fir *Abies maroccana* forest, and oak forests (Evergreen Oak *Quercus ilex*, Portuguese Oak *Quercus faginea*, Algerian Oak *Quercus canariensis*, Cork Oak *Quercus suber*), scrub, grassland and rocky ridges dominated by herbaceous vegetation. The known altitudinal distribution is 400–2300 m; over half of the 62 altitudinal records are at or above 1800 m (Fa *et al.* 1984, Fooden 2007).

Climate in the range of *M. sylvanus* is essentially Mediterranean, but greatly modified by altitude. At lower altitudes, in semi-arid scrub, mean annual rainfall is low (<400 mm) and concentrated during winter months; summers are very dry and hot (>30°C; Trewartha 1981, Fa 1982). At altitudes >1500 m mean annual precipitation is >800 mm, with much of this falling as snow from Dec to Mar (snow may fall Sep–May). In Deag's (1984) Aïn Kahla (Middle Atlas, Morocco) study area, snow fell during 39 days and lay on the ground in appreciable quantities for 82 days. Complete snow cover has a marked effect on the monkeys' feeding behaviour (Fa 1982, Deag 1984, Mehlman 1984). Winter temperatures in the Moyen Atlas and Rif Mountains are consistently low and drop to –18°C (Deag 1984, Drucker 1984, Mehlman 1984). Summer temperatures here are high, however, at >30°C.

Abundance In 1984, Fa *et al.* (1984) estimated the total natural population of *M. sylvanus* to be 14,000–23,000 individuals (9000–17,000 in Morocco, 5000–6000 in Algeria). In 1992, Lilly

& Mehlman (1993) indicated that the total population had declined to 10,000–16,000 individuals and, in 2005, Modolo *et al.* (2005; cf. Camperio Ciani & Palentini 2003) reported a further decline from 10,000 individuals. The number of *M. sylvanus* in Morocco declined from 4000–5000 individuals in 2005 to ca. 3000 individuals in 2008 (Van Lavieren & Wich 2010, A. Camperio Ciani pers. comm.). The Rif Mountains macaque populations, assessed in 1980 by Fa (1982) to be >1000 individuals in five sub-populations, were recently surveyed by Waters *et al.* (2007) and found to hold only ca. 300 individuals. The current situation for *M. sylvanus* in Algeria is unstudied. Current world wild population ca. 5000–6000 (Majolo *et al.* 2013).

Population density in *M. sylvanus* (12–70 ind/km²) apparently attains its maximum in relatively undisturbed cedar or mixed cedar/oak habitats (Deag 1984, Ménard & Vallet 1996, Van Lavieren & Wich 2010). As expected, degraded habitats, particularly those in the Moroccan Rif, support population densities that are much lower at (0.4–4.5 ind/km²; Mehlman 1989).

Adaptations Diurnal and semi-terrestrial. *Macaca sylvanus* is a highly adaptable species that is found in a variety of habitats with very different climates. The species exhibits much ecological plasticity (Ménard 2003). Fa (1994) discusses anatomical gut characteristics that correlate with *M. sylvanus*'s high herbaceous diet.

Macaca sylvanus spends most of the daylight hours on the ground; reported mean frequency of daytime terrestriality varies from 68% to 83% in Morocco, and from 58% to nearly 100% in Algeria. Infants and juveniles tend to be less terrestrial than adults (Merz 1976, Deag 1985, Ménard 1985, Ménard & Vallet 1986, Machairas *et al.* 2003). At Afennourir and Cèdre Gouraud (=Gouroud), Morocco, juveniles were 70% terrestrial and adult ♂♂ were 81% terrestrial (Machairas *et al.* 2003). Frequency of terrestriality also varies seasonally (Deag 1985, Ménard & Vallet 1986, 1997). Flee into trees to escape danger (Merz 1976, Deag 1985). Sleep in trees (Taub 1977, de Turckheim & Merz 1984, Mehlman 1989, Hammerschmidt *et al.* 1994) or in caves on rocky cliffs (MacRoberts & MacRoberts 1971, Alvarez & Hiraldo 1975, Fa *et al.* 1984, Mehlman 1984). Alvarez & Hiraldo (1975) report that *M. sylvanus* in the Rif Mountains migrate to lower altitudes during winter, but this is anecdotal.

Foraging and Food Omnivorous. Home-ranges of groups of *M. sylvanus* are, on average, smallest (18 ha, 12–25, n = 2) in the Moroccan Moyen Atlas (Fa 1986b, Drucker 1984), largest (804 ha, 307–1200, n = 6) in the Moroccan Rif (Fa 1986b, Mehlman 1989) and intermediate (280 ha, 39–424, n = 3) in the Algerian Grand Kabylie (Ménard *et al.* 1990, Ménard & Vallet 1996). Group home-ranges frequently overlap in all three areas (Deag & Crook 1971, Rumsey & Whiten 1972, Ménard & Vallet 1997, Mehlman 1989). A group in cedar-oak forest (Tigounatine-Djurdjura, Algeria) with a home-range of 376 ha shared 48% of its home-range with other groups, while a group in deciduous oak forest (Akkfadou) with a home-range of 424 ha shared 80% of its home-range with other groups (Ménard & Vallet 1996).

Day ranges vary considerably from site to site and from day to day at each site. In cedar-oak forest day ranges were 473–3240 m (mean 1856, n = 115 days) at Tigounatine-Djurdjura, 892–2274 m (mean 1583, n = 41 days) at Aïn Kahlaj and 1401–4188 m (mean 2794, n = 40 days) at Seheb, Middle Atlas, Morocco. In deciduous oak

forest at Akfadou, day range was 799–3472 m (mean 2336, n = 104 days) (Ménard & Vallet 1997, N. Ménard pers. comm.).

Diet of *M. sylvanus* includes a wide variety of plants (Fa 1984b). In the Moroccan Moyen Atlas at least 107 species of plants are eaten (cf. Deag 1983, Drucker 1984); in the Moroccan Rif, at least 100 species are eaten (Fa 1983a, Mehlman 1988); and in the Algerian Grand Kabylie, at least 130 species are eaten (cf. Ménard 1985, Ménard & Vallet 1986, 1996). The 100 species of food plants in the Moroccan Rif constitute 51% of 195 species of seed plants identified as present in that area. Similarly, the 130 species exploited in the Algerian Grand Kabylie constitute 48% of 271 species identified as present in that area. Also consumes fungi, lichens, mosses and animals (Deag 1983, Fa 1984b, Ménard 1985). Agricultural crops have been raided by *M. sylvanus* since at least the early sixteenth century (Leo Africanus 1896 edition, Mehlman 1988).

Eats flowers, fruits, seeds, seedlings, leaves, buds, bark, gum, stems, roots, bulbs and corms (Fa 1984b, Mehlman 1988, Ménard & Qarro 1999). Fa (1994) compared *M. sylvanus* diets with other *Macaca* spp. to show the species' high reliance on herbaceous plants, in comparison to the more frugivorous Asian macaques. Diet of *M. sylvanus* shows high seasonal variation (Deag 1983, Mehlman 1984, Ménard 1985, Ménard & Vallet 1986). Diet also varies by habitat. Seeds and leaves are the main foods (ca. 60–75%) in lowland oak forests in the Algerian Grande Kabylie (Ménard & Valet 1986), but more fruits are consumed in the Moroccan Moyen Atlas (Deag 1983, Drucker 1984, Ménard & Qarro 1999). In the higher altitude coniferous forests they eat large volumes of fir and cedar leaves during periods of high snowfall when conditions impede them from feeding on ground vegetation (Deag 1983, Drucker 1984, Mehlman 1988).

Animal prey includes snails, earthworms, scorpions, spiders, centipedes, millipedes, grasshoppers, termites, water striders, scale insects, beetles, butterflies, moths (including larvae), ants (including nests) and tadpoles (Fa 1983a, 1984b, Mehlman 1984, 1988, Ménard & Vallet 1986). Semi-free-ranging *M. sylvanus* monkeys pursue and/or catch birds, Red Squirrels *Sciurus vulgaris* and young European Rabbits *Oryctolagus cuniculus* but have not been observed to eat them (Kaumanns 1978, de Turckheim & Merz 1984); mice are, apparently, ignored.

Feeding occupies an average of 24% and 25% of daytime hours at two localities in the Moroccan Moyen Atlas (Fa, 1986b, Machairas *et al.* 2003), and also occupies 24% and 25% of daytime hours at two localities in the Algerian Grande Kabylie (Ménard & Vallet 1997). In winter, water may be obtained by eating snow (de Turckheim & Merz 1984, Mehlman 1988).

Social and Reproductive Behaviour Social. Mean size of 68 groups is 27.1 individuals (7–88). Mean group size is smallest (18.3 individuals, 10.0–27.5, n = 27) in the Moroccan Rif, largest (50.2 individuals, 27–88, n = 8) in the Algerian Grande Kabylie and intermediate (28.6 individuals, 12–40, n = 33) in the Moroccan Moyen Atlas. Group size generally is stable, but it is unstable in the population that inhabits a rocky habitat in the Djurdjura Mts, Algeria (Ménard *et al.* 1985, 1990, Ménard 2002); in this marginal habitat, groups frequently split into subgroups that subsequently reunite in various combinations. Solitary ♂♂, as far as 7 km from the nearest group, occur in the Moroccan Rif (Mehlman 1985, 1986).

Within natural groups, the number of adult ♂♂ averages only slightly less than the number of adult ♀♀. The ratio of adult ♂♂ to adult ♀♀ averages 0.70 in the Moroccan Moyen Atlas, 0.99 in

the Moroccan Rif and 0.84 in the Algerian Grande Kabylie (Whiten & Rumsey 1974, Taub 1980a, Fa 1982, 1986b, Deag 1984, Drucker 1984, Ménard *et al.* 1986, 1990, Mehlman 1989, Ménard & Vallet 1993a, Hammerschmidt *et al.* 1994, Ménard & Qarro 1999, Camperio Ciani & Machairas 2003, Machairas *et al.* 2003).

Most studies of *M. sylvanus* groups indicate that their composition is reasonably constant. Adult ♀♀ to immatures (infants and babies) ratio at Aïn Kahla, Moyen Atlas (Deag 1984) was 1:0.9 (1:0.5–1:1.2, $n = 5$), and 1:1.3 and 1:1.4 for the same area in a later study (Taub 1978). For the Rif Mountain groups studied by Mehlman (1984), the adult ♀:immature ratio averaged 1:1.2. The proportion of immatures in Algerian groups varied between 0.41–0.59 at Tigounatine, and 0.42–0.58 at Akfadou, according to the year (Ménard & Vallet 1996).

During the mating season, pairs of ♂♂ and oestrous ♀♀ form consortships (i.e. temporary sexual associations) in the course of which copulations occur (Taub 1978, 1980a, de Turckheim & Merz 1984, Fa 1986b). The duration of consortships varies from <1 min to 93 min (median 13, $n = 297$ consortships) in the Moroccan Moyen Atlas (Taub 1980a), and from ca. 1–240 min (85% less than 8 min) in Gibraltar (Fa 1986b). In Morocco the formation of most consortships is initiated by ♀♀ (55%; ♂♂ 28%; mutually originated 17%), and ♀♀ also are responsible for the termination of most consortships (72%) (Taub 1980a, Todt & Pohl 1984, Small 1992). The mean rate of exchange of consortship partners by ♀♀ in the Moroccan Moyen Atlas is one per 19.9 min (Taub 1980a, Small 1992, Paul *et al.* 1993). In a group that included six mature ♀♀ and 11 mature ♂♂, ♀♀ consorted with a mean of 6.1 ♂♂ per day (3–10 ♂♂; Fa 1986b, Small 1993, Ménard *et al.* 2001).

As in other *Macaca* spp., the ♂ typically mounts the ♀ dorsoventrally by gripping her trunk and shanks with his hands and feet, respectively (Fooden & Aimi 2005). *Macaca sylvanus* is a single-mount ejaculator. That is, copulations usually are restricted to a single mount–dismount sequence, during which the ♂ ejaculates following a brief series of pelvic thrusts (Taub 1980a, 1982, Mehlman 1986, Kuester & Paul 1989, 1992, Van den Bergh 1991, Semple 1998). The mean (S.D.) duration of 205 copulations in Aïn Kahla group was 8.7 (± 1.1) sec (6–14), and the mean number of pelvic thrusts to ejaculation was 9.1 (± 1.8 , 5–21; Taub 1980a, Mehlman 1986, Kuester & Paul 1989, 1992). The mean interval between consortship formation (see above) and onset of copulation was 2.3 min (<1–16 min).

Harassment of copulating pairs by other group members was not observed at Aïn Kahla (Taub 1980a), but 100 incidents of harassment by ♀♀ were observed in the Salem, Germany, semi-natural population (Kuester & Paul 1996). Of these harassment incidents, only 5% resulted in successful displacement of the harassed target. During the peak mating season at three Algerian localities, Ménard *et al.* (1985) observed an average of 1.1–1.3 copulations/h. During the concluding phase of copulation the ♀ utters a characteristic series of loud, low frequency grunts (Taub 1980a, Todt & Pohl 1984, Paul 1989, Van den Bergh 1991, Small 1992, Todt *et al.* 1995, Semple 1998). Males apparently are able to detect differences among copulation calls produced by ♀♀ at different stages of the oestrous cycle (Pohl & Todt 1984, Semple & McComb 2000, Fischer & Hammerschmidt 2002).

Interactions between infants and older ♂♂ are more frequent in *M. sylvanus* than in most *Macaca* spp. or *Papio* spp. (Fa 1984e, Taub 1985, Maestripieri 1998, Thierry 2000). Lahiri & Southwick (1966), who studied two newborn infants in captive groups for 12 weeks,

found that the infants consistently associated with the dominant ♂♂ in their respective groups for ca. 8% of the observation hours; during these interactions, the infants were held, groomed, or carried by the dominant ♂♂. Similar interactions between infants and adult ♂♂ (without grooming, however) were observed during a six-month study on Gibraltar (MacRoberts 1970, MacRoberts & MacRoberts 1971, Burton 1972).

In addition to dyadic male–infant interactions, Deag & Crook (1971), who studied natural *M. sylvanus* groups for two months in the Moyen Atlas, Morocco, observed triadic interactions involving one infant and two older ♂♂. In these interactions one of the ♂♂ (typically lower ranking) carried an infant to another ♂ (typically higher ranking) and presented the infant to that ♂. Deag & Crook hypothesized that presence of the infant tended to reduce tension between the low-ranking ♂ and the nearby high-ranking ♂. Accordingly, Deag & Crook designated dyadic interactions as ♂ care and triadic interactions as ‘agonistic buffering’.

Evidence concerning possible harm to infants in male–infant interactions is equivocal. Taub (1980b) reports that older ♂♂ handled infants carefully and that infants in the 535 interactions that he observed in the Moyen Atlas sustained no injuries. However, Fa (1986b) indicates that three infant deaths on Gibraltar were the result of ‘kidnapping’ by the dominant ♂, and Paul & Kuester (1988) attribute at least nine infant deaths at Salem to a similar cause. At Kintzheim, France, ♂♂ may carry and otherwise interact with dead infants in approximately the same way that they interact with live infants (Merz 1978). The functional significance of triadic male–infant interactions has been vigorously debated. On one side of this debate an exploitative agonistic-buffering function has been assigned to these triadic interactions (Deag & Crook 1971, Deag 1980, Small 1993, Paul & Kuester 1996). On the other side, an altruistic kin-investment function has been proposed (Taub 1975, 1978, 1980b, 1984, 1990, Smith & Pfeffer-Smith 1982, Taub & Redican 1984, Riechelmann *et al.* 1994). Recent genetic studies do not indicate that male–infant triads preferentially consist of closely related individuals (Kuester & Paul 1986, 2000, Paul *et al.* 1992, 1996, Ménard *et al.* 1992, 2001).

Macaca sylvanus is not territorial. As noted above, home-range overlap among groups can be extensive (up to at least 80%). Of 13 observed contacts between groups, only three (23%) were agonistic (Deag & Crook 1971, Mehlman & Parkhill 1988). Inter-group encounters at Riffian are described by Mehlman & Parkhill (1988) as either ‘neutral’ (in which little inter-group interaction took place) or ‘intermediate’ (in which one group slowly approaches another, causing it to retreat without any overt agonism exhibited). Deag (1973) observed similar inter-group encounters and displacement in the Moyen Atlas, with inter-group agonism being uncommon.

Fischer & Hammerschmidt (2002) provide an overview of *M. sylvanus* vocalizations using spectrographic displays of calls linked to accompanying facial gestures and the contexts in which each call is given, with special regard to the age and sex of the caller. The vocal repertoire of *M. sylvanus* mainly consists of ‘screams’, ‘shrill barks’, ‘geckers’, and low-frequency ‘pants’ and ‘grunts’, with gradation within and between call types. *Macaca sylvanus* typically produce series of several consecutive calls. Habitat, social structure and phylogenetic descent affect the morphology of the repertoire and call diversity in comparison to other species. Brum *et al.* (2005) report that *M. sylvanus* utter specific vocalizations while monitoring interactions

of other group members. As they did not direct other behaviours to the interacting group members, these vocalizations were referred to as 'vocal comments'. Most adult ♂♂ and adult ♀♀ of two studied groups produced low-amplitude calls when observing close contact interactions of other group members. The acoustic features of these calls varied with characteristics of the situation suggesting that such calls might not be directed towards the agents of the situation, but towards other group members. The vocal comments may signal the callers awareness of the observed interaction and possibly attract the attention of others to the situation.

Reproduction and Population Structure Although morphology of the glans penis and uterine cervix provides important taxonomic characters relevant to species relationships in the genus *Macaca* (Fooden 2006), little information is available concerning these structures in *M. sylvanus*. The glans in *M. sylvanus* is bilobed and relatively broad, as in the *silenus* taxonomic group (Fooden 1975). Hill (1974) provides measurements of two *M. sylvanus* bacula: length 11.2 mm, 11.5 mm; dorsoventral diameter 3.1 mm, 3.5 mm; and transverse diameter 2.2 mm, 2.0 mm.

During the mating season, *M. sylvanus* ♀♀ exhibit coordinated reproductive cycles of sexual skin swelling, oestrous behaviour and menstruation. During subsequent mating seasons, the swellings increase in area and thickness and often become bluish-grey until age ca. 7–15 years, after which the swellings gradually decrease in size, ultimately becoming inconspicuous beyond age ca. 20 years. At the stage of maximal development, the area of the circumanal swelling (ca. 200 cm²) is approximately four times as large as the area of the lateral vulval swellings (Fa 1984a, Möhle *et al.* 2005).

Of 12 ♀♀ in the Gibraltar population that were closely monitored during the 2001–02 mating season, ten exhibited two cycles of tumescence and detumescence, and two exhibited three cycles. Tumescence is associated with an increasing faecal oestrogen level, and detumescence is associated with an increasing faecal progesterone level. Ten of the monitored ♀♀ became pregnant during one of their cycles, and all ten of these ♀♀ exhibited a post-conception tumescence. The median interval between successive tumescence peaks was ca. 32 days (27–44 days; Möhle *et al.* 2005).

The oestrous cycle consists of a period of ♀ proceptive/receptive sexual behaviour, marked by a gradually increasing copulation rate, abruptly followed by a period of ♀ sexual inactivity (Kuester & Paul 1984a, 1989, Ménard *et al.* 1985, Paul & Kuester 1987, Small 1990b). Maximal copulation rate in an oestrous cycle is correlated with maximal sexual swelling/turgescence. Most ♀♀ exhibit two oestrous cycles per mating season (Small 1990b, Semple 1998). A female's first oestrous cycle of the season tends to be the longest, including 2–4 weeks (rarely 6 weeks) of sexual activity and ca. 2 weeks of sexual inactivity; subsequent oestrous cycles include about 1 week of sexual activity. Most ♀♀ are probably fertilized during the first oestrous cycle of the season (Kuester & Paul 1984b). During an oestrous cycle, several ♀♀ in the same group (five of 13 in one group; six of 14 in another) may be concurrently sexually active (cf. Ménard *et al.* 1985, Semple 1998).

The menstrual cycle in *M. sylvanus* has a median length of ca. 32 days (27–44, *n* = 10), including a median duration of menstrual bleeding of four days (Panouse 1957, Möhle *et al.* 2005). The median interval between the last day of maximal sexual skin swelling and the first day of menstruation is 16 days (12–18, *n* = 11; Möhle *et al.* 2005).

al. 2005). Post-conception bleeding occurs at ca. 3 weeks after fertilization (Kuester & Paul 1984a, Möhle *et al.* 2005).

In the Salem semi-natural population, gestation length was measured as the interval between the date of an infant's birth and the date of its mother's last copulation during a conceptional oestrus (Didier & Rode 1936, MacRoberts & MacRoberts 1966, Kuester & Paul 1984a, Paul & Kuester 1987). The mean (S.D.) gestation period for 67 ♀ infants was 165.3 (± 4.6) days (145–178), and for 56 ♂ infants was 163.2 (± 5.4) days (145–177). The difference between the mean gestation periods of ♀ infants and ♂ infants is statistically significant (*p* < 0.02; Paul & Kuester 1987). Weight at birth is ca. 450 g (Small 1990a). In a composite sample of 874 births reported in semi-natural populations, twinning frequency is 0.8%. Viability of *M. sylvanus* twins is low; of the ten pairs reported, six pairs were stillborn, 2.5 pairs died within eight days after birth and only 1.5 pairs survived.

Matings in natural populations of *M. sylvanus* are restricted to Sep–Apr (wet season), with a mating peak during Nov–Jan. Births in natural populations are restricted to Feb–Sep. Birth seasons vary locally. The median birth date at Akfadou (3 May) is significantly earlier than that at nearby Tigounatine (19 May) (Ménard & Vallet 1996).

In the Algerian Grand Kabylie, ♀♀ typically do not produce their first infants until >5 years of age (18 of 32 ♀♀), which indicates that these ♀♀ generally do not become sexually mature (capable of pregnancy) until >4.5 years of age (Ménard *et al.* 1985, Ménard & Vallet 1996). Only 1 of 37 ♀♀ (3%) in this population produced an infant at age four years, and none of 43 ♀♀ produced an infant at age three years. Males in the Algerian Grand Kabylie are capable of ejaculatory copulation at age 5–7 years, although they are not yet full grown (Ménard *et al.* 1985). The same is true of ♂♂ in the Moroccan Moyen Atlas (Deag 1980).

Macaca sylvanus infants begin to experiment with solid foods at age ca. 45 days and, during the next few months, mothers begin to resist nursing attempts by their infants (Burton 1972, Rumsey & Whiten 1972, Fa 1984e), although an infant generally continues to nurse sporadically until ca. 1 year of age or longer (if its mother does not produce a new infant). An orphan in a natural population was fully capable of feeding itself at age 6–8 months (Deag 1980, Kuester & Paul 1984a, Paul & Thommen 1984a, b, Ménard *et al.* 1985). In the Salem semi-natural population, older mothers wean their infants later than younger mothers (Paul *et al.* 1993).

Of 1040 *M. sylvanus* newborns, 538 were ♂♂ and 502 were ♀♀ (♂ : ♀ ratio = 1.07). Although the overall difference is not statistically significant (*p* > 0.10), the number of ♂ newborns equals or exceeds that of ♀ newborns in five of the seven available samples. Neonatal sex ratio is related to maternal rank in the Salem sample (Paul & Kuester 1990): the ♂ : ♀ sex ratio for newborns by high-rank mothers (102/74 = 1.38) significantly exceeds that for infants produced by low-rank mothers (86/95 = 0.91; *p* < 0.05); sex ratio for newborns of mid-rank mothers is intermediate (92/96 = 0.96).

The longest life-span reported for *M. sylvanus* ♀♀ in the semi-natural population at Salem is ca. 30 years (Burton & Sawchuk 1974, 1982, cf. Paul *et al.* 1993). The longest life-span reported for ♂♂ at Salem is 25 years (Kuester *et al.* 1995). The mean post-reproductive life-span for ♀♀ is around six years (3–8) in seven individuals at Salem that died after reaching estimated ages of at least 25 years (Paul *et al.* 1993). The post-reproductive life-span in a 25-year-old ♂ at Salem (see above) was one year (Kuester *et al.* 1995).

The mean annual birth rate in *M. sylvanus* is 0.59 in three natural groups (Mehlman 1989, Ménard & Vallet 1993b) and 0.70 in five semi-natural groups (Burton & Sawchuk 1982, Fa 1984d, Small 1990a, Paul *et al.* 1993, Fa & Lind 1996, Kümmerli & Martin 2005). Among factors known to affect the birth rate are natural food supply (Ménard & Vallet 1993b), age and parity of sexually mature ♀♀ (Paul & Thommen 1984a, Paul & Kuester 1988, Paul *et al.* 1993, Ménard & Vallet 1996), and human disturbance of semi-natural groups (Fa 1988). The mean annual death rate in three semi-natural populations ranged from 3.4% to 5.8% (Fa 1984d).

The mean annual population growth rate in two natural Algerian populations of *M. sylvanus* varies from 4.8% in a deciduous oak forest at Akfadou to 14.6% in a cedar–oak forest at Tigounatine. The annual growth rate in the Tigounatine population approaches that reported in the provisioned captive population maintained at Salem (18.3%).

Predators, Parasites and Diseases There are few records of ill health for wild *M. sylvanus* populations. Deag (1984) reported on the general good health of his study groups, although ailments such as coughs, sneezing and vomiting were recorded. Injuries and malformations were relatively rare. There was also a low incidence of wounding during mating seasons, reflecting the less aggressive nature of *M. sylvanus* in comparison to other macaques (Ruehlmann *et al.* 2005). *Macaca sylvanus* in Gibraltar have suffered from disease outbreaks (such as gastro-enteritis, viral pneumonia), probably as a consequence of higher densities and, at times, inadequate provisioning (Fa 1986b).

Under natural conditions the Leopard *Panthera pardus* and Barbary Lion *Panthera leo leo* probably were the major predator of *M. sylvanus* when these three species were broadly sympatric (Aulagnier & Thevenot 1986, Fa 1986a). Large eagles presumably also are predators; *M. sylvanus* respond to Golden Eagles' *Aquila chrysaetos* approach with alarm calls (Mehlman 1984); domestic dogs elicit a similar response, but Red Foxes *Vulpes vulpes* and Common Jackals *Canis aureus* do not (Ménard *et al.* 1986). In semi-free-ranging European populations, *M. sylvanus* give alarm calls in response to snakes, raptors and dogs (Paul & Kuester 1988, Fischer & Hammerschmidt 2002). In a European zoo an infant was killed by a hawk (Salzert 1978).

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix II.

The main factor responsible for the decline in the number of *M. sylvanus* is apparently anthropogenic destruction of habitat (Fa 1986a, Camperio Ciani *et al.* 2005, Majolo *et al.* 2013). Habitat loss and degradation caused by human consumption of wood, fire, clearing for cultivation, and over-grazing by sheep and goats have been inferred as major reasons for the decline of the species (Taub 1977, Fa *et al.* 1984, Camperio Ciani 1986, Ménard & Vallet, 1993a, Van Lavieren & Wich 2010). Because water shortage has become more severe in the last ten years, shepherds inhabiting forest habitats have been forced to settle near water sources. The shepherds' enclose open water sources with cement wells to extract water for their herds. As a result, *M. sylvanus* and other wildlife are excluded from water sources. This may force the monkeys to strip bark in order to obtain water (Ménard & Qarro 1999, Camperio Ciani *et al.* 2001a).

Live trade of *M. sylvanus* is presumed important, though not high. Most specimens taken from the wild are for the international pet

trade. In the 1960s, a large number of *M. sylvanus* were captured for use in laboratories in Casablanca, Tangier and Spain, but this is no longer permitted in Morocco. *Macaca sylvanus* are frequent captured and sold as pets in Morocco with reports of capture for the international pet trade dating back to 1977 (Deag 1977). Van Lavieren (2004, 2008) found that trade has increased markedly and estimates that 300 infants are taken annually from the wild in Morocco. This number now greatly exceeds the maximum sustainable offtake and thus poses a threat to wild populations (Van Lavieren & Wich 2010).

Macaca sylvanus receives some protection in Morocco under national and international legislation. Capture and sale of *M. sylvanus* is prohibited by the National Hunting Regulation (Art. 8). Collection and export of *M. sylvanus* are regulated by a system of permits in Morocco, but enforcement of the legislation is inadequate. The National Eaux et Forêts is the responsible authority. Deag (1977) mentions a maximum quota for trade of 100 macaques annually in Morocco. In 2000, the European Union suspended imports of *M. sylvanus* from Algeria and Morocco because such trade was deemed to have a harmful effect on the conservation status of the species.

Most *M. sylvanus* habitats in Algeria are found within protected areas. This is not the case in Morocco. The large population in the Rif Mts is partially included in Talassemtane N. P., but this Park is too small to support many macaques. The many *M. sylvanus* that are in oak forests and scrub are not in protected areas (Waters *et al.* 2007). A planned national park in the Moyen Atlas cedar/mixed forests would protect a substantial proportion of Moroccan *M. sylvanus*. In both Morocco and Algeria, the national forestry departments are responsible for management and protection of flora and fauna. However, the Moroccan National Eaux et Forêts until recently believed that *M. sylvanus* numbers in the Moyen Atlas forests were too high (due to the disappearance of predators), and that macaques are responsible for the degradation of cedar forests through their bark stripping behaviour. Suggestions have been made in the past to cull and/or translocate some of the monkeys. These actions would be premature without a thorough scientific investigation into the still unresolved conflict issues.

Measurements

Macaca sylvanus

HB (♂♂): 634 ± 25.7 (605–653) mm, n = 3

HB (♀♀): 557 ± 11.5 (540–566) mm, n = 4

T (♂♂): 14 ± 12.2 (0–22) mm, n = 3

T (♀♀): 1 ± 2.0 (0–4) mm, n = 4

HF (♂♂): 179 ± 7.9 (170–185) mm, n = 3

HF (♀♀): 168 ± 1.7 (166–170) mm, n = 4

E (♂♂): 51 ± 1.2 (50–52) mm, n = 3

E (♀♀): 10 ± 1.0 (8–12) mm, n = 18

WT (♂♂): 14.5 ± 1.8 (10.0–18.0) kg, n = 33

WT (♀♀): 9.9 ± 1.0 (8.0–12.0) kg, n = 18

GLS (♂♂): 136 ± 2.3 (133–138) mm, n = 5

GLS (♀♀): 119 ± 5.5 (114–126) mm, n = 4

GENUS *Cercocebus*

Drill-mangabeys (White-eyelid Mangabeys)

Cercocebus É. Geoffroy, 1812. Ann. Mus. Hist. Nat. Paris 19: 97.

Large, semi-terrestrial monkeys endemic to the moist forests of equatorial Africa. The most useful characters for distinguishing among the seven species of *Cercocebus* are the shape of the crest on the crown, and colour of the face, eyelids, crown, dorsum and ventrum. The number of species in this diverse genus has been long debated. In the past the species of *Cercocebus* were allocated to two taxonomic groups – indeed, formerly only two species were recognized (e.g. Schwarz 1928d, Allen 1939, Dandelot 1974, Wolfheim 1983). Booth (1956a) recognized five species, while Hill (1974) recognized three species. Note, however, that the Sanje Mangabey *Cercocebus sanjei* was not discovered until 1979, and not named until 1986. More recently, Groves (1993) and Grubb *et al.* (2003) provisionally recognized three species, but anticipated that more might be recognized given further study. Six species were recognized by Kingdon (1997) and Groves (2001, 2005c). Seven species are recognized here.

The genus *Cercocebus* is more restricted in content than was once thought. Studies by Barnicot & Hewett-Emmett (1972) and Cronin & Sarich (1976) found that the blood proteins of the *albigena/aterrimus*-Group are distinctly different from the *agilis/torquatus*-Group, and morphological investigations by Groves (1978) showed that the Grey-cheeked Mangabey '*Cercocebus albigena*' and the Black Mangabey '*Cercocebus aterrimus*' are closer to *Papio* than to *Cercocebus*. On this basis, Groves revived the name *Lophocebus* for these two species. Differences included the flat, instead of upturned, nasal bones; the facial skeleton more flexed on the braincase; the skull broader in general; the very elongated auditory tube; and the suborbital fossa. The suborbital fossa, the main feature that was formerly considered to unite all mangabeys, is less deep anteroposteriorly than in *Lophocebus* but the dorsoventral and mediolateral diameters are greater. Variations in suborbital fossa depth (which they term 'maxillary excavations') are discussed in McGraw & Fleagle (2006).

Fleagle & McGraw (2002) have shown that in some features of the postcranial skeleton, *Cercocebus* resembles *Mandrillus* and differs from all other Papionini in many respects. Notably, the scapula is supero-inferiorly deep compared to its dorsoventral length, the humerus has an exceptionally broad deltoid plane with projecting medial and lateral crests, the ilium is broad basally, and the medial lip of the patellar groove is at least as prominent as the lateral. The same authors also pointed out that, as in *Mandrillus*, *Cercocebus* have greatly enlarged posterior premolars, doubtless reflecting their reliance on hard nuts and seeds collected from the forest floor (Hoshino 1985, Fleagle & McGraw 2002). Molecular studies (Cronin & Sarich 1976, Disotell *et al.* 1992, Goodman *et al.* 1998) converge in indicating that *Cercocebus* have a closer genetic affinity with the Drill *Mandrillus leucophaeus* and Mandrill *Mandrillus sphinx* than with *L. albigena* or *L. aterrimus* (i.e. 'Baboon-mangabeys', Kingdon 1997).

The morphological feature that was considered diagnostic and to unite *Cercocebus* and *Lophocebus*, the peculiar suborbital fossa, has no perceptible function and is best interpreted as a buckling of the jugal plate and the result of phylogenetic retraction in a long-jawed ancestor. First interpreted in these terms by Kingdon (1971) (who linked these retractions and reduced body size with significant

changes in socio-sexual behaviour), this explanation is also considered probable by C. J. Jolly (pers. comm.) but they differ in their views of the likely sequence of evolutionary events that led to lighter build, retracted muzzles and more arboreal habits both in *Cercocebus* and *Lophocebus*.

Kingdon thinks that the facial shortening in the two mangabey groups is convergent (a view endorsed by Groves, 2001), and that *Papio*, *Mandrillus* and *Theropithecus* all represent highly differentiated descendants of a common, long-faced, ancestor living 7–9 mya (late Miocene), possibly of south-eastern African origin. Kingdon envisages sustained forest dwelling in an already large-muzzled, sexually dimorphic *Mandrillus*-like lineage giving rise to *Cercocebus* as a lighter-bodied, more arboreal and westerly taxon. That the shorter-muzzled mangabeys might have derived from longer-muzzled types was first proposed by Dobroruka & Badalec (1966); by this reckoning, the most conservative skull structure within *Cercocebus* is found in the Red-capped Mangabey *Cercocebus torquatus*, a species that occupies a 2500 km long arc from Bénin to the Congo R. Here they live in moist forests, mostly within 200 km of the coast. Within a generally western vicinity, Kingdon envisages an early *Cercocebus* lineage altering its social and spatial relations (probably fewer expressions of inter-male competition among smaller-bodied animals in substantially diminished and more stable home-ranges). Later, populations expanded in all directions but most notably eastwards to the Indian Ocean. Also, judging from the recent discovery of a mid-Pliocene *Cercocebus*-like mangabey in Sterkfontein, South Africa, mangabeys once penetrated deeply to the south, presumably during periods of particularly benign climate (Gilbert 2007). Apart from changing climates, the ultimate influence on what is now a highly fragmented and relictual distribution for *Cercocebus* spp. (especially the two easternmost species, Tana River Mangabey *C. galeritus* and *C. sanjei*) is probably the rise of competing species of cercopithecines (guenons), most particularly members of the generalized Gentle Monkeys-Group *Cercopithecus (nictitans)*, which ranges over much of tropical and south-eastern Africa.

C. J. Jolly (pers. comm.) also thinks that competition from cercopithecines was a significant factor in afro-papionin evolution and that there were always many semi-terrestrial cercopithecids throughout the African Neogene. He envisions the spread of open habitats giving rise to a more terrestrial, long-faced 'baboon' resembling the fossil genus *Parapapio*, and that this stock underwent facial retraction. Unlike Kingdon, however, he thinks that facial retraction happened only once, and that it was *Cercocebus* mangabeys that gave rise to *Mandrillus*, which re-acquired long faces and a larger body. Likewise, he sees 'pre-*Lophocebus*' mangabeys (which would have resembled *Cercocebus*) giving rise to *Papio* (initially in the southern savannas), to *Theropithecus* (initially in the northern savannas), and to (arboreal) *Lophocebus* in the forests of central Africa. In Jolly's view, *Mandrillus* and *Papio* became large-bodied and long-faced convergently. In this way he explains why all mangabeys look cranially much alike – because they are conservative. They do not look like macaques, because of the 'cranial retraction' phase in

their common ancestor; Nakatsukasa (1994b, 1996) also thought that most features of mangabeys were derived from larger, more terrestrial ancestors. Patterns of shape variation in papionins and the bearing of cranial differences on their biogeography, phylogeny and systematics have been further discussed by Singleton (2002), Leigh *et al.* (2003) and Frost *et al.* (2003).

Groves takes a slightly different view, noting striking, presumably symplesiomorphic, resemblances between the two extremities of the genus, Sooty Mangabey *Cercocebus atys* in the extreme north-west and *C. sanjei* in the extreme south-east. Central African Agile Mangabey *Cercocebus agilis* also retains a very plesiomorphic morphology. Centrifugal speciation mechanisms have produced two highly autapomorphic centrally distributed species: *C. torquatus*, a derivative of the *atys*–*sanjei* axis, and Golden-bellied Mangabey *Cercocebus chrysogaster*, derived from *C. agilis* and convergent on *Mandrillus*.

Cercocebus share with *Mandrillus* a nasal ridge that runs between the zygomatic arch and the incisors; vastly inflated in *M. sphinx*, this ridge is most prominent in *C. torquatus* (Gilbert *et al.* 2006, McGraw & Fleagle 2006, Gilbert 2007). These authors also note that *Mandrillus* spp. and *C. torquatus* exhibit virtually identical orientations and development of the temporal lines. Based on these cranial features, they suggest that the shorter-muzzled *C. agilis* exhibits primitive cranial morphology while *C. torquatus* and *Mandrillus* spp. display the derived condition. Jolly (2007) has also suggested that the foraging behaviours and social structures of *Mandrillus* spp. are presaged in *Cercocebus*.

This is a diametrically opposite conclusion from that of Kingdon, who regards *M. sphinx*, *M. leucophaeus*, *C. torquatus* and *C. chrysogaster* as four divergent lineages but all more conservative than the five shorter-muzzled (and slightly more arboreal) *Cercocebus* spp. He notes that large-bodied primates that move about in large groups rely upon resources that are seasonal in abundance and widely dispersed, requiring large ranges that cross many vegetation types. These expansive subsistence strategies are most likely to develop in habitats with strongly seasonal climates and clumped sources of food. As such, the majority of baboon-like monkeys, both extant and fossil, come from non-forest habitats, where they probably originated, and that were most widespread during drier periods. Because masting and other expressions of localized and temporary abundance also occur in forests there are opportunities (over the course of several climatic fluctuations and through evolutionary time) for *Mandrillus*-like primates to transplant or adopt similar expansive patterns of land use within the forest zone. Thus large groups of large imposing ♂♂ can intimidate both predators and competitors in forests just as well as in woodlands, thickets and savannas and exaggerated ♂ dimorphism can be selected for in any of these habitat types.

Only very rich resources can sustain an expansive system that can regularly bring many hundreds of animals together. That fact helps explain the restriction of *Mandrillus* to the wettest and most highly diversified area of forest in Africa. Once an ancestral *Mandrillus*-like lineage had become established in such an area residual limitations in their expansive strategy would have become most apparent on the margins of their range. Here conditions would have become less predictable, especially during arid phases of climate. Here ancestral *Mandrillus* would have been subject to selection for more intensive, efficient and localized use of resources, especially when fruit sources become fragmented. These more marginal conditions,

even if ‘temporary’, would have favoured selection for more cryptic, smaller-bodied animals living in smaller groups in smaller home-ranges, often within sub-types of vegetation. Such animals would have had less use for intense inter-male competition resulting in strong selection for greatly reduced ♂ dimorphism. These would have been plausible geographic, ecological and behavioural contexts for the emergence of *Cercocebus*. In the now well-studied cranial morphology of *Cercocebus* and *Lophocebus* Kingdon envisages a common trend for sexually dimorphic, long-muzzled baboon-like ancestors with expansive subsistence strategies giving rise to retracted-muzzled mangabey-like primates with more intensive ways of living and not the other way round. In spite of such controversies, all authors, including Grubb (1978, 1982), are in general agreement that *C. torquatus* is a sister taxon of *Mandrillus*. It can be predicted that additional molecular data will eventually settle which of these scenarios is the more likely.

Goodman *et al.* (1998) and Perelman (2011) calculated that *Cercocebus* and *Mandrillus* separated only 4–5 mya (early Pliocene), too recently to qualify for generic separation under their proposed criteria. If *Cercocebus* and *Mandrillus* are to be combined, and one of us (C. G.) supports this, the prior name is *Cercocebus*. If this date, derived from molecular clock techniques, is correct, it would have occurred during a short period of warmer and wetter climate, during which forests probably expanded after the prolonged and widespread aridity of the Messinian period (and establishment and spread of the Sahara). Not only would formerly isolated forests have spread and connected, but adaptation to forest-living and a trend towards more arboreal habits (particularly in marginal or terrestrial primates) would have been favoured. This would support the supposition that the main expansion of *Cercocebus*, notably for the antecedents of today’s eastern species, would have been during this more benign part of the mid-Pliocene and before cold and aridity set in again later in the Pliocene. It seems likely that the two eastern species of *Cercocebus* that remain today (i.e. *C. galeritus* and *C. sanjei*) first became isolated and diverged during the arid late Pliocene.

Some resemblance between the distinctive ‘whoop-gobble’ loud-calls of *Lophocebus* and *Cercocebus* has been invoked as evidence for a close relationship between these two genera, but sonograms demonstrate a closer structural resemblance between the loud-calls of *Cercocebus* and *Mandrillus* than with those of *Lophocebus* (Gautier 1999). The ‘whoop’ is a separate component that alerts all neighbours to pay attention to the coming species-specific ‘gobble’ (for which listeners have to wait several seconds). The ‘whoop’ only has to be loud. As such, the attention-getting first part of the loud-call (i.e. the ‘whoop’) can derive from any pre-existent loud-call.

The two more widespread West African species, *C. atys* and *C. torquatus*, are phenotypically very different from one another (*contra* Groves 1978). If, as we suspect, they are *not* sister species, then the species that is geographically and, to some degree, phenotypically intermediate between them, White-naped Mangabey *Cercocebus lunulatus*, poses numerous questions. The differences among *atys*, *torquatus* and *lunulatus* are consistent. There are no specimens obtained from within the geographic range of *lunulatus* that could be taken for a specimen of *atys* or *torquatus*, or that even vary in their direction. Keeping *lunulatus* as a subspecies of *atys* is therefore meaningless. The intermediate condition of *lunulatus* raises at least three possibilities. First, that *lunulatus* is a species of hybrid origin that has long since

stabilized as a homogeneous entity. Second, that *lunulatus* represents a population that has conserved an intermediate condition in the evolution of *atys* from a shared ancestry with *torquatus*. This condition could be characterized as a progressive cline, *atys*–*lunulatus*–*torquatus*, going from primitive to derived or vice versa. Third, and least likely, *lunulatus* could be a population conserving features of an ancestor common to both *atys* and *torquatus*. See McGraw & Fleagle (2006) for a discussion of clinal distribution of characters.

The curious phenotypic and geographic aspects of this genus defy any simple hypothesis of interrelationships. The identification of *Parapapio*, from the mid-Pliocene of Sterkfontein, South Africa, as *Procercopithecus* (Gilbert *et al.* 2006, Gilbert 2007) is of great interest here. The mid-Pliocene was, as noted above, a time of forest expansion as the climate became wetter and warmer. The South African occurrence of a proto-mangabey would, if correct, indicate that the distribution of this genus has contracted hugely over time and reinforces the possibility that species that are geographically closest to one another at the present time are not necessarily the most closely related (e.g. *C. torquatus* and *C. agilis*, *C. galleritus* and *C. sanjei*).

Cercopithecus chrysogaster is a particularly puzzling species: in its robust build, considerable sexual dimorphism, slightly elongated

skull, shorter tail and reddish-gold throat and ventrum, it is the most *Mandrillus*-like of the *Cercopithecus* spp. How to interpret these resemblances remains contentious. Field studies of this threatened species would be of considerable interest and might help resolve whether *C. chrysogaster*'s *Mandrillus*-like characteristics are indicative of a convergent, conservative or shared derived condition.

Members of the genus are all semi-terrestrial, feeding on hard seeds and invertebrates that abound on the forest floor (especially in the case of *C. agilis* and *C. galleritus*) after the recession of floods in the riverine environments that they favour. *Cercopithecus* and *Mandrillus* both forage for nuts and other hard objects using their hands and arms with a fast and muscular style. There are, according to Groves (1978), Nakatsukasa (1994b, 1996), Fleagle & McGraw (1999, 2002), adaptive features in their limb anatomy that are not found in *Lophocebus*, *Papio* or *Theropithecus* (see above). The stiff-legged stance and the tail, which is characteristically held stiffly forward over the back from an angle at the base, contrast strongly with the flexible gait and exceptionally long, ragged and mildly prehensile tail of *Lophocebus*.

Jonathan Kingdon & Colin P. Groves

Cercopithecus galleritus TANA RIVER MANGABEY

Fr. Mangabé de la Tana; Ger. Tana-Mangabe

Cercopithecus galleritus Peters, 1879. Monatsb. K. Preuss. Akad. Wiss. Berlin 1879: 830. Mitole, Tana R., Kenya (02° 10' S, 40° 10' E).

Tana River Mangabey *Cercopithecus galleritus* adult male.

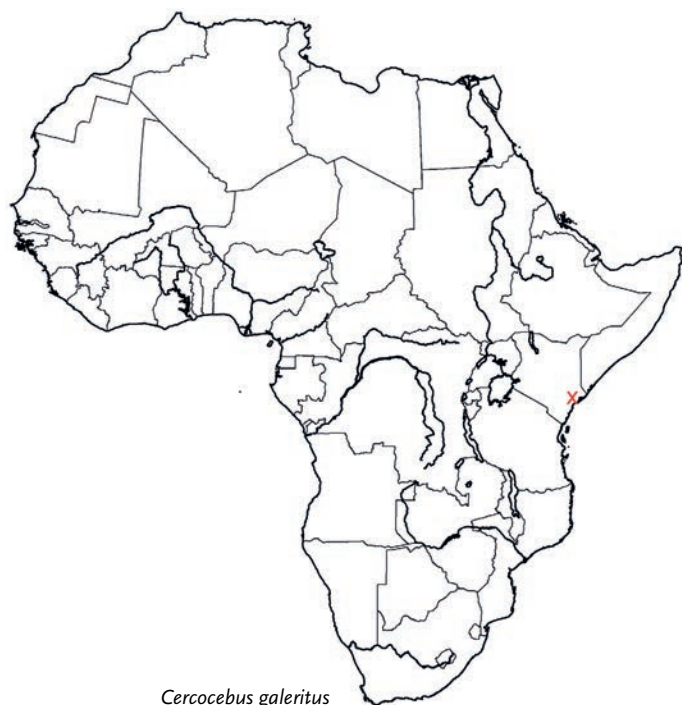

Taxonomy Monotypic species. Originally given full species status by Peters (1879), and that classification retained by Elliot (1913b), Dobroruka & Badalec (1966), Groves (1978, 2001, 2005c) and Kingdon (1997). Considered by some to be a subspecies *C. g. galleritus*, with the conspecifics Sanje Mangabey *C. g. sanjei*, Golden-bellied Mangabey *C. g. chrysogaster* and Agile Mangabey *C. g. agilis* (Schwarz 1928d, Dandelot 1974, Hill 1974, Napier 1981, Grubb *et al.* 2003). Synonyms: none. Chromosome number: 2n = 42 (Groves 1978).

Description Medium-sized, long-tailed, gracile, semi-terrestrial, pale greyish-brown monkey with conspicuous crest on crown and white eyelids. Sexes alike in colour. Adult ♀ has HB and tail measurements ca. 75% as long as adult ♂. Pelage long, coarse, wavy and dull. Face bare, black skin rimmed with white pelage. Cheeks and temples whitish. Eyelids bright white, contrasting with face. Forehead white, hair projecting forward. Ears black. Crest on crown with long (>100 mm), limp, medium grey to blackish-brown hairs, parted down the middle, sweeping back and to the sides, and falling over the ears. Dorsum pale yellowish-grey to greyish-brown, tinged olive. Throat and ventrum yellowish-white. Ventrum pelage long and sparse. Outer lower forelimbs dark grey to blackish-brown. Inner limbs white to yellowish-grey. Hands and feet dark grey to blackish-brown. Tail dark grey to blackish-brown with paler terminal ca. 25%. Tail with slight tuft. Hairs of crown, neck and shoulders annulated. Callosities joined in ♂♂ and separate in ♀♀. Occasionally holds tail in 'question-mark' pose above the back. Infants with pink face, ears and limbs, and without the characteristic crest on crown.

Geographic Variation None recorded.

Similar Species None within the small geographic range of this species.

Distribution Coastal Forest Mosaic BZ. Endemic to flood-plain forests along 60 km of the lower Tana R., SE Kenya, from Kanjonja in the north to Tana Delta in the south (01° 24' S to 02° 24' S, 40° 06' E to 40° 19' E, 20–40 m asl) (Butynski & Mwangi 1994, 1995, Hamerlynck *et al.* 2012).

*Cercocebus galeritus*

Habitat Flood-plain forest and adjacent woodland and bushland. Forest within the geographic range occurs in 71 fragments that range in size from 1 to 1100 ha and comprise a total forest area of ca. 37 km². In 1994 mangabeys inhabited 27 of these forests and occupied a total area of ca. 26 km² (Butynski & Mwangi 1994, 1995). Mangabeys move up to 1 km through non-forest habitat between forests (Wieczkowski 2010). Flood-plain forest comprised of plant species from four floristic regions, and characterized by high inter-forest species variation that is determined by forest location on the flood-plain (Medley 1992). The most common tree species are *Phoenix reclinata* (13%), *Polysphaeria multiflora* (12%), *Garcinia livingstonei* (7%) and *Sorindea madagascariensis* (5%) (percentages are of all trees ≥ 10 cm DBH sampled in 49,850 m² in 31 forests; D. Mbora & J. Wieczkowski pers. obs.)

Forest size and density of trees > 10 cm DBH are the only variables that are significantly positively correlated with mean number of mangabey groups/forest (Wieczkowski 2004).

Lower Tana R. is a highly seasonal environment. Mean annual rainfall 470 mm (120–1020 mm; Decker 1994a). Rainfall mostly limited to Mar–Jun and Nov–Dec. Mean monthly minimum daily temperatures are 17–25 °C, and mean monthly maximum daily temperatures are 30–38 °C (Butynski & Mwangi 1994). The coolest months are Jul–Sep and the hottest months are Oct–Jun.

Abundance Common within its small ca. 26 km² range. Densities within individual forests range from 0–6.8 animals/ha. Density within the entire forested area of the range is ca. 0.45 animals/ha. A total of 48 groups located during a survey of the entire range in 1994 when the total population was estimated at 1000–1200 animals (Butynski & Mwangi 1994). This is a decline from the 1975 estimate of 1200–1600 (Marsh 1978). Changes in the size of this population from 1972–94 are summarized in Butynski & Mwangi (1994).

Adaptations Diurnal and semi-terrestrial. Spends 56% of time on ground, 32% of time in vegetation to 10 m, and 12% of time

above 10 m ($n = 1$ group; J. Wieczkowski pers. obs.). *Cercocebus* spp. have a dental morphology and muscular jaws believed to be adapted to eating seeds and hard nuts (Fleagle & McGraw 2002). This interpretation is supported by the preponderance in the diet of seeds (Kinnaird 1990a, Wieczkowski 2003) that have high crushing resistance values (Wieczkowski 2009). Also adapted to the seasonality of fruit availability, and the temporal and spatial heterogeneity of its habitat, through flexibility in diet, grouping, ranging patterns and inter-group interactions (Homewood 1976, Kinnaird 1990a, Wieczkowski 2003). Spends more time foraging and moving when food less available, and more time in social behaviours when food more available (Kinnaird 1990a).

Foraging and Food Frugivorous. Average time spent feeding (eating and foraging) is 58% (46–65, S.D. = 8, $n = 6$ groups; Homewood 1976, Kinnaird 1990a, Wieczkowski 2003). Time spent eating is fairly constant throughout day, while foraging peaks morning and mid-day (Kinnaird 1990a). Feeds predominantly on the ground and up to 2 m (Homewood 1978a). Average daily travel distance for 431 sample days is 1511 m (1040–2618, S.D. = 562, $n = 10$ groups). Annual home-ranges ca. 17, 19, 20, 30, 47, 51, 53, 57, 70 and 101 ha (mean = 46.5 ha). Amount of overlap with neighbouring groups varies from 25% (70 ha range) to 36% (53 ha range) to 100% (17 and 19 ha ranges) (Homewood 1976, Kinnaird 1990a). Home-range size varies negatively with habitat quality and population density, and positively with group size (Homewood 1976, Kinnaird 1990a, Wieczkowski 2005b, Mbora *et al.* 2009).

Predominantly eats seeds and fruit, but also stems, leaves, insects and fungi. Adult ♀ observed with a small bird that was discarded (M. F. Kinnaird pers. comm.) and adult ♂ photographed repeatedly pulling an adult African Wood Owl *Strix woodfordii* from a tree-hole but left without killing the owl (Schuetz & Razakarivony 2004). Average annual diet is 44% fruit (26–71, S.D. = 18, $n = 6$ groups) and 32% seed (7–46, S.D. = 16, $n = 6$ groups; Homewood 1976, Kinnaird 1990a, Wieczkowski 2003), although there appears to be a shift to a preponderance of seeds in the latter two studies: fruit 32% (26–36, S.D. = 5, $n = 4$ groups) and seeds 42% (34–46, S.D. = 5, $n = 4$ groups). Eats unripe, ripe and dry fruit and seeds (Homewood 1976, Kinnaird 1990a, Wieczkowski 2003).

Observed feeding on total of 96 species of plants, though eight species each individually account for $> 10\%$ of the annual diet (*Aporrhiza paniculata*, *Acacia robusta*, *Diospyros mespiliformes*, *Ficus sycomorus*, *Hyphaene compressa*, *Pachystela msolo*, *Phoenix reclinata* and *Saba comorensis*) (Homewood 1976, Kinnaird 1990a, J. Wieczkowski pers. obs.). Species and items in the monthly diet closely follow the fruiting seasons of the top food species. High food availability from Nov–Apr; low food availability from Jun–Oct (Homewood 1976, Kinnaird 1990a).

Social and Reproductive Behaviour Social. Lives in multifemale groups with one or more adult ♂♂. Changes in group size from 1972 to 1992 are summarized in Butynski & Mwangi (1994). Mean group size has fluctuated over time: 26 (17–36, $n = 4$; Homewood 1976); 20 (15–28, $n = 7$; Kinnaird & O'Brien 1991); and 31 (6–62, $n = 17$; J. Wieczkowski pers. obs.). Mean for all years is 27 animals/group, consisting of a mean 2.2 adult ♂♂, 7.0 adult ♀♀, 2.4 subadult ♂♂, 2.0 subadult ♀♀, 9.6 juveniles and 3.3 infants ($n = 9$; Kinnaird & O'Brien 1991, J. Wieczkowski pers. obs.).

Agonistic behaviour includes eyelid flashes, lunges, chases, grabs, bites, grapples, branch shaking and vocalizations. These are described by Gust (1994), who did not observe damaging contact or serious wounding during a 210 h, 6-week study. Amicable behaviour includes stylized presentations, grooming and play. Territorial behaviour varies temporally. When fruit is scarce, groups avoid one another, using different areas of their overlapping ranges. When fruit is abundant and uniformly distributed, groups often move and feed together for several hours. When fruit is patchily distributed and defendable, territorial behaviour is exhibited. This includes approaching the other group, which may lead to an aggressive encounter. Aggressive encounters have site-dependent outcomes (Kinnaird 1990a, 1992b).

The dominant ♂ secures the majority of copulations with oestrous ♀♀ (Kinnaird 1990b). Copulation described by Gust (1994).

Adult ♂♂ emit a loud, long 'whoop-gobble' call that aids in inter-group spacing. Mean duration of the whoop-gobble is 90.5 sec (S.E. = 10.0, n = 136; Gust 1994). About 66% of whoop-gobbles are given between 06:30h and 11:00h (n = 562; Kinnaird 1992b). This call is audible to a distance of >1 km. Other vocalizations include 'screams' and 'wherrs' that are given during aggressive encounters (Gust 1994), as well as 'grunts', a bleating contact call and various alarm calls (J. Wiczowski pers. obs.).

Does not form polyspecific associations with other species of primates. Although often found with Pousargues's White-collared (Sykes's) Monkey *Cercopithecus mitis albitorquatus*, associations do not occur more often than expected by chance (Homewood 1976). Sometimes grooms Sykes's Monkey and the Tana River Red Colobus *Procolobus rufomitratus rufomitratus* (J. Wiczowski pers. obs.). Interactions with Yellow Baboon *Papio cynocephalus* are variable (fights, avoidance, supplants, toleration). Seen mounting and grooming Harvey's Duiker *Cephalophus natalensis harveyi* on several occasions (Homewood 1976, M. F. Kinnaird pers. comm., J. Wiczowski pers. obs.).

Reproduction and Population Structure Adult ♀♀ exhibit large, monthly, oestrous swellings lasting 4–5 days (Kinnaird 1990b). Mean gestation is 180 days (S.E. = 4.49, n = 7 pregnancies; Kinnaird 1990b). Details of parturition given in Kinnaird (1990b). Single births during Aug–Apr (Kinnaird & O'Brien 1991), generally a time of high food availability (Homewood 1976; Kinnaird 1990a). Twins not observed. About 63% of adult ♀♀ give birth during a given year (9–100%, n = 6 groups; Homewood 1976, Kinnaird 1990b). Infants suckle until 6–10 months; inter-birth interval is 18–24 months (Homewood 1978b). Infanticide by adult ♂♂ during dominance turnovers is thought to occur (Kinnaird 1990b). Post-conception sexual swelling lasting 8–9 days occurs after the first two months of pregnancy (mean = 62 days, S.E. = 3.6, n = 7), and two of seven pregnant ♀♀ under study copulated at this time (Kinnaird 1990b).

Based on studies of closely related species, ♀♀ probably first breed at ca. 6.5 years. Males probably first breed at seven years. Longevity estimated at 19 years (Homewood 1976, Kinnaird & O'Brien 1991). Adult ♂ to adult ♀ ratio in groups ranges from 1 : 2 to 1 : 6 (n = 9 groups). Adult and subadult ♂ to adult and subadult ♀ ratio in groups ranges from 1 : 1.2 to 1 : 6 (n = 11 groups). Adult to young (subadult, juvenile and infant) ratio in groups ranges

from 1 : 0.8 to 1 : 2.8 (n = 9 groups; Homewood 1976, Kinnaird & O'Brien 1991, J. Wiczowski pers. obs.). In one well-studied group of 20 mangabeys, two out of four adult ♂♂, and one out of five infants died in one year (Homewood 1976).

Predators, Parasites and Diseases Central African Rock Python *Python sebae* thought to be the most common and important predator (Homewood 1976, M. F. Kinnaird pers. comm., J. Wiczowski pers. obs.). Likely predators include African Crowned Eagles *Stephanoaetus coronatus* (Wiczowski *et al.* 2012), Martial Eagles *Polemaetus bellicosus*, Nile Crocodiles *Crocodylus niloticus* (Homewood 1976, J. Wiczowski pers. obs.) and Leopards *Panthera pardus*. An adult ♀ attacked by an (unidentified) eagle died of her wounds two days later. Twelve nematodes (*Abbreviata* sp., *Ascaridia galli*, *Capillaria* sp., *Heterakis* sp., *Oesophagostomum* sp., *Physaloptera* sp., *Streptopharagus* sp., *Strongyloides fuelleborni*, *Toxascaris* sp., *Toxocara* sp., *Trichostrongylus* sp. and *Trichuris trichura*) and three protozoans (*Entamoeba coli*, *E. histolytica*, *E. hartmani*) found in mangabey faecal samples from 82 individuals. The most common parasites were *E. coli* (20% of individuals), *T. trichura* (20%), *Heterakis* sp. (10%) and *Trichostrongylus* sp. (6%). *Entamoeba histolytica*, pathogenic in humans, was found in 1% of individuals (Mbora & Munene 2006).

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix I.

Ranked in 2002 as one of the world's 25 most threatened primates (Konstant *et al.* 2003). Greatest threat is forest degradation through taking of forest products and loss of forest for farmland (Butynski & Mwangi 1994, 1995), both of which increased dramatically after 1994 (Wiczowski & Mbora 2000, Wiczowski 2005a, Moinde-Fockler *et al.* 2007). Of special concern is decimation of local *P. reclinata* populations by humans (Kinnaird 1992a, Wiczowski & Mbora 2000); this palm is the mangabey's top food resource (Homewood 1976, Kinnaird 1992a, Wiczowski & Kinnaird 2008). Between 1994 and 2000, ca. 30% of the forest cover within the range of *C. galleritus* was lost to clearance for agriculture (Butynski & Mwangi 1994, Wiczowski 2005a). There was a 20% loss of forest inside the Tana River Primate National Reserve (TRPNR; 169 km²) and a 41% loss of forest outside this Reserve. In addition to *C. galleritus*, there is another Endangered primate that is endemic to the forests of the lower Tana R., *P. r. rufomitratus*. As such, the forests along the lower Tana R. represent the most important site in East Africa for primate conservation actions (De Jong & Butynski 2012). The history of research and conservation actions on behalf of *C. galleritus*, *P. r. rufomitratus* and the forests of the lower Tana R. is reviewed in Butynski & Mwangi (1994) and Wiczowski (2005a).

A five-year Kenya Wildlife Service (KWS) and Kenya Forest Department Project, funded by World Bank's Global Environmental Facility (GEF), was initiated in 1996 to enhance conservation and protection of the biodiversity and forests of the lower Tana R. Unfortunately, this potentially important project was terminated prematurely due to poor project management. This left the responsibility for the conservation and protection of the Tana River's biodiversity and forests entirely to KWS.

The TRPNR was gazetted in 1976 in approximately the northern half of the distribution of *C. galleritus* and *P. r. rufomitratus* (Marsh 1976). Officially a County Council Reserve, the Tana River County

Council had given management authority of the Reserve to KWS. In February 2007 the High Court of Kenya ruled in favour of Tana R. residents who brought a lawsuit stating the Reserve had been gazetted without their permission. Therefore, the TRPNR must be degazetted. Consequently, none of the habitat of *C. galeritus* or *P. r. rufomitratus* is legally protected. The residents say that they are interested in creating a community wildlife sanctuary but the way forward for the formal establishment of a community wildlife sanctuary and its effective management is unclear at this time (Mbora & Butynski 2007, Allen & Mbora 2012).

Habitat degradation and loss along the lower Tana R. has been further exacerbated by the failure of the 250 km² Tana Delta Irrigation Project's (TDIP) rice-growing scheme (under the administration of the Tana and Athi Rivers Development Authority [TARDA] with financing from Japan International Cooperation Agency [JICA]) to protect forest patches on their land. Some of the best forest habitat for *C. galeritus* and *P. r. rufomitratus* has been lost to TDIP (Butynski & Mwangi 1994, Moinde-Fockler *et al.* 2007). Now TARDA is promoting the establishment of a 400 km² sugar-cane plantation in the Tana Delta and of a 300 km² sugar-cane plantation slightly up-stream of the Delta. Beyond this, two jatropha biofuel farms (500 km², 280 km²) are being proposed for near the Delta (Hamerlynck *et al.* 2012). These new plantations will result in loss of forest, a large influx of people and an increase in the demand for forest resources, thereby putting even more pressure on the last remaining habitat for these two threatened monkeys (Mbora & Butynski 2007, Hamerlynck *et al.* 2012).

Priorities for research on *C. galeritus* include long-term monitoring and ecological studies in the southern half of the geographic range.

Priority conservation actions include habitat protection, community conservation education, establishment of forest corridors, planting of woodlots, creation of a permanent field research station at Mchelelo, and surveys of the newly discovered population in the Tana Delta (Butynski & Mwangi 1994, Wiczowski 2005a).

Measurements

Cercocebus galeritus

HB (♂ ♂): 600, 620 mm, n = 2

HB (♀): 450 mm, n = 1

T (♂ ♂): 620, 730 mm, n = 2

T (♀): 520 mm, n = 1

HF (♂ ♂): 158, 160 mm, n = 2

HF (♀): 133 mm, n = 1

E (♂): 39 mm, n = 1

E (♀): 32 mm, n = 1

WT (♂ ♂): n.d.

WT (♀): ca. 3.7 kg, n = 1

GLS (♂ ♂): 123 (122–127) mm, n = 5

GLS (♀ ♀): 107 (106–107) mm, n = 3

GWS (♂ ♂): 82 (79–84) mm, n = 5

GWS (♀ ♀): 70 (68–72) mm, n = 3

Tana R. (Elliot 1913b, Allen & Lawrence 1936, C. P. Groves pers. comm., T. Butynski & J. Wiczowski pers. obs.)

Cercocebus agilis AGILE MANGABEY

Fr. Mangabé agile; Ger. Olivmangabe

Cercocebus agilis Milne-Edwards, 1886. Revue Scientifique 12: 15. Republic Poste des Ouaddas (junction Oubangui R. and Congo R.), DR Congo.

Taxonomy Monotypic species. Often considered a subspecies of *Cercocebus galeritus*, along with other subspecies *galeritus*, *sanjei* and *chrysogaster* (Dandelot 1974, Napier 1981, Gautier-Hion *et al.* 1999, Grubb *et al.* 2003). Groves (1978) revised the genus, resurrecting *Cercocebus agilis*. (See also Groves 2001, 2005c.) Synonyms: *fumosus*, *hagenbecki*, *oberlaenderi*. Chromosome number: 2n not known, but probably 42, as for all Papionini for which chromosome number has been determined (Romagno 2001).

Description Medium-sized, lanky, brownish-grey, semi-terrestrial monkey with long tail. Sexes alike in colouration. Adult ♀ ♀ ca. 60% the weight of adult ♂ ♂. Muzzle moderately prognathic with short vibrissae. Face, ears, palms and soles black. Capacious cheek-pouches. Eyelids pale grey, but not as light as in Red-capped Mangabey *Cercocebus torquatus*. Face with white border formed by light bases to the hairs. Crown with whorl of hairs radiating 360° out from naked whitish skin, parting (creating a projecting brow). Crown, dorsum, outer limbs and upper tail heavily speckled brownish-grey, darkest on crown and lower limbs; hairs short, fine and agouti-banded. Chin, throat, inner limbs, ventrum and undertail unspeckled yellowish-white. Tail long

Agile Mangabey *Cercocebus agilis* adult male.

Lateral, palatal and dorsal views of skull of Agile Mangabey *Cercocebus agilis* adult male.

(ca. 140% of HB) and tapered, with variable presence of a whitish terminal tuft. Tail often carried arched or horizontal above the back, with tip almost touching the head. Ischial callosities separate in ♀♀, continuous in ♂♂. Infants born with red faces, which become black over time.

Geographic Variation Groves (1978) distinguishes a light morph and a dark morph, based on pelage colour; these co-occur, in different proportions, throughout the range of the species. Although four taxa (*agilis*, *hagenbecki*, *fumosus* and *oberlaenderi*) were described from different parts of the range in the early 1900s, Groves assessed that the level of geographic variation is not sufficient to warrant subspecies differentiation. Body size is larger in the west of the species' geographic range (Groves 2001).

Similar Species

Cercocebus torquatus. Geographic range to the west of *C. agilis*; only zone of contact is around Mevo/Sangmelima, Cameroon (Gautier-Hion *et al.* 1999). Crown chestnut. Collar white.

Lophocebus albigena. Widely sympatric with *C. agilis*. Pelage dark brown, longer and scruffier. Mane (= cape = mantle) over neck and shoulders.

Distribution Endemic to equatorial central Africa. Rainforest BZ. From SE Cameroon, NE Gabon, SW Central African Republic and N Congo to E DR Congo (Gautier-Hion *et al.* 1999). In Gabon from left bank of Ivindo R. as far south as Koungou Waterfalls, and

Cercocebus agilis

possibly along Mvounou R. (S. Lahm pers. comm.). Unclear how far west the range extends in the Minkebe area of N Gabon, although present on Sing R. and Nouna R. (S. Lahm pers. comm.), and on Mvounou R., a tributary of the Ntem R. (L. White pers. comm.). Western limit thought to be Lobo R., around Sangmelima, ca. 75 km west of Dja R., Cameroon (Gautier-Hion *et al.* 1999), but recently reported farther west at Campo-Ma'an N. P., SW Cameroon (Matthews & Matthews 2002, Etoga & Foguekem 2009). Distribution extends north in Cameroon to Nyong R. In Central African Republic the range extends north following the forest limit between Nola and Berberati, dipping down into the Ngotto Forest near Mbaiki. Agile Mangabeys were in the hills outside Bangui, but the forest there had been heavily degraded (N. Shah pers. obs.) so now probably absent there. From Bangui the distribution is to south of the left bank of Oubangui R., south of Gbadolite, DR Congo, then north again to the forests around Bangassou (A. Blom pers. comm.). Between the Oubangui R. and Congo R., DR Congo, distribution uncertain, as forests are highly fragmented and have not been much surveyed. Hicks (2010), however, found them in most areas surveyed north and south of Uele R. between Mbomu R. to the north and Rubi/Itimbiri R. to the south in the area around Aketi and Bambesa. Present almost as far east as Garamba (E. de Merode pers. comm.). The eastern limit in DR Congo likely the forest-savanna ecotone. Southern limit in DR Congo not clear: present in Ituri Forest north to Nepoko Forest and south of the Ituri R. (Hart & Thomas 1986) and in the Maiko N. P. (Hart & Sikubwabo 1994) but not in the Kahuzi-Biega lowlands (J. Hart pers. comm.). In Congo southern limit probably the limit of the forest block, around Likouala R., as this species is not found in forest fragments along Alima R. (A. Gautier-Hion pers. comm.), nor at Léfini or Konkouati. Reports (Sabater Pi & Jones 1968) of Agile Mangabeys in Equatorial Guinea (Rio Muni) require verification.

Habitat Often in riverine, seasonally inundated, or swamp forests, but can inhabit *terra firma* forest exclusively in some places.

Uses both primary and secondary forests, but prefers habitat with dense ground vegetation. Uses all forest strata, from ground to canopy. Occasionally in more open *Gilbertiodendron*-monodominant forest (Shah 2003, Devreese 2011). Travels and forages primarily on the ground, but climbs into trees to find fruit and to sleep. Large groups may spend more time on ground (72%; Devreese 2011) than small groups (12–22%; Quris 1975, Shah 2003). Adult ♂♂ more terrestrial than adult ♀♀ (36% vs. 24% of time on ground; Shah 2003).

Abundance More often heard than seen, and thought to be uncommon throughout most of its range. Difficult to estimate densities due to human hunting pressure, its semi-terrestrial nature and preference for habitats with dense ground vegetation. Quris (1975) estimated a density of 6.7–12.5 ind/km² along riverbanks in swamp forest in NE Gabon. At Mondika, in Ndoki Forest, S Central African Republic/N Congo, density ca. 6.9 ind/km² (Shah 2003) in terra firma forest. In Ituri Forest, DR Congo, Thomas (1991) estimated 0.25 groups/km², or ca. 2 ind/km², whereas Kambale Saambili (1998) estimated 38.3 ind/km² in the same area. In 1999, D. Brugière (pers. comm.) found 0.92 groups/km², or ca. 18.9 ind/km² in a narrow strip of flooded forest along the Mbaéré R. in the Ngotto Forest, Central African Republic. Densities ranged from 0.4 to 2.0 groups/km² (or ca. 7.2–41.0 ind/km²) in different stretches of this habitat; densities related to human hunting pressure. At this site Agile Mangabeys are restricted to a narrow strip of flooded forest along the river (i.e. not the entire flooded forest habitat).

Adaptations Diurnal and semi-terrestrial. Capacious cheek-pouches for storing food, and extra-laryngeal air sacs for long-distance vocalizations. Large molarized posterior premolars with thick enamel for crushing seeds, and well-developed forelimb flexor muscles for aggressive manual foraging (Fleagle & McGraw 1999, 2002).

Fruits and seeds are available to Agile Mangabeys on a longer temporal scale than for other sympatric monkeys, since they are able to consume many fruits before they are ripe and then dig up seeds that persist on the forest floor for months after the fruiting season. Additionally, they procure food at all forest levels, from the ground to the canopy, expanding their food niche relative to strictly arboreal monkeys.

Foraging and Food Frugivorous. Agile Mangabeys spend 64–76% of feeding time eating fruits, including seeds (Quris 1975, Kambale Saambili 1998, Shah 2003, Devreese 2011). At Mondika, of those observations where foods could be identified, 76% were fruit (including seeds), 16% pith and shoots of terrestrial herbs, 5% invertebrates, 2% mushrooms and 2% roots (Shah 2003). At Bai Hokou, SW Central African Republic: 68% fruit (including seeds), 21% plant structural parts, 6% animal matter and 5% mushrooms (Devreese 2011).

Agile Mangabeys eat a wide variety of fruits and seeds in ripe, unripe and over-ripe (i.e. rotting) stages. They also consume old seeds and nuts, which persist on the forest floor for months, or that they find by digging up or by sifting through Forest Elephant *Loxodonta cyclotis* dung (Ekondzo & Gautier-Hion 1998, N. Shah pers. obs.) or Western Gorilla *Gorilla gorilla* dung (N. Shah pers. obs.). They use their powerful jaws, broad cheekteeth and thick dental enamel to open tough pods and fruits, crunch hard seeds, and their incisors to scrape a hole to open lignified fruits. These morphological adaptations allow them to consume foods that most other monkeys cannot access.

During a one-year study at Mondika, the three species of fruit most eaten by Agile Mangabeys were *Diospyros pseudomespilus*, *Erythrophleum ivorense* and *Anonidium mannii*. The second-most-eaten category of food was the protein-rich shoots and terminal tips of Marantaceae herbs, especially *Haumania danckelmaniana* (Kambale Saambili 1998, Shah 2003). *Raphia* shoots are also often eaten (Quris 1975). Other plant food items include mushrooms, roots, tubers, seedlings and flowers. Animal prey includes termites, centipedes, butterflies, millipedes, beetles, gastropods, birds' eggs, rodents and small snakes (Shah 2003, Devreese 2011, A. Todd pers. comm.).

Agile Mangabeys hunt larger mammals at Bai Hokou (Knights *et al.* 2008, L. Devreese pers. comm.). Prey taken include infant Blue Duikers *Philantomba monticola*, infant Water Chevrotain *Hyemoschus aquaticus* and infant Peters' Duikers *Cephalophus callipygus*. Preliminary data indicate that infant Blue Duikers are taken ten times as often as other prey. Only adult ♂ Agile Mangabeys were observed to hunt these species. Hunts are opportunistic and solitary, and meat sharing has not been observed (although other individuals will take dropped pieces of meat). Preliminary data yield an average of 2–3 hunts/month (0–6; Knights *et al.* 2008).

For a small group at Mondika, about 33% of the time is spent feeding, 31% travelling, 13% inactive, 10% engaged in social/sexual behaviour, 8% foraging and 5% in other behaviours (Shah 2003). Adult ♀♀ spend more time searching for food (i.e. foraging and travelling) than adult ♂♂ (39% vs. 26%; Shah 2003). For a very large group at Bai Hokou (ca. 130 animals), about 25% of time spent feeding, 42% travelling, 10% inactive, 6% in social/sexual behaviour, 15% foraging, and 3% in other behaviours (Devreese 2011). Average daily travel distance is 1155 m (390–1985, n = 54) in terra firma at Mondika (Shah 2003), and 1215 m (n = 12, range unreported) in inundated habitat in NE Gabon (Quris 1975). For the much larger group at Bai Hokou, average daily travel distance is ca. 3884 m (Devreese 2011) to 3200 m (n = 79, range unreported; C. Cipolletta pers. comm.). During periods of fruit scarcity, Agile Mangabeys at Mondika travel longer distances, spend more time on the ground and spend a greater proportion of time searching for food (Shah 2003). Home-range for the group at Mondika was >303 ha (Shah 2003). The group in NE Gabon had a long and narrow home-range of 200 ha, following the course of a marshy river (Quris 1975). The very large group at Bai Hokou ranged over 1500 ha (L. Devreese pers. comm., A. Todd pers. comm.).

Social and Reproductive Behaviour Social. Group sizes vary enormously. Difficult to obtain accurate group counts, because of Agile Mangabeys' terrestrial locomotion in habitats with dense undergrowth. Smaller group counts are 8–18 individuals in NE Gabon (n = 1; Quris 1975), 21 individuals at Mondika (n = 1; Shah 2003), 24 individuals in Ituri Forest (9–55, n not given; Kambale Saambili 1998) and ca. 20 individuals in the Ngotto Forest (D. Brugière pers. comm.).

Large groups (50 to >200 animals) are occasionally reported in SE Cameroon (Uongo & Fimbel 1995), in NE Gabon (Quris 1975), in Ituri Forest (Kambale Saambili 1998) and in SW Central African Republic (A. Turkalo pers. comm., C. Cipolletta pers. comm., N. Shah pers. obs.). It is not always clear whether these counts represent larger groups, temporary aggregations of groups, or greater population densities. At Bai Hokou one group maintained a size of ca. 125 individuals for several months, appeared to merge with another group and maintained a size of ca. 230 individuals for 2 years, dropped to 134 for several months, then increased to 330 individuals (C. Cipolletta, A. Todd, K. Knights, M. Santochirico & L. Devreese pers. comm.).

Smaller groups have one adult ♂ (Quris 1975), while larger groups are age-graded or multimale (Quris 1975, Shah 2003, Devreese 2011). One group at Mondika comprised two adult ♂♂, two subadult ♂♂, 7–8 adult ♀♀ and 11 juveniles and infants (Shah 2003). At Bai Hokou the group of ca. 230 individuals comprised 32 adult ♂♂ and 22 subadult ♂♂ (M. Santochirico pers. comm.), and when it was 134 individuals there were 19 adult ♂♂ and 48 adult ♀♀ (Devreese 2011). In NE Gabon ♂♂ and ♀♀ both transferred between groups during inter-group encounters. Solitary ♂♂ were observed at this site (Quris 1975). In NE Gabon neighbouring groups have overlapping home-ranges. Here, a group of 7–18 individuals with a long and narrow home-range along a river had extensive overlap with other groups (Quris 1975), whereas at Mondika, a group of 21 individuals had a home-range of >303 ha in terra firma forest, with minimal overlap with other groups (Shah 2003).

Relations between conspecific groups are variable: sometimes affiliative, with individuals intermingling in temporary associations called 'supergroups' (Quris 1975, Shah 2003), and at other times agonistic (Shah 2003). During these agonistic encounters, adult ♂♂ vocalize, display and chase ♂♂ of other groups. It is not clear whether relations with the same neighbouring groups are affiliative at some times, and agonistic at others, or whether relations with certain neighbouring groups are always affiliative, and with others always agonistic. Groups temporarily fragment into subgroups (Quris 1975, Kambale Saambili 1998, L. Devreese pers. comm.).

Adult ♀♀ display oestrous swellings and have visible menses. Males sometimes mate-guard oestrous ♀♀. There can be high levels of aggression between ♂♂ over an oestrous ♀ (N. Shah pers. obs.). Weaning conflicts between mothers and their offspring begin when infants are about seven months old, but ♀♀ occasionally nurse offspring as old as 18 months. Infants are sometimes carried by adult and subadult ♂♂, particularly in tense encounters between ♂♂, where they potentially serve to buffer aggression (N. Shah pers. obs.).

Adult ♂♂ emit long-range vocalizations, beginning with a loud 'whoop' (very similar to the 'whoop' of the sympatric Grey-cheeked Mangabey *Lophocebus albigena*) followed by a 'gobble' or 'cackle'. These calls, audible to observers at up to 1000 m, are thought to play a role in both intra-group coordination and inter-group communication (Quris 1973, 1980). Most 'whoop-gobbles' (or 'whoop-cackles') are emitted around dawn. Individuals within a group also communicate using a variety of other vocalizations, including a soft 'contact' grunt that is audible only to ca. 25 m and that is thought to help maintain group cohesion in dense understorey (N. Shah pers. obs.).

Agile Mangabeys occur in polyspecific associations with other primate species 11% of the time at Mondika (Shah 2003) and 6% of the time in NE Gabon (Quris 1976), but these are usually short-lived associations, often at shared feeding trees. Inter-specific interactions are generally neutral, but occasionally may be agonistic or affiliative. Agile Mangabeys sometimes supplant or chase other monkeys (e.g. *L. albigena*, Putty-nosed Monkeys *Cercopithecus nictitans*, Moustached Monkeys *Cercopithecus cephus*, Crowned Monkeys *Cercopithecus pogonias*) out of feeding trees (Shah 2003). Juveniles, however, occasionally engage in reciprocal grooming bouts with adult ♂♂ and juveniles of other monkey species (e.g. *C. cephus* and *C. pogonias*) (Shah 2003). Other animals, such as guineafowl (several species), Red River Hogs *Potamochoerus porcus* and various species of duikers (*Philantomba monticola*, *Cephalophus* spp.), often forage with Agile Mangabeys. Agile Mangabeys react to alarm calls of all of these species (A. Todd, M. Santochirico & N. Shah pers. obs.).

Reproduction and Population Structure When in oestrus, ♀♀ have perineal swellings that they sometimes present to ♂♂. Gestation is ca. 24 weeks in captivity (E. Dols pers. comm.). At Mondika one ♀ gave birth six months after she was last observed copulating (N. Shah pers. obs.). One infant is born at a time. Twins not reported. Birth-weights are not available. Inter-birth intervals at Mondika are greater than 21 months (N. Shah pers. obs.). In NE Gabon infants are born in Dec–Feb (Quris 1975). At Mondika births occur during two periods: Dec–Feb and Jun–Aug (N. Shah pers. obs.). At Bai Hokou, ca. 60 km to the north of Mondika, births occur in May–Aug (K. Knights & M. Santochirico pers. comm.). Infants are weaned at 7–18 months at Mondika (N. Shah pers. obs.) and at about six months in captivity (E. Dols pers. comm.). In a small group at Mondika the ratio of adults and subadults to juveniles was 1 : 1, and the ratio of adult ♂♂ to adult ♀♀ varied from 1 : 3.5 to 1 : 4.0 (Shah 2003). In a group of 134 animals at Bai Hokou, the ratio of adult ♂♂ to adult ♀♀ was 1 : 2.6 (Devreese 2011). Longevity in the wild not known. One animal in captivity lived to 21 years of age (E. Dols pers. comm.).

Predators, Parasites and Diseases Gabon vipers *Bitis gabonica*, Leopards *Panthera pardus* and African Crowned Eagles *Stephanoaetus coronatus* are known predators of Agile Mangabeys (A. Todd & L. Devreese pers. comm.). Central African Rock Pythons *Python sebae* and cobras (*Naja* spp.) unsuccessfully attacked Agile Mangabeys (A. Todd pers. comm.).

Agile Mangabeys carry high levels of parasites, such as *Entamoeba histolytica*, *Entamoeba coli*, *Balantidium coli*, *Iodamoeba butschlii* and trichomonads. All of these parasites are transmitted back and forth between humans and the monkeys (Lilly *et al.* 2002). Agile Mangabeys also harbour a strain of simian immunodeficiency virus (SIV) (Apetrei *et al.* 2002).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The primary threat to Agile Mangabeys is hunting for the bushmeat trade. Because of their semi-terrestrial habits, they are vulnerable to snare hunting. A secondary threat is habitat loss, degradation and fragmentation. Agile Mangabeys are notorious crop

raiders (Kambale Saambili 1998), which may make them vulnerable to reprisals in areas where they live close to plantations.

Measurements

Cercocebus agilis

HB (♂ ♂): 572 (500–625) mm, n = 6

HB (♀ ♀): 489 (440–530) mm, n = 5

T (♂ ♂): 684 (570–760) mm, n = 6

T (♀ ♀): 530 (450–600) mm, n = 5

HF (♂ ♂): 169 (153–180) mm, n = 5

HF (♀ ♀): 139 (130–150) mm, n = 4

E (♂ ♂): 370 (350–400) mm, n = 5

E (♀ ♀): 360 (340–400) mm, n = 3

Various localities (Hill 1974)

HB (♂ ♂): 550 (?–?) mm, n = 11

HB (♀ ♀): 465 (?–?) mm, n = 11

T (♂ ♂): 745 mm, n = 11

T (♀ ♀): 635 mm, n = 11

WT (♂ ♂): 8.8 (4.8–10.0) kg, n = 7

WT (♀ ♀): 5.4 (4.3–6.2) kg, n = 5

Makokou area, Gabon (Gautier-Hion *et al.* 1999)

WT (♂ ♂): 9.0, 10.0 kg, n = 2

WT (♀ ♀): 4.3, 6.2 kg, n = 2

Ngotto Forest, Central African Republic (Colyn 1994)

Cercocebus chrysogaster GOLDEN-BELLIED MANGABEY

Fr. Mangabé à ventre doré; Ger. Goldbauchmangabe

Cercocebus chrysogaster Lydekker, 1900. Novitates Zoologicae 7: 279. Upper Congo, DR Congo.

Golden-bellied Mangabey *Cercocebus chrysogaster* young adult male.

Taxonomy Monotypic species. Originally given full species status by Lydekker (1900), and that classification retained by Elliot (1913b), Dobroruka & Badalec (1966), Kingdon (1997) and Groves (2001, 2005c). Also classified as *Cercocebus galeritus chrysogaster* (Schwarz 1928d, Dandelot 1974, Hill 1974, Napier 1981, Grubb *et al.* 2003) and as *Cercocebus agilis chrysogaster* (Groves 1978, 1993, Gautier-Hion *et al.* 1999). Synonyms: none. Chromosome number: 2n = 42 (Dutrillaux *et al.* 1979).

Description Robustly built monkey with a golden-yellow to orange-gold or reddish-gold belly. Only mangabey without a brow (frontal) fringe. Adult ♀ like adult ♂, but less robust and smaller; body weight ca. two-thirds that of adult ♂. Muzzle robust. Bare skin of chin, lips, muzzle, face and ears dark brown to blackish. Eyes brown. Eyelids whitish or pinkish. Cheek whiskers cream-yellow, long and swept back from near corner of mouth to behind ears giving a 'mutton-chop' appearance, especially in mature ♂ ♂; pelage bordering face and sides of head off-white. Light cream to reddish patch behind ears. Forehead lacks parting or whorl in adults, but whorl present in some juvenile museum skins (Groves 1978). Crown and neck brownish-olive to reddish-olive, speckled with black, tipped yellow or light orange. Shoulders, back, flanks and outer limbs colour of crown and neck but paler and less speckled, especially on the flanks and outer hindlimbs. Inner forelimbs light yellow or pale orange proximally, becoming cream towards wrists and ankles. Inner hindlimbs light reddish-gold. Hands and feet grey, dark greyish-brown to blackish. Throat, front of upper arms and chest pale orange to light reddish-gold, darker towards midline. Shoulders and upper arms of adult ♂ with a mane (= cape = mantle) of long, thick pelage. Belly light yellow to golden-yellow to reddish-gold, becoming brighter towards the lower belly. Belly with median fringe of long hairs. Rump broad, poorly furred. Buttocks of adult ♂ each have a patch of cream-white pelage and a patch of pink bare skin to either side of base of tail; absent in ♀ ♀. Ischial callosities wide, light pink, rosy-pink, or violet-grey; fused in ♂ ♂, separate in ♀ ♀. Broad ring of off-white pelage around ischial callosities. Tail pelage short; above speckled like dorsum at base, rest unspeckled grey or sooty-black, paler below, especially near base. Tail about equal in length to HB. Penis bright scarlet. Scrotum bluish.

Infant colouration differs from adult; head pelage black, skin pale pink and belly pale beige or white. A golden band appears on forehead at ca. 8 weeks of age and adult colouration gradually expands over the head; skin darkens to greyish-brown by 14 weeks

with contrasting non-pigmented eyelids visible by 20 weeks (Field 2007).

Sexes markedly dimorphic in size (Dorst & Dandelot 1970, Groves 1978); adult ♂♂ noticeably more robust, with canines about three to four times longer than in adult ♀♀ (Field 2007). GLS for adult ♀ (n = 2) is 82% that of adult ♂ (n = 9; Groves 1978). In captive animals weight of adult ♀♀ ca. 62% that of adult ♂♂, and HB length of ♀♀ ca. 83% that of ♂♂ (Field 2007).

Geographic Variation Upon examination of 15 study skins, the only variation that Groves (1978: 17) found was that the one specimen from the westernmost locality (Luaza) had a belly that 'is hardly yellow at all,' in sharp contrast to the golden-yellow or bright orange colouration on the belly of the other 14 specimens. Both this specimen, and the one from the south-easternmost locality (between Lusambo and Pania), were only weakly speckled on the flanks.

Similar Species None within geographic range.

Distribution Endemic to the western and central Congo Basin, DR Congo. Rainforest BZ. Geographic distribution not well-known. There is no evidence for *C. chrysogaster* in the NE Congo Basin; absent in the Lomako Forest and in the 70,000 km² 'Maranga-Lopori-Wamba Landscape' as indicated by extensive ground surveys in the region and by the absence of *C. chrysogaster* from among the ca. 12,000 carcasses examined in the Basankusu (01° 13' N, 19° 49' E) bushmeat market. This market is fed largely by hunters operating in forests along, and between, the Maranga and Lopori Rivers (J. Dupain pers. comm.). Based on a specimen from Irebu Village (00° 37' S, 17° 45' E), the western limit is the Congo R. (Schouteden 1944a, Hill 1974). A specimen from Lulonga (= Lubonga) Village suggests that the north-west limit (and northern extreme) is the lower Lulonga R. (ca. 00° 24' N, 18° 14' E; Groves 1978, Gautier-Hion 1999). *Cercocebus chrysogaster* is present, but uncommon, in the bushmeat market south of Lulonga R. at Mbandaka (00° 03' N, 18° 15' E; J. Hart pers. comm.). Absence of *C. chrysogaster* from the Basankusu bushmeat market (see above) to the north of the Lulonga R. indicates that this species does not occur along the upper reaches of the Lulonga R., nor north of the Lulonga R. Distribution appears to be south-south-east from Lulonga R. (Groves 1978) to Momboyo R. at about Imbonga Village (00° 41' S, 19° 39' E; J. Hart pers. comm.), and then to the Lokoro R. at Luikotale Village (which is the western boundary of the South Sector of the Salonga N. P.). J. Eriksson (pers. comm.) found *C. chrysogaster* to be uncommon at Luikotale, but already more common just 10 km to the west, and fairly abundant ca. 50 km to the west at Lokolama Village and Mimia Village, as well as between Lokolama and the right bank of the Lukénie R. at Oshwe. From Luikotale, the range appears to extend south-east to the Ngendo R. (ca. 03° 28' S, 21° 13' E), a northern tributary of the Lukénie R. Inogwabini & Thompson (2004) state that *C. chrysogaster* occurs west of the Ngendo R., but not to the east. From here the distribution becomes particularly poorly known, but at some point the range probably meets the Sankuru R. to the south. The distribution likely extends east along both the Lukénie and Sankuru Rivers to at least Samangwa Village (04° 14' S, 24° 06' E). The south-east limit

Cercocebus chrysogaster

appears to be between Lusambo Village and Pania Village (05° 00' S, 23° 24' E). At least four specimens obtained in the vicinity of Samangwa, Lusambo and Pania (Schouteden 1944a, Hill 1974, Groves 1978). Samangwa is only ca. 75 km from the west bank of the Lomami R. As such, Hill (1974) suggests that the Lomami R. is the likely eastern limit for *C. chrysogaster*. Known south-west limit, based on a specimen, is Luaza Village (03° 25' S, 17° 11' E) on the Kwilu R., a southern tributary of the Kasai R. One specimen collected at Oshwe (03° 23' S, 19° 30' E) on the south bank of the Lukénie R. (Schouteden 1944a, Hill 1970, Groves 1978, Gautier-Hion *et al.* 1999), and J. Eriksson found *C. chrysogaster* to be common here. Inogwabini & Thompson (2004) did not find *C. chrysogaster* east of 20° 30' E along the Kasai-Sankuru R. and, thus, believe that the Lukénie R. is the southern boundary for *C. chrysogaster* in this region, not the Kasai-Sankuru R. as indicated by Gautier-Hion *et al.* (1999).

The information available suggests that *C. chrysogaster* may occur in two populations (a western population and an eastern population), or else these two ranges are connected by a narrow corridor that runs along, or in the vicinity of, the Lukénie R. and/or Sankuru R. A. Gautier-Hion (pers. comm.) notes that there are patches of savanna to the south of the South Sector of the Salonga N. P. and that this presence of unsuitable habitat may account for what appears to be a fragmented distribution for *C. chrysogaster* in this region. It is of conservation importance that *C. chrysogaster* appears to be absent from the North Sector of Salonga N. P. (Gautier-Hion *et al.* 1999, G. Reinartz pers. comm., J. Hart pers. comm., J. Thompson pers. comm.). J. Hart (pers. comm.) and his colleagues undertook surveys over much of Salonga N. P. (36,560 km²), encountered >200 groups of primates and never observed *C. chrysogaster*. J. Thompson (pers. comm.) conducted surveys in the southern half of the South Sector of Salonga N. P. and never encountered *C. chrysogaster*. The map in Gautier-Hion *et al.* (1999) shows *C. chrysogaster* as present in the South Sector of Salonga N. P., although this map is based on information collected from interviewees and not on the authors'

direct observations of *C. chrysogaster* in this region (A. Gautier-Hion pers. comm.). If *C. chrysogaster* is present anywhere in the Salonga N. P. it is most likely in the south-west corner of the South Sector on the Lula R. between Luikotale Village and the Ngendo R.

Not known to be sympatric with Agile Mangabey *Cercocebus agilis*, the two species being separated by the Congo R. (Groves 1978, Gautier-Hion *et al.* 1999).

Habitat Prefers seasonally flooded and swamp forests (Groves 1978, Gautier-Hion *et al.* 1999, Inogwabini & Thompson 2004). Can be common in secondary forest (J. Eriksson pers. comm.). The altitude limits of the distribution of *C. chrysogaster* are ca. 300 and 500 m (Inogwabini & Thompson 2004).

Abundance Few data. What information is available strongly suggests that *C. chrysogaster* not only has a small and fragmented distribution, but that the area actually occupied is small.

Adaptations Diurnal and semi-terrestrial (Hill 1974, Gautier-Hion *et al.* 1999). Not studied in the wild. J. Eriksson (pers. comm.) is of the opinion that *C. chrysogaster* moves mainly on the ground.

Foraging and Food Unknown. Kingdon (1997) suggests diet is largely frugivorous. J. Eriksson (pers. comm.) observed *C. chrysogaster* eating seeds out of Forest Elephant *Loxodonta cyclotis* dung and often saw duikers *Cephalophus* spp. foraging within *C. chrysogaster* groups.

Social and Reproductive Behaviour Social. No detailed information available on social structure or social organization from wild populations. Gautier-Hion *et al.* (1999) suspect that group size averages ca. 15 animals, if similar to *C. agilis*. J. Eriksson (pers. comm.) estimated group size for *C. chrysogaster* as often >100 animals, and sometimes had the impression that groups might be between 200–300 animals (in the vicinity of Lokolama, Mimia and Oshwe).

Data from captive heterosexual pairs of *C. chrysogaster* indicate sex differences in behaviour, with ♂♂ displaying significantly more aggression, and ♀♀ more social grooming and vocalization (Mitchell *et al.* 1988). Posture is more similar to that of macaques (*Macaca* spp.) than to other *Cercocebus* spp. (Hill 1974), and overall appearance reminiscent of some of the more robust macaque species; these are the strong impressions one gets upon seeing this species for the first time (T. Butynski & C. L. Ehardt pers. obs.). Unlike all other mangabeys, immatures and adults both carry the tail in a backward arch with the tip directed at the heels. While apparently never arched high over the shoulders and/or back (Dandelot 1974, Kingdon 1997), the tail may be swung forward at such an acute angle that the mid-part of the tail touches a shoulder and the tip touches an upper arm (T. Butynski pers. obs.). In captivity at least one aggressive display involves a wide yawning expression with the upper lip pulled back, all teeth showing, and eyebrows raised (Hill 1974, T. Butynski pers. obs.).

One vocalization is described by Hill (1974: 165) as ‘a deep guttural croak, somewhat like a baboon’s bark’. A rapid, low, ‘ooh-ooh-ooh-ooh’ given by a captive ♂ in what appears to be greeting behaviour (C. L. Ehardt & T. Butynski pers. obs.). A ‘ha-ha-ha-’ call

given in aggressive situations (Mitchell *et al.* 1988). Not known to give the ‘whoop-gobble’ loud-call of some other *Cercocebus* spp.

Reproduction and Population Structure No data available from wild populations. Data on reproductive parameters collected on five captive ♀♀ (two wild-caught). Two ♀♀ began cycling at 2.5 and 2.6 years with first menses at 2.7 years; menses heavy and highly visible. Mean menses is three days. Oestrous cycles average 30.7 days (20–51, n = 149 cycles), with duration of peak perineal swelling averaging 5.8 days (2–22, n = 151 cycles). First pregnancy at 4.9 years (Walker *et al.* 2004).

Gestation ca. 5.8–5.9 months (n = 2 births). Mean interval from parturition to resumption of swelling 8.6 months (5.5–10.0, n = 3 ♀♀). Inter-birth interval for captive ♀♀ with infants surviving >1 month averages 19.9 months (16.6–24.8, n = 4 ♀♀ producing nine births; Walker *et al.* 2004). There is a post-conception swelling. Females solicit adult ♂ cage-mates during periods of post-conception swelling, and copulations have occurred at this time (Walker *et al.* 2004, Field 2007). No twin births observed in captivity (n = 15). Birth-weight of one individual was 750 g (Field 2007). No pronounced birth season in captivity (Field 1995a, 2007).

Predators, Parasites and Diseases No information. Most important predators are likely to include Leopards *Panthera pardus* and African Crowned Eagle *Stephanoaetus coronatus*. Humans are undoubtedly the most important predator (see below).

Conservation IUCN Category (2012): Data Deficient. CITES (2012): Appendix II.

As indicated above, and in Inogwabini & Thompson (2004), it now appears that *C. chrysogaster* has a considerably smaller range and lower numbers than once believed. Assessment by the IUCN Primate Specialist Group at this time would likely find that *C. chrysogaster* deserves threatened species status. Habitat degradation and loss, as well as hunting by humans, are major threats (Wolfheim 1983, Inogwabini & Thompson 2004). Hunting rates are high, as indicated by the many *C. chrysogaster* on the streets of Kinshasa and elsewhere, both for meat and the pet trade; it is also an agricultural pest in some areas. Young are often kept as pets as they seem to tame readily (Inogwabini & Thompson 2004, G. Reinartz pers. comm., J. Eriksson pers. comm.). Sixteen wild- and captive-born *C. chrysogaster* (seven ♂♂, nine ♀♀) are present in six North American zoos (Field 2007); four European zoos currently house ten ♂♂ and 18 ♀♀ (ISIS 2007). This is one of Africa’s least-known primates and, potentially, one of Africa’s most unique primates. Research is needed on all aspects (distribution, abundance, ecology, conservation status, threats) of this likely threatened monkey.

Measurements

Cercocebus chrysogaster

T (♂♂): 510 (470–550) mm, n = 4

T (♀♀): 460 mm, n = 1

WT (♂♂): 11.6 (10.1–13.6) kg, n = 4

WT (♀♀): 9.0 kg, n = 1

Captive individuals at Sacramento Zoo (L. Field pers. comm.)

HB (♂): 790 mm, n = 1

T (♂): 430 mm, n = 1

HF (♂): 130 mm, n = 1
 Locality not stated (Elliot 1913b)

HB (♂♂): 530 mm
 HB (♀♀): 440 mm
 T (♂♂): 540 mm
 T (♀♀): 450 mm
 WT (♂♂): 11–15 kg
 WT (♀♀): 8 kg

Based on an unknown number of captive individuals at various sites (Field 2003); ranges and sample sizes not available

GLS (♂♂): 131 (129–134) mm, n = 9

GLS (♀♀): 105, 109 mm, n = 2

GWS (♂♂): 85 (82–89) mm, n = 9

GWS (♀♀): 67, 68 mm, (n = 2)

From various localities (RMCA) (Groves 1978, C. P. Groves pers. comm.)

Cerrocebus sanjei SANJE MANGABEY

Fr. Mangabé Sanje; Ger. Sanje-Mangabe

Cerrocebus sanjei Mittermeier, 1986. In: Else & Lee (eds), Primate Ecology and Conservation, p. 338. Sanje Waterfall, Mwanihana Forest, Udzungwa Mts, Tanzania.

Sanje Mangabey *Cerrocebus sanjei* adult male.

Taxonomy Monotypic species (Kingdon 1997, Groves 2001, 2005c). Originally considered a subspecies (*Cerrocebus galeritus sanjei*) (Homewood & Rodgers 1981). No museum specimen exists and no holotype has been designated. Synonyms: none. Chromosome number: 2n = unknown, but 42 for all *Cerrocebus* spp. and *Lophocebus* spp. for which the chromosome number determined (Dutrillaux *et al.* 1979, T. Disotell pers. comm.).

Description Medium-sized, long-tailed, semi-terrestrial, grizzled-grey monkey. Sexes alike in colour. Adult ♂♂ moderately larger than ♀♀, but no body measurements exist against which to accurately assess sexual dimorphism. Muzzle grey to dark grey, moderately projecting with numerous dark vibrissae. Face pale pinkish and grey. Eyelids slightly less pigmented, pale beige, contrasting with surrounding skin. Skin on forehead and under eyes pale pinkish-cream. Cheek skin along hair line pale blue. Skin on body bluish-white, with skin on hands, feet and ears dark greyish. Crown hairs long, slightly parted along midline or forming a slight whorl, with shorter seam of hair extending forward along the brow. Hairs on crown, brow and extending back around face blackish at base, then dark greyish-brown. (Note: Previous descriptions of crown hairs swept back and upward to give a 'bouffant' appearance are inaccurate. These were based on the appearance of the crown of a captive adult ♂ at the Mount Meru Game Sanctuary, Arusha, Tanzania, which did not resemble any observed free-living animal. The 'bouffant' crown of this captive might have been due to the fact that it received a haircut as a juvenile pet and/or repetitive rubbing of the crown against the wire mesh of its cage.) Dorsum hairs long, light creamy-grey at base, then a darker grey band followed by a yellowish-orange band and black tip. Ventrums hairs long, pale orange. Pelage darker grey or blackish on distal part of limbs and on hands and feet. Paracallosal skin greyish with pink tinge. Ischial callosities pink; fused in ♂♂, separate in ♀♀. Tail long, grey, with slight tuft at tip. Infants have dark greyish-black coat and pink skin on face, ears, hands and feet.

Geographic Variation None recorded.

Similar Species None within geographic range.

Distribution Coastal Forest Mosaic and Afromontane–Afroalpine BZs. Endemic to two forests within the Udzungwa Mts, SC Tanzania: Mwanihana Forest (7°40'–7°57'S, 36°46'–36°56'E) within Udzungwa Mountains N. P. (UMNP), and Udzungwa Scarp F. R. (USFR; 7°39'–7°51'S, 35°51'–36°02'E) (Rodgers & Homewood 1982, Ehardt *et al.* 1999, 2005, Dinesen *et al.* 2001). The area of closed

canopy in the Mwanihana Forest is ca. 131 km², while that in the USFR is ca. 100 km². Reported presence in Ndundulu Forest in West Kilombero F. R. (Dinesen *et al.* 2001) resulted from misidentification of the Kipunji *Rungwecebus kipunji* (Jones *et al.* 2005, Ehardt & Butynski 2006a, b). Historical distribution may have included lowland forests of the Kilombero Valley below the south-eastern escarpment of the Udzungwa Mts (Homewood & Rodgers 1981).

Habitat In mosaic habitats and moist forest at altitudes from ca. 300–1800 m (Rodgers & Homewood 1982, Ehardt *et al.* 1999, 2005, Dinesen *et al.* 2001, Rovero *et al.* 2009). Occasionally observed in low altitude (300–500 m) miombo *Brachystegia* spp. woodland near human habitation and bordering secondary forest; reported to raid crops in these areas. Most abundant in mosaic habitats composed of mid-altitude (transitional) mixed evergreen and semi-deciduous forest, and in tall evergreen forest with canopy heights 40–50 m. One habituated study group ranges 700–900 m altitude in Mwanihana Forest. Main habitats and some of the common tree species within each of the habitats present within the home-range of this group of Sanje Mangabeys are summarized as: mature primary evergreen forest with canopy to 40 m (*Parinari excelsa*, *Tabernaemontana pachysiphon*, *Bombax rodhagnaphalon*, *Lagynias pallidiflora*); dominant *Tabernaemontana* forest with closed canopy to 15 m (*Anthocleista grandiflora*, *Harungana madagascariensis*, *Ficus* spp.); dry slopes covered in bracken fern *Pteridium aquilinum* and *Rubus* spp. with scattered trees to 15 m (*Bridelia micrantha*, *Vernonia mariacancia*, *Vitex doniana*, *Annona senegalensis*); and valley bottoms with predominant *Aframomum* spp. Other prominent trees in less-disturbed evergreen forest include: *Albizia gummifera*, *Parkia filicoidea*, *A. grandiflora* and *Treulia africana*. Sanje Mangabeys are frequently encountered in forested valleys near streams and rivers, which are numerous in both Mwanihana Forest and USFR. Annual rainfall along the south-eastern escarpment of the Udzungwa Mts varies 1500–2500 mm, with a distinct dry season May–Nov (Lovett *et al.* 1988).

Abundance Size of fragmented population uncertain but estimated at <1300 animals (Ehardt *et al.* 1999, 2005). Greatest abundance may be in Mwanihana Forest. Ehardt *et al.* (2005) estimate 200–270 animals in USFR and 700–900 animals in Mwanihana Forest. Line-transect censuses located 0.155 groups/km in USFR (S. D. = 0.223, n = 134 transects, total 479 km) and 0.058 groups/km in Mwanihana Forest (S. D. = 0.125, n = 180 transects, total 702 km; Rovero *et al.* 2012). These transects yield estimates of 1050–1400 animals in 30–40 groups for USFR, and 1750–2100 animals in 50–60 groups for Mwanihana Forest, giving a world population of ca. 2800–3500 animals (Rovero *et al.* 2009).

Adaptations Diurnal and semi-terrestrial. Occupies all forest strata, but most often <10 m above ground. Spends ca. 50% of time on the forest floor (Ehardt *et al.* 2005). Percentage time in different canopy strata for the habituated study group in Mwanihana Forest is as follows: lower canopy (3–6 m height) 10%; middle canopy (7–15 m height) 7%; upper canopy (>15 m height) 34% (C. L. Ehardt pers. obs.). Sleeps in large (>30 m tall), clumped trees such as *P. excelsa*. Study group in Mwanihana Forest utilized eight areas of tall trees for sleeping, scattered through their large home-range; each site might or might not be used during consecutive nights (C. L. Ehardt pers. obs.).

Adult ♂♂ emit ‘whoop-gobble’ loud-calls, audible to >1 km, which likely function as a group-spacing mechanism. These are given at all times of the day, but are most common in early morning, with ca. 70% given before 12:00h. Whoop-gobbles are frequently given in sleeping trees before the group begins foraging, and when conspecific groups are encountered. Other vocalizations include: high-pitched, repetitively emitted ‘barks’ given when the group is alarmed, which may differ in structure depending on the source of the threat (alarm calls); low volume, low frequency, short duration ‘moo’ calls that group members emit periodically when the group is spread out and resting (contact calls); multi-syllabic ‘hee-aw’ calls by oestrous ♀♀ after ♂ ejaculates and ♀ runs forward, breaking copulatory mounted position (post-copulatory calls); and rapidly repeated ‘geckers’ given by infants and young juveniles, especially in context of weaning (C. L. Ehardt pers. obs.).

Foraging and Food Omnivorous. Forages in all strata of the forest, but most often on the ground and in understorey trees and shrubs (Ehardt *et al.* 2005). On the forest floor Sanje Mangabeys manually search through leaf litter and decomposing wood for invertebrates, fallen seeds and nuts, and fungi, as well as dig for subterranean roots as deep as 500 mm (e.g. *Costus* sp.). The Sanje Mangabey has large posterior premolars, which are similar to other *Cercocebus* mangabeys (Fleagle & McGraw 2002), used to crack open hard seeds and nuts (e.g. *P. excelsa*) (C. L. Ehardt pers. obs.). Groups often fission into foraging parties, regrouping ≤6 h later (Ehardt *et al.* 2005). Invertebrates, such as ants, millipedes, slugs and snails, are taken from epiphytes in the branches of trees, and from rotting wood and leaf litter. When foraging on abundant fruit in single trees (e.g. *Ficus* sur), or on large fruits that cannot be consumed quickly, Sanje Mangabeys frequently place whole fruits or chunks of fruit in their cheek-pouches and move into other trees to process and consume. Also observed to place *P. excelsa* nuts gathered while moving along the forest floor into cheek-pouches to consume in trees, often in

early evening when moving toward sleeping trees (C. L. Ehardt pers. obs.).

Diet includes fruit pulp (ca. 50% of diet items consumed; $n = 5084$ food item scores over 19 months), seeds and nuts (27%), invertebrates (6%), shoots and stalks (4%), fungi (4%), mature and young leaves (4%), flowers (2%) (C. L. Ehardt pers. obs.). Consumed in smaller relative amounts (each $\leq 1\%$ of total diet items) are buds, petioles, herbs, roots, bark, lichen, tree gum or latex, birds, amphibians and reptiles (e.g. frogs and chameleons), and several invertebrates, such as snails and crabs found in or near rivers and streams (Wasser 1993, Ehardt *et al.* 2005, C. L. Ehardt pers. obs.). Plants utilized by non-systematically observed groups (near Sanje River Falls, ca. 600 m in Mwanihana Forest [Wasser 1993]), and by one study group at 700–900 m in the Sonjo River Valley in Mwanihana Forest (Ehardt *et al.* 2005, C. L. Ehardt pers. obs.), are: *Acacia polyacantha*, *Acacia siberiana*, *Aframomum* sp., *A. gummifera*, *A. senegalensis*, *A. grandiflora*, *Antiaris toxicaria*, *B. micrantha*, *Celtis gomphophylla*, *Costus* sp., *Diospyros natalensis*, *Dovyalis* sp., *Dracaena mannii*, *Entada rheedii*, *Ficus cyathistipula*, *F. sur*, *Ficus vallis-choudae*, *H. madagascariensis*, *Hoslundia* sp., *Kigelia africana*, *L. pallidiflora*, *Lettowianthus stellatus*, *Macaranga capensis*, *Mangifera indica*, *Milicia excelsa*, *Olyra* sp., *Oxytenanthera abyssinica*, *P. excelsa*, *P. filicoidea*, *Psychotria capensis* subsp. *riparia*, *Rhaphiostylis beninensis*, *Saba comorensis*, *Sorindeia madagascariensis*, *Strombosia scheffleri*, *Syzygium cumini*, *T. pachysiphon*, *Tarennia pavettoides*, *Toddalia asiatica*, *T. africana*, *Trema orientalis*, *Tricholysia* sp., *Trilepisium madagascariensis*, *V. mariacancia*, *V. doniana* and *Voacanga africana*. Foraging occurs most frequently in the morning, early afternoon, late afternoon and early evening (groups tend to rest for 1–2 h at mid-afternoon).

Home-range of Mwanihana Forest study group is ca. 2 km and overlaps that of two conspecific groups (Ehardt *et al.* 2005, C. L. Ehardt pers. obs.). Rovero *et al.* (2009) report home-ranges of 4–6 km² with overlap of home-range with up to three other groups. No evidence of territoriality. Intra-specific group encounters produce frequent ‘whoop-gobble’ vocalizations and alarm calls, with occasional chasing/fleeing. Mean daily path length ca. 1350 m (500–1650 m, $n = 190$ days; C. L. Ehardt pers. obs.).

Social and Reproductive Behaviour Social. Groups are multimale/multifemale. From 3–8 adult ♂♂ in Mwanihana study group; ♀♀ are philopatric. Group size counts and estimates in Mwanihana range from 1 to 40 individuals (mean 10, Wasser 1993; mean = 15, $n = 14$, Ehardt 2001). Rovero *et al.* (2009) report that mean group size is between 40 and 60 individuals. The study group in Mwanihana increased from 39 to 58 animals across ca. 3.5 years (C. L. Ehardt pers. obs.); another group in UMNP grew from 35 to 49 members over five years (Jones *et al.* 2006). Solitary adult ♂♂ occur (Homewood & Rodgers 1981, Wasser 1993, Dinesen *et al.* 2001, Ehardt 2001, Ehardt *et al.* 2005). In 2005 the study group of 47 animals in Mwanihana was comprised of five adult ♂♂ (number fluctuated from two to five), 23 adult ♀♀, ten subadults, five juveniles and four clinging infants (ratio adult ♂♂ to adult ♀♀ = 1 : 4.6; immatures to adults = 1 : 1.47) (C. L. Ehardt pers. obs.).

Groups form polyspecific associations with most of the other diurnal primate species in the Udzungwa Mts (Udzungwa Red Colobus *Procolobus gordonorum*, Peter’s Angola Colobus *Colobus angolensis palliatus*, Sykes’s Monkey *Cercopithecus mitis*) (Wasser 1993, Ehardt *et al.* 2005). One adult ♀ Udzungwa Red Colobus moved and foraged

with the Mwanihana Forest study group of Sanje Mangabeys for three consecutive days; interactions between this ♀ and group members were infrequent, although juvenile and subadult Sanje Mangabeys groomed her (C. L. Ehardt pers. obs.). In Mwanihana Forest Sanje Mangabeys were in polyspecific associations for ca. 28% of the sightings; the most frequent interspecific association for the Sanje Mangabeys was with Sykes’s Monkeys (ca. 52%, $n = 25$), ca. 54% of which involved a single adult ♂ Sykes’s Monkey. Associations with Udzungwa Red Colobus (28% of mangabey sightings) and Peter’s Angola Colobus (20% of mangabey sightings) were less frequent. Sanje Mangabey groups also associate with Natal Red Duiker *Cephalophus natalensis* and Crested Guineafowl *Guttera pucherani* (C. L. Ehardt pers. obs.).

Oestrous adult ♀♀ copulate with multiple adult ♂♂; adolescent and juvenile ♂♂ mount young adult ♀♀ in first oestrus without interruption by adult ♂♂. Dominant adult ♂ observed numerous times travelling and resting with an infant clinging to his ventrum. Male emits low, repetitive ‘ooh-ooh-ooh grunts’ when infant is clinging, especially following locomotion and before ♂ sits and infant dismounts. Male arches tail up and over back with tip at crown or side of head when giving the vocalization. Mother of infants follows behind ♂ and retrieves infant when it dismounts (C. L. Ehardt pers. obs.).

Reproduction and Population Structure Little known. Females exhibit perineal swellings and emit post-copulatory vocalizations; ♂♂ are single-mount ejaculators. Infants are carried on the ventrum during the first year; young juveniles sometimes carried ventrally for short distances. Singletons usually born, but one set of twins born in the habituated study group in Mwanihana Forest ($n = >12$ births). No pronounced mating/birth seasons, although birth peaks may exist; births in the habituated Mwanihana study group were not highly clumped across the year-long study but did not occur in all months (C. L. Ehardt pers. obs.).

Predators, Parasites and Diseases Predators include African Crowned Eagles *Stephanoaetus coronatus*, which are common in the Udzungwas and seen or heard on ca. 50% of observation days in Mwanihana Forest (Ehardt *et al.* 1999, 2005). Sanje Mangabeys give an alarm call when an eagle is detected. An adult African Crowned Eagle ♀ was attacked and killed by an adult Sanje Mangabey ♂ as the bird attacked a subadult mangabey feeding in a *Ficus* tree (Jones *et al.* 2006). Other predators known to take primates in the Udzungwa forests are Leopards *Panthera pardus*, Lions *Panthera leo*, various venomous snakes, and humans (see below). There is no information on parasites or other diseases.

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix II.

Sanje Mangabeys are threatened due to habitat loss and alteration, continued fragmentation of their small populations, and hunting by local people (Ehardt *et al.* 2005, Ehardt & Butynski 2006a, Rovero 2007, Rovero *et al.* 2012). Hunted with dogs and nets by local non-Muslim people (Homewood & Rodgers 1981). Hunting is largely controlled in UMNP, but mangabeys are sometimes caught in snares (A. R. Marshall pers. comm., C. L. Ehardt pers. obs.), that were likely set for other prey such as small antelope.

Concern for the persistence of this Tanzanian endemic monkey is great, especially given that ca. 40–50% of the world’s population

resides outside of UMNP, in the poorly protected USFR. The two most important actions that can be taken on behalf of the long-term conservation of the Sanje Mangabey are to upgrade the status of USFR to that of a Nature Reserve, and to establish the 'Mngeta Conservation Corridor' as this would link USFR with the southern forests of UMNP (Marshall *et al.* 2007, Rovero *et al.* 2012).

Measurements

Cercocebus sanjei

GLS (♀ ♀): 104, 113 mm, n = 2

GWS (♀ ♀): 72, 76 mm, n = 2

No body measurements available, and only two skulls, both collected in Mwanihana Forest, one by A. R. Marshall and one by F. Rovero.

Cercocebus atys SOOTY MANGABEY (SMOKY MANGABEY)

Fr. Mangabé fuligineux; Ger. Russmangabe

Cercocebus atys (Audebert, 1797). Histoire Naturelle des Singes et des Makis 4 (2) 13. West Africa.

Sooty Mangabey *Cercocebus atys* adult male.

Cercocebus atys

Taxonomy Monotypic species. Considered by some to be a subspecies of the Red-capped Mangabey *Cercocebus torquatus* (Dandelot 1974, Groves 1978, Napier 1981, Grubb *et al.* 1998) but not by most authorities, particularly in recent years (Booth 1956a, 1958b, Hill 1974, Oates 1996a, Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003). Type locality given as 'Indes orientales' but type label is marked 'Afrique occidentale' (Schwarz 1928d). White-naped Mangabey *Cercocebus lunulatus* often treated as a subspecies of *C. atys* (e.g. Booth 1956a, 1958b, Groves 1978, 2001, 2005c, Kingdon 1997, Grubb *et al.* 2003) but recognized as a species by Oates (2011) and here. Synonyms: *aethiopicus*, *aethiops*, *fuliginosus*. Chromosome number: $2n = 42$ (Brown *et al.* 1986).

Description Medium-size, slender, slate-grey (sometime light brown) monkey with long limbs and tail. Sexually dimorphic. Body

weight of adult ♀ ♀ about 60% that of adult ♂ ♂. Sexes similar in colour. Muzzle and ears blackish. Whiskers light grey. Face greyish-pink or pinkish. Eyelids off-white (not pure white). Iris olive. Crown usually without crest or whorl. Dorsum usually slate-grey though light brown in some individuals. Ventrums and inner limbs cream to light grey. Hands, feet and top of tail slightly darker grey than dorsum. Palms and soles black. Scrotum pinkish. Sexual skin of ♀ rosy pink. Depressions in the skull's suborbital region combined with facial prognathism give a hollow-cheeked appearance. Infants and juveniles like adults, though suborbital excavation not as pronounced.

Geographic Variation None recorded.

Similar Species

Cercocebus lunulatus. Between Sassandra and Volta Rivers. Nape (posterior crown) with concentric, V-shaped, or oval whitish

patch. Whorl of hairs on crown. Crown hairs without straw-coloured band. Ventrums pure white. Distinct, dark spinal stripe.

Distribution Rainforest BZ. Endemic to Upper Guinea Forests from Niadiou Village, Senegal (12° 30' N, 16° 05' W; Struhsaker 1971a) to the Nzo–Sassandra River System, Côte d'Ivoire (Wolfheim 1983, Kingdon 1997, Grubb *et al.* 1998, Groves 2003).

Habitat Primary forest preferred, but present, even abundant, in secondary forest. In high forest, gallery forest, coastal forest, *Raphia* palm swamp and mangrove, and farm bush. Probably always near water (Booth 1956a, Oates *et al.* 1990, Fimbel 1994b, Grubb *et al.* 1998, McGraw & Sciulli 2011). A frequent crop raider able to effectively utilize cultivated areas (Hill 1974, Fimbel 1994b).

Abundance One of the more common monkeys in West Africa (Wolfheim 1983, Kingdon 1997). Surveys and reports from Côte d'Ivoire, Liberia and Sierra Leone suggest that this species' abundance is due to its ability to exploit a variety of habitat types (Davies 1987, Oates *et al.* 1990, Fimbel 1994a). Reported densities are 11.9 ind/km² at Tai N. P., Côte d'Ivoire (McGraw & Zuberbühler 2007), and 38.5 ind/km² on Tiwai I., Sierra Leone (Oates *et al.* 1990). The following estimates are based on a 2006–08 study in Tai N. P. (3300 km²); 10.5 ind/km², 0.64 groups/km², and total of ca. 63,000 individuals (N'Goran *et al.* 2012).

Adaptations Diurnal and predominantly terrestrial. Males have large canines. Light-coloured eyelids are flashed as threats during agonistic encounters. During these threats ♂♂ commonly arch the tail over the rump in combination with yawns to display canines. The high masticatory forces needed to crush hard nuts are evident in various craniodental characteristics: these monkeys possess powerful jaws and teeth, their premolars are greatly expanded and the cheekteeth become heavily worn at early ages (Fleagle & McGraw 1999, Daegling *et al.* 2011, McGraw *et al.* 2011, 2012). Features of the humerus, ulna and radius reflect the frequent and aggressive use of the forelimbs to search for and process foods from the forest floor (Nakatsukasa 1996, Fleagle & McGraw 1999, 2002).

When alarmed on the ground, Sooty Mangabeys jump into short trees. Flight from predators, however, occurs on the ground. Experimental evidence from the Tai Forest indicates that of the seven sympatric cercopithecids present, *C. atys* is the best at detecting ground predators from the greatest distance (McGraw & Bshary 2002).

Vocal repertoire consists of 19 distinct vocalizations including 'grunts', 'twitters', 'screams' and 'growls' (Range & Fischer 2004). Copulation calls given by ♀♀ only. Adult ♂♂ give 'whoop-gobble' long/loud call, that is similar to whoop-gobbles given by *Lophocebus* (Struhsaker 1971a, Waser 1982). Males and ♀♀ both give distinct alarm calls to snakes (e.g. Gabon Viper *Bitis gabonica*, Black-necked Spitting Cobra *Naja nigricollis*), African Crowned Eagles *Stephanoaetus coronatus* and Leopards *Panthera pardus* (Range & Fischer 2004).

Foraging and Food Omnivorous. Foraging occurs at all forest levels but most food is obtained from the forest floor and includes fallen fruits and seeds, mushrooms, insects and leaves (Bergmueller 1998,

Fleagle & McGraw 2002, McGraw & Zuberbühler 2008, McGraw *et al.*, 2011). In Tai N. P., spends 67% of time, 85% of travel, and 71% of foraging on the ground (McGraw 2007a). Mean home-range size for groups in Tai N. P. is 4.92 km² with the largest home-range being 8.0 km². Average daily path length for one group followed for 58 days was 2.2 km (0.8–3.8) (Rutte 1998). Sooty Mangabeys have spatial memory of fruiting states of trees and this helps shape foraging routes (Janmaat *et al.* 2006). Two particularly important foods are *Sacoglottis gabonensis* and *Anthonata fragrans* (Bergmueller 1998, Rutte 1998, Daegling *et al.* 2011, McGraw *et al.* 2011).

Considerable foraging time is spent pawing through the leaf litter on the forest floor looking for fallen fruits, nuts and seeds. Skeletal adaptations of the forelimb and dentition reflect this reliance on manual foraging and seed predation. Compared to arboreal mangabeys (genus *Lophocebus*), the forelimb bones of *C. atys* possess much larger muscle markings indicative of frequent and aggressive use of forelimbs to access food on or near the ground. In these respects, the foraging ecology and accompanying morphology of *Cercocebus* are similar to those of Drills *Mandrillus leucophaeus* and Mandrills *Mandrillus sphinx* (Fleagle & McGraw 1999, 2002).

Social and Reproductive Behaviour Highly social. Live in large, multimale, multifemale groups with a complex social organization. Typical groups number 75–100 individuals. One group of 120 individuals studied for 10 months consisted of 6–10 adult ♂♂, 24–34 adult ♀♀, 29–34 juvenile ♂♂, 17–26 juvenile ♀♀ and 4–22 infants (Range & Noë 2002, 2004, Range 2005, 2006). The group's core consists of related ♀♀; ♂♂ disperse from their natal groups. Home-ranges overlap significantly with those of neighbouring groups. Territorial encounters between groups are infrequent and inter-group spacing appears to be maintained by the whoop-gobble calls of adult ♂♂. During inter-group encounters, both sexes may engage in threats and chases though such incidents usually involve ♀♀ only (F. Range pers. comm.). Non-resident adult ♂♂ are often seen travelling and foraging alone. The dominance system in captive *C. atys* is not based on maternal dominance rank (Bernstein 1976, Ehardt 1988, Gust & Gordon 1994, Gust 1995). In contrast, studies on grooming partners and association frequencies of free-ranging populations in Tai N. P. indicate that the dominance system is matrilineal-based (Range & Noë 2002, Range *et al.* 2007).

Polyspecific associations with arboreal monkeys are common but there are no data quantifying the frequency of these associations. Arboreal monkeys often respond to the presence of Sooty Mangabeys by descending and foraging to lower forest levels, including the ground (McGraw & Bshary 2002). In captivity and the wild, ♀♀ typically carry infants but ♂♂ also do so (Busse & Gordon 1984, W. S. McGraw pers. obs.).

Reproduction and Population Structure Visible changes in sexual skin of ♀♀ include a bright pinkening in the peri-anal region and correspond to ovulation (Gust 1995). Gestation (captivity) is ca. 175 days and a single infant is born (n = 198; Gust *et al.* 1990, Gordon *et al.* 1991). Twins have not been reported (Gust *et al.* 1990). There is a distinct mating season in Tai N. P. from Jun–Oct and the birth season is Oct–Mar (n = 52 births) with a peak during the Dec–Feb dry season. Interbirth interval ca. 2 years (Range *et al.* 2007). Females (captivity) first reproduce at 3.1 years (Ross 1991). Males

(captivity) reach sexual maturity at ca. 7 years (Gust & Gordon 1991, Gust *et al.* 1998). Birth rate (captivity) is 0.92. Maximum life-span (captivity) is 18 years (Ross 1991).

Predators, Parasites and Diseases Sooty Mangabeys frequently preyed upon by African Crowned Eagles *Stephanoaetus coronatus* and Leopards *Panthera pardus* (Shultz *et al.* 2004, McGraw *et al.* 2006a, Shultz & Thomsett 2007, Zuberbühler & Jenny 2002, 2007). Occasionally eaten by Robust Chimpanzees *Pan troglodytes* (Boesch & Boesch-Acherman 2000). The Sooty Mangabey is the primate reservoir of HIV-2, a less common strain of the AIDS virus. Transmission of this disease to humans probably occurred the first half of the twentieth century and involved the butchering of monkeys killed for consumption (Hirsch *et al.* 1989, Chen *et al.* 1996, Hahn *et al.* 2000, Lemey *et al.* 2003, Silvestri 2005).

Conservation IUCN Category (2012): Near threatened. CITES (2012): Appendix II.

There are no recent census data on the species, but numbers are undoubtedly decreasing owing to habitat loss and poaching (McGraw 2007b, Oates 2011). Dwindling habitat has forced this monkey to exploit cultivated lands, where farmers hunt them with dogs.

Measurements

Cercocebus atys

HB (♂): 580 mm, n = 1

HB (♀ ♀): 500 (470–520) mm, n = 3

T (♂): 600 mm, n = 1

T (♀ ♀): 580 (520–645) mm, n = 2

HF (♂): 157 mm, n = 1

HF (♀ ♀): 146 (145–147) mm, n = 3

E (♂): 28 mm, n = 1

E (♀ ♀): 31 (26–35) mm, n = 3

WT (♂ ♂): 10.6 (9.5–11.4) kg, n = 4

WT (♀ ♀): 6.2 (5.6–7.0), kg, n = 4

GLS (♂ ♂): 132 mm, n = 11

GLS (♀ ♀): 115 mm, n = 2

GWS (♂ ♂): 87 mm, n = 11

From various localities. Linear body measurements from Hill (1974).

Body weights from Oates *et al.* (1990) and W. S. McGraw (pers. obs.).

Skull measurements from Groves (1978); ranges not provided.

W. Scott McGraw

Cercocebus lunulatus WHITE-NAPED MANGABEY (WHITE-CROWNED MANGABEY)

Fr. Mangabé couronné; Ger. Weißcheitelmangabe

Cercocebus lunulatus (Temminck, 1853). Esquisses Zoologiques sur la Côte de Guinée, p. 37. Forest along Boutry R., Gold Coast [Ghana].

White-naped Mangabey *Cercocebus lunulatus*.

Taxonomy Monotypic species. Described, named and first recognized as a species by Temminck (1853). This designation subsequently supported for many years by a number of taxonomists, including Pocock (1906) and Elliot (1913b), and is the taxonomy used by Oates (2011) and in this profile (see below). Note that the type locality, 'Boutry R.' is better known (at least today) as the 'Ankobra R.' with Princes' Town (= 'Butri') at its mouth.

Treated as a subspecies of the Red-capped Mangabey *Cercocebus torquatus* by Schwarz (1928d) and others, including Dandelot (1974), Groves (1978d) and Napier (1981). More recently regarded as a subspecies of the Sooty Mangabey *Cercocebus atys* by Booth (1956a, b, 1958b), Dobroruka & Badalec (1966), Hill (1974), Grubb (1978, 1982), Kingdon (1997), Groves (2001, 2005c), Grubb *et al.* (2003) and McGraw & Fleagle (2006).

Grubb (1978, 1982) and McGraw & Fleagle (2006) argue that *lunulatus* derived from *C. atys* and that *C. torquatus* derived from *lunulatus*. However, both phenotypically and morphologically, *lunulatus* appears to be intermediate to *C. atys* and *C. torquatus* (Groves 1978, 2001) – although the number of available *lunulatus* specimens for study is small. For example, *lunulatus* is intermediate in colour of the eyelids, colour and banding of the hairs of the crown, colour of the dorsum, ventrum, tail and limbs, extent of white on the head and neck, development of the dorsal stripe, and size of the skull (perhaps also size of the body). In addition, the geographic distribution of *lunulatus* lies between *C. atys* and *C. torquatus*. As such, C. P. Groves, J. Kingdon and W. S. McGraw (pers. comm.) now suspect that *lunulatus* derived from an ancient hybridization between *C. atys* and *C. torquatus*. Synonyms: none. Chromosome number: $2n = 42$ (Groves 1978).

Description Medium-sized, gracile, brownish-grey monkey with long limbs and tail, and white or off-white patch on posterior of crown (i.e. nape). Sexes similar in colour but ♀ ♀ smaller; skull

measurements of adult ♀ ca. 90% that for adult ♂♂ (Groves 1978). Adult ♀♀ body weight ca. 54% that of adult ♂♂. Face and ears pinkish. Muzzle sometimes light grey (A. Galat-Luong pers. comm.). Eyelids off-white. Whiskers form horizontal crest half-way down cheeks with convergence of dark grey hairs of upper cheek with upwards-directed white hairs of lower cheek. Forehead with line of sparse, black, vibrissal hairs. Anterior of crown with blackish-brown whorl; hairs not banded or speckled straw-yellow. Nape with large V-shaped, oval, or crescent-shaped patch of pale yellowish-white or white, bordered with black. Parietal-occipital and temporal lines bounding crown brownish-black or indistinct. Dorsum variable, from pale gold-blond to dark sooty-grey (A. Galat-Luong pers. comm.). Flanks, outer limbs, tail tip and underside of tail usually brownish-grey or smoky-grey, sometimes yellowish-brown. Dorsal stripe from neck to tail distinct, dark brown to greyish-brown. Dark flanks sharply demarcated from light underparts. Tail dark grey or blackish above and on sides – almost as dark as dorsal stripe. Hands and feet brownish-black, only slightly darker than outer limbs. Sides of head, front of shoulders, throat, ventrum and inner legs pure silvery-white, sometimes yellowish-white on belly. Throat and upper chest sometimes yellow (A. Galat-Luong pers. comm.). Callosities pink. Sexual skin of adult ♀ bright rosy pink. Juvenile with dorsum more yellowish or reddish, especially on limbs; nape-patch slightly rusty (Hill 1974). Infant born with pale skin on face, hands and feet, and without dorsal stripe or white patch on nape. Dorsal stripe and white on nape begin to appear at about four days and about ten weeks, respectively (Field 1995a).

Geographic Variation None recorded.

Similar Species

Cerrocebus atys. Apparently narrowly sympatric. West of Nzo-Sassandra R. System, Côte d'Ivoire. Booth (1958b) observed both *C. atys* and *C. lunulatus*, but no intermediate forms, between the Nzo R. and Sassandra R. in the vicinity of Guiglo (06° 31' N, 07° 30' W; on Lac de Buyo near mouth of Nzo R.). Groves (1978), however, reports an intermediate (hybrid?) specimen from this region that lacks the white on the nape yet has a whitish ventrum. Nape black or blackish. Hairs of crown with straw-coloured band. Crown without a whorl. Dorsal stripe absent or indistinct. Ventrum light grey. More robust (A. Galat-Luong pers. comm.).

Distribution Endemic to Côte d'Ivoire, Ghana and Burkina Faso. Rainforest BZ. Distribution highly fragmented. East of Nzo-Sassandra River System, W Côte d'Ivoire, from coast north to near Guiglo (ca. 06° 44' N, 07° 20' W), and near Goudi (ca. 06° 07' N, 05° 06' W, near Lamto along Bandama R.; Bourlière *et al.* 1974), eastward into SW Ghana where southern limit is the coast, eastern limit known to approach to ca. 55 km of the Volta R., northern limit is the Afram R. (Booth 1958b) and north-east limit is the Digya N. P. (07° 23' N, 00° 37' W; R. Dowsett & F. Dowsett-Lemaire pers. comm.; S. Gatti & S. Wolters pers. comm. to J. Oates). From the distribution map in Grubb *et al.* (1998), northern limit in Ghana does not reach the Tain R., or the towns of Wenchi or Techiman, and is at ca. 07° 24' N.

Formerly 'regularly' encountered in forest islands and gallery forest of the Comoé N. P., Côte d'Ivoire (Mühlenberg & Steinhauer-

Burkart 1982, G. Galat & A. Galat-Luong pers. comm.). Present as an isolated population along the Comoé R. in southern Comoé N. P. (ca. 09° 01' N, 03° 44' W; Fischer *et al.* 2000). Present also in a newly discovered, and apparently isolated, population along the Comoé R., ca. 140 km farther up river in AGEREF/Comoé-Léraba Reserve, SW Burkina Faso (09° 55' N, 04° 37' W; Galat & Galat-Luong 2006b). Mangabeys reported to be to the north of Guiglo between Nzo R. and Sassandra R. on Mt Péko and in Mt Sangbé N. P. If present, the species of *Cerrocebus* there needs to be determined (G. Campbell pers. comm.).

Extent of occurrence roughly 51,000 km² (Y. de Jong & T. Butynski pers. obs.) but area of occupancy much less than this.

Habitat In primary and secondary moist forest, mangrove, coastal forest, gallery forest and inland swamps, especially *Raphia* palm swamps. Of 11 encounters in Comoé N. P., seven in gallery forest, three in forest islands and one on a cliff (G. Galat pers. comm.). B. Kunz (pers. comm.) encountered *C. lunulatus* 22 times in Comoé N. P. and estimates that these represented four or five groups. Sixteen encounters in or on the edge of gallery forest, three in savanna, and three in or on the edge of forest islands. Apparently always in or near damp or wet habitats (e.g. palm swamps and seasonally flooded forest). Enters rice paddies and farm bush (Booth 1956a, 1958b). Mean annual rainfall over geographic range of *C. lunulatus* ca. 900 mm in SW Burkina Faso to 2000 mm on coast of Ghana and Côte d'Ivoire. Mean annual temperature over geographic range ca. 25–28 °C. Altitudinal range is from near sea level to roughly 300 m (e.g. at Comoé N. P.; F. Fischer pers. comm.).

Abundance Already rare throughout most of range during 1990s (see Conservation). 'Regularly' encountered in forest islands and gallery forest of the Comoé N. P. Of the 183 groups of primates encountered by G. Galat & A. Galat-Luong (pers. comm.) during 1980–86, 11% were *C. lunulatus*. Of the eight species of diurnal

primates in Comoé N. P., *C. lunulatus* was the fourth most abundant behind the Olive Baboon *Papio anubis* (34%), White-thighed Colobus *Colobus vellerosus* (19%) and Lowe's Monkey *Cercopithecus lowei* (12%).

Density in gallery forest of the Comoé R., in AGEREF/Comoé–Léraba Reserve, is about 5 ind/km² (G. Galat & A. Galat-Luong pers. comm.). In the protected areas in Ghana where Magnuson (2002) found *C. lunulatus*, the encountered rate was 0.03–0.08 groups/km. Observed seven times during 2006–08 in Ankasa Resource Reserve, Ghana (0.07/h, $n = 2468$ h; 0.002/km, $n = 3704$ km; Gatti 2009).

Adaptations Diurnal and semi-terrestrial. Sleeps in trees in gallery forest or on forest islands.

Foraging and Food Omnivorous. In AGEREF/Comoé–Léraba Reserve group home-range extends for >1.5 km in the ca. 100 m wide gallery forest along the Comoé R. and adjacent savanna. *Cercocebus lunulatus* enters savanna for a distance of ca. 1 km to feed in fruiting trees (G. Galat & A. Galat-Luong pers. comm.). One group of ten individuals at AGEREF/Comoé–Léraba Reserve had a home-range of >2 km² (G. Galat & A. Galat-Luong pers. comm.).

Cercocebus lunulatus probably spends the majority of its time on the forest floor but uses all forest strata. In Comoé N. P. eats ripe fruits of *Lannea welwitschii*, *Tamarindus indica* and *Dialium guineense*, unripe and ripe fruits of *Lannea acida* and *Diospyros mespiliformis*, unripe fruit and leaves of *Sarcocephalus latifolius*, unripe seeds of *Daniellia oliveri*, *Cynometra megalophylla* and *Parkia biglobosa*, flower buds of *Ceiba pentandra* and the bases of green grasses (B. Kunz pers. comm.). Eats maize and rice in Ghana (Booth 1958b, Jeffrey 1970), and fruits of *Saba senegalensis* and *Dialium guineense* in Burkina Faso (Galat & Galat-Luong 2006b).

Social and Reproductive Behaviour Social. Groups of 3–23 animals in Comoé N. P.; one group of 23 comprised six infants in May 1998 (Fischer *et al.* 2000). Here, B. Kunz (pers. comm.) made complete counts of three groups (23, 25–30, 58 individuals, mean = ca. 36). Two groups in AGEREF/Comoé–Léraba Reserve comprised six and 13 individuals. The group of 13 comprised one adult ♂, four adult ♀♀, seven young and one clinging infant (A. Galat-Luong & G. Galat pers. comm.). In Ghana hunters commonly report historic sightings of groups of >50 individuals (L. Magnuson pers. comm.).

Vocalizations include: 'chirps', 'shreeks', 'coh coh' grunts, 'woof woof' grunts, 'whoop-gobbles' and 'karakoo' barks. Whoop-gobble and karakoo barks only given by adult ♂♂. Whoop-gobble + karakoo bark bouts include 2–8 whoops followed by 10–75 sec silence, followed by four to many karakoo barks. The karakoo barks may continue to be given for >20 min. For some karakoo bark bouts, the last call is a 'karakoo oo oo'. Whoop-gobble + karakoo barks most frequent at night (01:00–05:00h) in series of two or three bouts, and in the early morning (05:00–07:45h). Duets of numerous whoop-gobbles occur between two groups, with only the last whoop-gobble followed by karakoo barks (A. Galat-Luong & G. Galat pers. comm.). In captivity ♀ emits 'coh' call before copulation and ♂ emits 'oh oh oh' call during copulation (A. Galat-Luong pers. comm.). In AGEREF/Comoé–Léraba Reserve territorial conflicts include whoop-gobbles and karakoo barks of adult ♂, karakoo bark

choruses of other adults and of subadults, chirps of young and other individuals, and contact fights between adults (A. Galat-Luong & G. Galat pers. comm.).

In Comoé N. P., G. Galat & A. Galat-Luong (pers. comm.) observed *C. lunulatus* in associations with other species of monkey 4% of the time ($n = 183$ encounters); *C. lowei*, Lesser Spot-nosed Monkey *Cercopithecus petaurista*, *P. anubis* and *C. vellerosus*. *Cercocebus lunulatus* was sometimes in association with up to at least three other species at one time; for example, with *C. lowei*, *C. petaurista* and *P. anubis*, or *C. lowei*, *C. petaurista* and *C. vellerosus*. In AGEREF/Comoé–Léraba Reserve *C. lunulatus* forms polyspecific associations with Green Monkeys *Chlorocebus sabaeus* (Galat & Galat-Luong 2006a). In Ghana observed with *C. lowei* and Roloway Monkeys *Cercopithecus roloway* (L. Magnuson pers. comm.).

Inter-specific interactions include supplantation of an adult ♀ + clinging infant *C. lowei*; whoop-gobble + karakoo bark bouts in response to Patas Monkey *Erythrocebus patas* and *P. anubis* barks; and karakoo bark-induced *C. lowei* loud-calls (A. Galat-Luong & G. Galat pers. comm.). On one occasion B. Kunz (pers. comm.) observed several Olive Baboons chase 3–5 *C. lunulatus* from a fruiting *D. mespiliformis* in which they were feeding. On another occasion one *C. lunulatus* fed near a group of Olive Baboons on unripe pods of *P. biglobosa*.

Cercocebus lunulatus in captivity spontaneously use sticks (tools) to scratch (groom) themselves in order to decrease stress. Sticks 10–40 cm long are prepared by removing the leaves and twigs. If the stick is too long it is broken into two pieces. Two sticks may be used simultaneously, either hand + hand, or hand + foot. Body parts that are difficult or impossible to reach with the hands or feet are scratched (e.g. inside of the ears) (Galat-Luong 1984, A. Galat-Luong pers. comm.).

Reproduction and Population Structure Minimum length of oestrous cycle in captivity is 19 days. Gestation is reported as 152–180 days (Field 1995b). Gestation at London Zoo and Dublin Zoo reported as 5.5–6.0 months and 5.0 months, respectively (A. Payne pers. comm.). Flamingo Land reports a gestation of 5.5 months. Over 51 births in captivity, including 36 at Ménagerie du Jardin des Plantes (G. Pothet pers. comm.). Thirty-seven per cent of the 51 infants born in captivity died, most of them when <2 months of age. Only single infants reported as live births but stillborn twins observed at Flamingo Land (D. Cross pers. comm.). Birth weights at Ménagerie du Jardin des Plantes ranged 400–580 g (sample size not provided; G. Pothet pers. comm.). Female at Dublin Zoo lived to ca. 31 years (S. Devaney pers. comm.).

Predators, Parasites and Diseases Humans, by far, are the most important predator for *C. lunulatus* (Oates *et al.* 1997, McGraw & Oates 2002). Commonly hunted with the use of dogs in Ghana (L. Magnuson pers. comm.). Found in seven Leopard *Panthera pardus* scats ($n = 371$) collected in Comoé N. P., accounting for 1.4% of the prey items and 1.2% of the prey biomass consumed. Not found in any of the Leopard scats ($n = 188$) collected in Marahoué N. P., Côte d'Ivoire, nor in any of the Lion *Panthera leo* scats ($n = 89$) collected in Comoé N. P. (Bodendorfer *et al.* 2006). Probable predators of *C. lunulatus* include African Crowned Eagles *Stephanoaetus coronatus*, Robust Chimpanzees *Pan troglodytes* and Central African Rock Pythons *Python sebae*.

In Comoé N. P. *C. lunulatus* has been observed mobbing a Leopard – while giving karakoo barks and in association with *C. vellerosus* and *C. lowei*. In another instance, gave karakoo barks in response to a Martial Eagle *Polemaetus bellicosus* attack on *C. lowei* and *C. petaurista* (while *C. lowei* and *C. petaurista* gave loud-calls). While giving karakoo barks, the adult ♂ looked up towards the sky and stayed in an open situation, chest exposed, while the members of his group hid or fled (G. Galat & A. Galat-Luong pers. comm.).

Conservation IUCN Category (2012): Endangered as *C. a. lunulatus*. CITES (2012): Appendix II.

Considered to be one of the world's most threatened primate taxa (McGraw *et al.* 2006b). Galat & Galat-Luong (2006a) estimate the wild population to total <1000 individuals. The Upper Guinean Forest in which *C. lunulatus* lives has been reduced by >90% as a result of logging and agriculture (Asibey 1978, McGraw *et al.* 2006b). Hunting is intensive throughout the range (Wolfheim 1983, Oates *et al.* 1997, 2000a, McGraw & Oates 2002, Galat & Galat-Luong 2006a, Oates 2006, 2011, Gonedélé Bi *et al.* 2012). In Ghana in the late 1960s to mid-1970s *C. lunulatus* present in Sefwi Wiawso, Sukusuku, Dadieso F. R. and Yoyo F. R., abundant in Ankasa Resource Reserve and Nini-Suhien N. P., and rare in Bia N. P. (Jeffrey 1970, Asibey 1978, Wolfheim 1983). Oates *et al.* (1997) surveyed nine sites during 1993–95 in SW Ghana and never encountered *C. lunulatus*. They concluded (p. 142) that, 'Based on hunters' reports, our guess is that this species is still present in several areas, but in very low numbers.'

In Ghana, *C. lunulatus* in Ankasa Resource Reserve, Nini-Suhien N. P., Draw River F. R., Krokosua Hills F. R., Boi Tano F. R., Dadieso F. R. and Yoyo F. R. during the 1990s and early 2000s but rare at all sites (Abedi-Lartey 1999, Oates *et al.* 2000a, Magnuson 2002). More recently, Oates (2006) surveyed four forests in SW Ghana: Mamiri F. R., Boi Tano F. R., Krokosua Hills F. R. and Bia N. P. and Resource Reserve. He concluded that *C. lunulatus* had been extirpated from all four sites. In 2004–05, R. Dowsett & F. Dowsett-Lemaire (pers. comm.) spent six months in Ghana surveying birds in all of the Ghana Wildlife Division's protected areas and received convincing reports for *C. lunulatus* in only three areas: Atewa Range F. R., Cape Three Points F. R. and Digya N. P. (3478 km²). S. Gatti (pers. comm. to J. Oates) observed *C. lunulatus* at Cape Three Points F. R. and Digya N. P. in Dec 2006. Still present, but rare, in Ankasa Resource Reserve in 2006–08 (Gatti 2009).

In Côte d'Ivoire, reported in Marahoué N. P., Dassioko F. R., Niegre F. R., Comoé N. P. and Ehy Forest (= Tanoé Swamp Forest; Fischer *et al.* 2000, McGraw & Oates 2002, McGraw *et al.* 2006b, Koné *et al.* 2007a, b), but see Gonedélé Bi *et al.* (2012). In Burkina Faso, in the AGEREF/Comoé-Léraba Reserve, there is a small, isolated population restricted to the gallery forest of the Comoé R. It appears that this is a recently established population. Previous surveys of the mammals of the AGEREF/Comoé-Léraba Reserve never recorded *C. lunulatus* (Bousquet 1992), and local people, including park rangers and hunters, did not know this monkey until its discovery by Galat & Galat-Luong (2006a, b) in 2005. In the area where one group was observed in 2005, at least three groups were present 1.5 years later. Galat & Galat-Luong (2006a, b) suggest that

C. lunulatus was able to move into AGEREF/Comoé-Léraba Reserve in ca. 2004 from Comoé N. P. as a result of a corridor of protected area that was created between the two parks and that became effective in ca. 2004.

Priorities for the conservation of *C. lunulatus* are to: (1) upgrade the Nini-Suhien N. P./Ankasa Resource Reserve/Draw River F. R. complex to one national park; (2) consolidate Bia N. P. and Bia Resource Reserve into one national park; (3) greatly improve protection of all sites in which *C. lunulatus* occurs; and (4) conduct surveys to further assess the status of forest primates at the above sites as well as Atewa Range F. R., Cape Three Points F. R., Digya N. P. and Ehy Forest (Oates 1996a, 2006, 2011, Oates *et al.* 1997, McGraw *et al.* 2006b, Koné *et al.* 2007a, b, R. Dowsett & F. Dowsett-Lemaire pers. comm.). Several sites where *C. lunulatus* is present are also sites important for the Endangered *C. rolaway* and the Vulnerable *C. vellerosus* (Magnuson 2002, McGraw *et al.* 2006b, Oates 2006, 2011). Any actions that protect *C. lunulatus* and *C. rolaway* may, however, already be too late to save another taxon that once occurred at some of these sites, the Critically Endangered, probably extinct, Miss Waldron's Red Colobus *Procolobus badius waldronae* (Oates *et al.* 2000a, McGraw & Oates 2002).

There are ca. 50 *C. lunulatus* in ten European zoos. The West African Primate Conservation Action Project (WAPCA) focuses on primate protection and reproduction in Ghana.

Cercocebus torquatus RED-CAPPED MANGABEY (WHITE-COLLARED MANGABEY)

Fr. Mangabé à collier blanc; Ger. Rotkopfmangabe

Cercocebus torquatus (Kerr, 1792). Animal Kingdom, p. 67. West Africa.Red-capped Mangabey *Cercocebus torquatus* adult male.

Taxonomy Monotypic species (Kingdon 1997, Groves 2001, 2005c). Previously classified at the subspecies level, *Cercocebus torquatus torquatus*, with the Sooty Mangabey *C. t. atys* and the White-naped Mangabey *C. t. lunulatus* comprising the other two subspecies (Dorst & Dandelot 1970, Groves 1978). Synonyms: *collaris*, *crossi*. Chromosome number: $2n = 42$ (Dutrillaux *et al.* 1979).

Description Large, slate-grey, moderately long-muzzled, semi-terrestrial monkey with red crown and white collar. Sexes alike except markedly dimorphic in size. Adult ♀♀ weigh about 55% as much as adult ♂♂. Face skin dark grey to black with eyelids bright white and sharply contrasting with face skin. Ears naked, dark greyish-black, extending above white collar. Crown russet to dark maroon-red, outlined by the white collar and broad temporal line, and may show whirl or slight medial partition. Chin, sides of the neck, cheeks and throat white. Cheek stripe grey, of variable thickness, separating white cheeks from white throat. Whiskers white, short, directed backward. Nape with white patch. Dorsum chestnut brown to dark grey with darker dorsal stripe. Outer limbs darker grey at distal end and on feet. Ventrums and inner limbs sharply-demarcated white. Hands and feet with brownish-black skin. Tail darker grey than dorsum, whitens distally with white tuft. Callosities brownish-pink, fused in ♂, separate in ♀. Skin and pelage colour different in infants: skin of face, hands and feet pink; eyelids lighter than face skin. Head auburn. Dorsum brownish-grey. Crown red by four months of age; full adult colouration by five months (Field 1995a).

Suborbital fossae shallow relative to other *Cercocebus* spp., whereas the paranasal ridges are the most pronounced of the *Cercocebus* spp. (McGraw & Fleagle 2006). These features, and the presence of straight temporal lines are, among the *Cercocebus* species, the most similar to

Lateral, palatal and dorsal views of skull of Red-capped Mangabey *Cercocebus torquatus* adult male.

Mandrillus. This suggests that *C. torquatus* is the sister taxon to *Mandrillus* within the *Cercocebus*–*Mandrillus* clade (McGraw & Fleagle 2006).

Geographic Variation Skull size and breadth substantially variable across populations, although not in a pattern justifying distinct subspecies (Groves 1978). Length of white on tail also variable (90–235 mm) across populations (Hill 1974, Groves 1978).

Similar Species None within geographic range.

Distribution Endemic to West Africa. Rainforest BZ. From W Nigeria (from west of Niger R.) through Cameroon (east as far as E Dja Reserve), Equatorial Guinea (Rio Muni), and the Gabon coast (to south of Nyanga R. in Mayumba N. P.) into S Congo (Conkouati-Douli N. P.) (Rosevear 1953, Gartlan & Struhsaker 1972, Hapold 1973, Schlitter *et al.* 1973, Blom *et al.* 1992, Groves 2001, Oates 2011). Distribution patchy across range. Almost all populations within 350 km of the coast (Maisels *et al.* 2007b).

Western limit uncertain. Hapold (1973) stated that the Red-capped Mangabey occurs in forest relics in the derived savanna zone of W Nigeria, near the Dahomey Gap (e.g. within the Igangan F. R.).

Cerrocoebus torquatus

Schlitter *et al.* (1973) state that the species might occur in remnant forests west of the Nigerian border in Bénin. This is supported by Campbell *et al.* (2008b), who obtained verbal reports of Red-capped Mangabeys in SE Bénin.

Habitat Occupies a variety of habitat types, although principally relatively wet habitats: swamp forest or seasonally/intermittently inundated forests, mangroves, lowland riverine and coastal forest. Also in primary and secondary *terra firma* dry forest, and utilize agricultural areas such as rice fields and gardens (Sabater Pi & Jones 1967, Jones & Sabater Pi 1968, Gartlan & Struhsaker 1972, Hill 1974, Napier 1981, Garcia & Mba 1997, Gautier-Hion *et al.* 1999, Cooke 2005). Garcia & Mba (1997) observed Red-capped Mangabeys frequently associated with nipa palm trees *Raphia* spp. in riparian forests along the Uolo R. and Laña R. in Monte Alén N. P., Equatorial Guinea. The majority of sightings by Sabater Pi & Jones (1967) were in lowland forests (<350 m asl) of the coastal region, in riverine forest and confluences of rivers and the ocean, or in swamps characterized by tangles of red mangrove *Rhizophora mangle* roots and stands of *Pandanus* sp., with dense closed canopies 10–12 m high composed of plants such as *Raphia* spp., *Sclerosperma mannii*, *Mitragyna ciliata*, *Oxytenanthera abyssinica* and *Cytosperma senegalense*. Vegetation near the coast of Rio Muni where Red-capped Mangabeys were observed was 10–25 m plants such as *Phoenix reclinata*, *Cocos nucifera*, *Canavalia ensiformis*, *Urena lobata*, *Pennisetum purpureum* and *Terminalia cattappa* (Jones & Sabater Pi 1968). Annual rainfall across the geographic range of Red-capped Mangabeys ca. 1400–3200 mm with wet seasons from Mar to May (minor) and Sep to Dec (major) (Mitani 1991, Blom *et al.* 1992, Garcia & Mba 1997). Found at altitudes from sea level along the Atlantic coast to <1000 m, with most reported locations below 500 m.

Abundance Abundance decreases from west to east both in Cameroon and Gabon (Matthews & Matthews 2002); rarely encountered east of Campo Forest in Campo-Ma'an N. P., S

Cameroon (Mitani 1990), and apparently absent in SE Cameroon (Lobéké N. P.) (Davenport & Usongo 1997). Although Gartlan & Struhsaker (1972) found Red-capped Mangabeys in E Dja Reserve, later surveys here did not locate them (Ngandjui 1997). Struhsaker (1972) reported this species as 'common' in both Douala-Edéa R. and Korup N. P. Densities have since declined: 0.23 groups/km² in 1999; 0.14 groups/km² in 2000 (Waltert *et al.* 2002); 0.01 groups/km² in 2004–05 (Linder 2008); 0.02 groups/km² in 2006–08 (Astaras *et al.* 2011). Matthews & Matthews (2002) reported 0.51 groups/km² in Campo Forest, and significantly higher densities in areas of lower levels of human disturbance (0.71 groups/km² on Dipikar I., with minimal disturbance, vs. 0.36 groups/km² in a heavily exploited logging concession area; $p < 0.01$). These censuses indicated Red-capped Mangabeys were largely restricted to the coastal areas, only reaching 80–100 km inland. In Gabon, early reports also suggested that Red-capped Mangabeys are less abundant in the interior (Malbrant & Maclatchy 1949). Non-systematic surveys confirmed this observation in the protected areas of Moukalaba and Sette Cama; Red-capped Mangabeys were reported to be 'abundant' although restricted in distribution to areas near the coast (Blom *et al.* 1992). Cooke (2005) found Red-capped Mangabeys to be the most abundant cercopithecoid near the village of Sette Cama, south of Loango N. P., Gabon. Morgan (2007) encountered 36 groups in Loango N. P. and estimated mean group density at 0.97 groups/km² in this coastal protected area.

Generally rare in the interior of Equatorial Guinea (Jones & Sabater Pi 1968, Garcia & Mba 1997), but locally abundant. Declining in all areas of Equatorial Guinea (C. Jones pers. comm. in Wolfheim 1983). In Nigeria, rare or not abundant west of the Niger R. (Happold 1973, Schlitter *et al.* 1973). In Okomu N. P., SW Nigeria, White (1988) found ca. 85 groups, although the area was threatened by hunting and habitat alteration, worsened by the negative consequences of a programme of agricultural development assistance to migrant farmers (Oates 1995). Here, in 2008–09, Akinsorotan *et al.* (2011) found 0.1 groups/km² and 2.2 groups/km². Surveys (since 1995) in S Nigeria indicate that the Red-capped Mangabey is locally extinct or rare in a number of areas of the Niger Delta and Akwa Ibom (Z. Tooze pers. comm.).

These observations support Kingdon's (1997) evaluation that the Red-capped Mangabey was once a widespread, successful species that is declining from all areas where habitat loss to agricultural expansion and intensive hunting occur.

Adaptations Diurnal and semi-terrestrial (Jones & Sabater Pi 1968, Mitani 1989, Gautier-Hion *et al.* 1999). Red-capped Mangabeys spend considerable time on the ground, frequently descend to the ground to feed or to flee when alarmed, and utilize forest strata from the ground to 40 m high in the canopy (Jones & Sabater Pi 1968, Mitani 1989, 1991). In Campo Forest, the vertical distribution of Red-capped Mangabeys differed by activity patterns: 'escape' (fleeing observers) occurred on the ground in 85% of 21 observed instances; 'move' (locomotion) and 'socio-rest' (including both grooming and resting) were recorded most frequently at 0–5 m (ca. 58% of 185 observations and ca. 63% of 161 observations, respectively); whereas 'feed' (search, approach, manipulation, consumption of food) correlated positively with distribution of fruit production, with a mode height of 25–30 m (Mitani 1989).

Red-capped Mangabeys, like other semi-terrestrial *Cercocebus* spp., exhibit a suite of skeletal and dental features associated with foraging on the forest floor for sparsely distributed, hard object foods, such as nuts and seeds, which require extensive gnathic processing – features and associated ecological behaviour shared with *Mandrillus* (Hoshino 1985, Rogers *et al.* 1996, Kingdon 1997, Fleagle & McGraw 1999). These features include greatly enlarged upper and lower posterior premolars that approach the first molars in size and that function to open and process seeds and nuts (Fleagle & McGraw 2002). The expanded premolars are used by Red-capped Mangabeys to process seeds of *Guibourtia tessmannii*, *Lacouli carlifolia* and *Craibia laurentii* in Sette Cama (Cooke & McGraw 2007).

The robust, well-developed forelimb skeletal morphology is functionally adaptive for extensive, forceful manual foraging in forest litter and rotting wood as well as for vertical climbing. The similarly developed hindlimb and hip skeletal features further facilitate the vertical climbing of tree trunks by species in the *Cercocebus*–*Mandrillus* clade of African papionins (Fleagle & McGraw 2002). Jones & Sabater Pi (1968) describe Red-capped Mangabeys ascending vines head first with hand-over-hand movements, and descending from arboreal substrates by backing down utilizing similar hand-over-hand movements. Similar locomotory behaviour in the Sanje Mangabey *Cercocebus sanjei* (C. L. Ehardt pers. obs.).

Foraging and Food Omnivorous. Forages on the forest floor and in the canopy. In Campo Forest, forages in the lowest strata (0–5 m) for monocotyledonous shoots and young leaves of shrubs; foraging for fruit is most frequent in the canopy (ca. 57% of 103 observations at 25–30 m) (Mitani 1989, 1991). Group fissioning into foraging parties of variable age/sex composition was noted by Jones & Sabater Pi (1968) in Rio Muni and by Mitani (1989) in Cameroon. Mitani (1989) reported mean foraging group size of 21.11 ± 2.55 (range 14–38, $n = 9$) and foraging group age/sex composition (ratio adult ♂♂ to adult ♀♀ to immatures) as 1 : 1.2 : 1.9. Ranging area varied seasonally with spatial distribution of fruiting trees in this study, averaging ca. 50% of the annual home-range size in each of the wet/dry seasons sampled over 15 months.

Home-range of one study group in Cameroon encompassed 247.4 ha over 15 months and partially overlapped (ca. 30%) the ranges of two conspecific groups, although neighbouring groups avoided one another (Mitani 1989). A three-month study of two groups of Red-capped Mangabeys in Sette Cama found home-ranges of ca. 2 km² and day ranges of ca. 1 km (Cooke & McGraw 2007).

Diet consists largely of fruit and seeds/nuts, supplemented with leaves; monocotyledon shoots, stems and roots; flowers (e.g. *Halopegia azurea*); grasses (e.g. *Haumania danckelmaniana*); mushrooms; and insects (Jones & Sabater Pi 1968, Mitani 1989, Gautier-Hion *et al.* 1999). Red-capped Mangabey groups raid crops, including Cacao and Ground-Nut plantations (Jones & Sabater Pi 1968, Wolfheim 1983). In Cameroon, fruit was the major food item consumed across all seasons (ca. 60% of diet), there was no seasonal difference in species diversity of food fruits or number of fruit species eaten, and the seasonal range size of groups correlated with the spatial distribution of fruiting trees. The study group's fruit diet came predominantly (73%) from only five plant species: *Grewia coriacea*, *Anthonotha cf. cladantha*, *Sacoglottis gabonensis*, *Scorodophoeus zenkeri* and *cf. Khaya ivorensis*. Seeds were the second most consumed food, contributing 20% of the diet for this

Red-capped Mangabey *Cercocebus torquatus* adult male showing bright white eyelids.

study group (Mitani 1989). In Rio Muni, Red-capped Mangabeys utilize *Raphia vinifera* and *Ancistrophyllum secundiflorum* in the swamp forest areas of their range, and *Antrocaryon klaineianum*, *Chytranthus macrophyllus*, *Ficus hochstetteri* and *Pycnanthus angolensis* in primary and secondary forest areas (Jones & Sabater Pi 1968).

Social and Reproductive Behaviour Social. Groups are multimale-multifemale, ♀♀ are philopatric and solitary ♂♂ occur (Jones & Sabater Pi 1968, Mitani 1989). In SW Cameroon mean group size ca. 19 (S.D. = 3; sample size not reported; Matthews & Matthews 2002). Twenty-five individuals in one study group; adult ♂ to adult ♀ ratio of 1 : 1.75 (Mitani 1989). In Rio Muni, group sizes were 14–23 individuals ($n = 11$ groups, Jones & Sabater Pi 1968), and 20–60 individuals (mean = 35, $n = 5$, C. Jones, pers. comm. in Wolfheim 1983). Morgan (2007) encountered ten groups in censuses of Loango N. P. and reported mean group size of 17.7 (S.E. = 1.18).

Polyspecific associations common. Red-capped Mangabeys associate with Wolf's Monkey *Cercopithecus wolffi*, Moustached Monkey *Cercopithecus cephus*, Red-bellied Monkey *Cercopithecus erythrogaster*, Putty-nosed Monkey *Cercopithecus nictitans* and De Brazza's Monkey *Cercopithecus neglectus* (Jones & Sabater Pi 1968, Oates 1985, Mitani 1991, Cooke 2005). Associates infrequently with Talapoin Monkey *Miopithecus talapoin* in Rio Muni (Jones & Sabater Pi 1968). Most frequent association in Campo Forest was with *C. wolffi* ($n = 30$ of the 49 two-species associations observed for Red-capped Mangabey groups); association with Mandrill *Mandrillus sphinx* ($n = 4$) also exceeded expected frequency based on numbers of foraging groups for each taxon. Here, Red-capped Mangabey groups exhibited seasonal variation in frequency of polyspecific associations (mean = 7.11, $p < 0.05$), forming more associations during the two dry seasons (Mitani 1991).

'Whoop' vocalizations given in series, which may be in quick succession and descending in tone; may be similar to the initial portion of the 'whoop-gobble' loud call of several other mangabey species, but the 'gobble' portion not given. A two-syllable 'bark' is emitted both by ♂♂ and ♀♀, most frequently in the early morning and without evident eliciting stimuli (Cashner 1972, Waser 1982). Jones

& Sabater Pi (1968) report that Red-capped Mangabeys in their study area ceased vocalizing when groups were disturbed by their presence; this contrasts with other mangabey species that respond to disruption with distinctive loud ('alarm') calls (Waser 1982).

Reproduction and Population Structure The following reproductive parameters are from captive Red-capped Mangabeys. Males become sexually dimorphic at about five years. Females begin to cycle at 2.2–3.0 years of age; cycle length 30–33 days. First conception at 3.3 years; mother's age at first birth ca. 6.5 years. Gestation 170–175 days. Birth interval reported as 13 months by Harvey *et al.* (1987) and as 16 months by Field (2007). Females exhibit dark pink, prominent perineal swellings during oestrus. Post-conception swellings also occur, 1.5–2 months into pregnancy; these swellings appear similar to those of a normal ovulatory cycle but stay at maximum tumescence longer and detumescence is slower, lasting 15–25 days (Harvey *et al.* 1987, Field 1995a). No evidence of mating/birth seasonality. No twin births recorded for North American captive populations (Jones & Sabater Pi 1968, Field 2007).

Maximum recorded ages in captive Red-capped Mangabeys of known birth dates are 26 years for ♂♂, 24+ years for ♀♀ (Field 1995a).

Predators, Parasites and Diseases African Crowned Eagles *Stephanoaetus coronatus* and Leopards *Panthera pardus* are known predators. Human hunters are undoubtedly the Red-capped Mangabey's most significant predator in many areas (Mitani 1989, Blom *et al.* 1992, Fa & Garcia Yuste 2001, Waltert *et al.* 2002, Willcox & Nambu 2007). Wild populations in Nigeria and Cameroon harbour novel simian immunodeficiency viruses (SIV) (Beer *et al.* 2001, Telfer *et al.* 2003) and novel simian T-cell lymphotropic viruses (STLV) (Meertens *et al.* 2002). These are similar to those found in wild populations of *Mandrillus*, further emphasizing the phylogenetic closeness of *Cercocebus* and *Mandrillus* (Beer *et al.* 2001, Telfer *et al.* 2003), and may facilitate research addressing disease ecology and immunology of related human viral pathogens (HIVs and HTLVs).

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Although Red-capped Mangabeys reside in a number of legally protected areas (e.g. Korup N. P. [ca. 1253 km²] and Campo-Ma'an N. P. [ca. 2640 km²]; Okomu N. P. [ca. 181 km²]; Loango N. P. [ca. 1550 km²]; Monte Alén N. P. [ca. 2000 km²]; and Conkouati-Douli N. P. [ca. 5045 km²]), high levels both of hunting for the bushmeat trade and habitat alteration/destruction persist. The causes are many, but include insufficient law enforcement and ill-designed development schemes that destroy the natural resource base and that conflict with effective conservation.

Populations of Red-capped Mangabeys have declined considerably, or have been extirpated, in many places, a situation exacerbated by the species' restricted distribution and often low densities. They are widely hunted using shotguns, and their semi-terrestrial behaviour subjects them to additional risk from snares, which may have been set for other animals such as Blue Duikers *Philantomba monticola*, other duikers *Cephalophus* spp., Emin's Giant Pouch Rat *Cricetomys emini* and cane rats *Thryonomys* spp. In many areas, such as along the Cameroon-Nigerian border, hunting is the major cause of primate declines (Oates

1999), feeding what has become a billion-dollar bushmeat industry. In addition, a portion of the range is within the Guinean Forests of West Africa Biodiversity Hotspot, a region that has already lost >85% of its original forest cover. Continued high levels of deforestation due to commercial and slash-and-burn agriculture, logging and large-scale mining are significant contributors to continued forest degradation, loss, fragmentation in the region, including the coastal forest and swamp forest habitats preferred by Red-capped Mangabeys. Protected areas within the range of the Red-capped Mangabey are inadequate in number, size, connectivity and levels of law enforcement; improving conservation will require multi-national cooperation, extensive effort to reverse historically deep patterns of land use, and curtailment of the highly destructive bushmeat trade.

In 2007 there were 27 Red-capped Mangabeys (14 ♂♂, 13 ♀♀) in eight North American zoos (Field 2007) and 50 (30 ♂♂, 20 ♀♀) in ten European zoos (ISIS 2007).

GENUS *Mandrillus*

Mandrills

Mandrillus Ritgen, 1824. *Natürliche Eintheilung der Säugethiere*, p. 33.

The first published description and depiction of either a Drill or a Mandrill was by Gesner (1554), who referred to it as a kind of wolf. Gesner's description was the chief basis for the Linnaean name *Simia sphinx*. To straighten out the nomenclature, a neotype for the name *sphinx* was nominated. For a summary of this unusual taxonomic history see Napier (1981).

Mandrillus includes two species of 'forest baboon': the Drill *Mandrillus leucophaeus* and the Mandrill *Mandrillus sphinx*. The ♂♂ are among the most extreme and flamboyant examples of sexual dimorphism among primates, indeed, among mammals. In spite of this distinction there are arguments for this genus to be subsumed in the much less spectacular and monkey-like genus *Cercocebus*. One of us (C. P. G.) finds these arguments compelling although in this instance we adhere to traditional nomenclature. Molecular study puts the time of divergence between *Mandrillus*/*Cercocebus* and *Papio*/*Lophocebus* at 6.7 mya (late Miocene; Perelman *et al.* 2011).

Left: Mandrill *Mandrillus sphinx* adult male grimace.

Right: Drill *Mandrillus leucophaeus* adult male head tilt.

Drills and Mandrills are heavily built, baboon-like animals with long muzzles and very short, forward-tilted tails that help to emphasize the colourful genital area. Although their pelage is a grizzled olive, the broad, mostly hairless rumps of ♂♂ in both species are brightly coloured, as are their facial areas, which have been elaborated into species-specific 'masks'. The faces and proportions of the much smaller ♀♀ resemble small, short-tailed baboons but are distinguished by contracted, drabber versions of the male's face-mask. Males of both *Mandrillus* spp. have long faces with nasal ridges that connect the zygomatic plate with the canines and incisors. This elongated facial skeleton protrudes in front of the braincase with no downward deflection, unlike *Papio*. Large bony paranasal ridges extend the length of the muzzle on either side of the nasal bones; these ridges undergo rapid secondary enlargement in some adult ♂♂ (Elton & Morgan 2006), and they also differ between the two species. The bony paranasal ridges are hollow, inflated and creased in *M. sphinx* and are covered in white and blue, sometimes red, skin.

This, together with the red skin that covers the nasal bone, apparently mimics and enhances an expression that resembles a carnivore-like 'snarl'. In *M. leucophaeus* the ridges are smooth and shiny black, forming a contrast to the bright red streak below the lower lip. Above and behind the brows and eye sockets, the forward parts of large temporal muscles are attached to ridges on a flat but anteriorly broadened frontal bone. These superior temporal lines are sharply set off from the surface of the braincase; they begin on the posterior side of the lateral edges of the supraorbital ridges, and converge gradually, overhanging the postorbital constriction before reaching the braincase. This arrangement correlates with an exceptionally powerful bite on a tooththrow that is strengthened by enlargement of the premolars (Hoshino 1985, Fleagle & McGraw 2002).

Externally, the genus is characterized by large, forward-facing nostrils, pointed ears with a hairless patch behind, noticeable circumoral vibrissae and a large sternal gland whose sticky secretion, in breeding ♂♂, continuously saturates the breast hair. Morphologically *Mandrillus* spp. differ from *Papio* spp. and most other papionins in that they have distinctive shoulder-blades, upper arms, knees and pelvis, all modifications that assist in manipulation of vegetation and the substrate in their search for food, much of which is hidden (Hoshino 1985, Nakatsukasa 1994a, 1996, McGraw & Fleagle 2006).

Sexual dimorphism in body size is greater in this genus than in any other monkey, possibly greater than for any other primate. Asymptotic body mass in wild Mandrill ♀♀ is 8.9 kg, in ♂♂ 30.4 kg, a ratio of more than 3 : 1.

These two allopatric species are confined to the Ogooué R. Basin and a broad coastal strip running between the mouth of the Congo R. and the Sanaga R. (Mandrill), and between the Sanaga R. and the Cross R. (Grubb 1973). Also on Bioko I. (Drill). There are two noteworthy features about this limited distribution. One is that the range of these two species coincides with the highest rainfall in Africa. The other peculiarity is that to the immediate east of their distribution the presently continuous forest belt has been vulnerable to degradation during past arid periods, creating a dry corridor that has periodically connected the northern and southern savannas. Both these environmental peculiarities may have a bearing on our understanding of the origins of *Mandrillus*, of extreme constriction in the distribution of this genus and on the evolution of their subsistence strategy. It is noteworthy that three loriform genera, *Arctocebus*, *Euticus* and *Sciurocheirus*, are restricted to much the same general area.

Mandrillus ranges may not have shrunk greatly in historic times, although populations within those ranges have declined and become fragmented. There are no recorded instances of them living far from their present overall distribution around the Bight of Bénin. As such, any hypothetical retraction over a more extensive area would have had to be prehistoric.

This limited distribution (originally, perhaps, some 10% of the forest zone) is in striking contrast with the wide ranges of many other forest primates and with the pan-sub-Saharan range of

mainly savanna-living baboons *Papio*, which share similar foraging patterns to *Mandrillus*, with many animals covering extensive areas (>50 km²). The *Mandrillus* social structure is unlike that of *Papio* in that huge 'hordes' of >600 individuals may assemble in which ♀♀ preponderate. They are also unlike baboons in their highly seasonal breeding and polygynous mating.

In common with *Papio*, *Mandrillus* are heavy, mainly terrestrial primates that periodically move about in large groups. They rely upon two types of foods: the first are fruits or nuts that are of high nutritional value, often well dispersed throughout the forest at appropriate seasons and best harvested, as they ripen, by smaller, equally dispersed groups of monkeys. The second type of food consists of ubiquitous vegetation, old dropped kernels and invertebrates under the leaf litter, or seasonal masting over extensive areas of forest. These allow *Mandrillus* spp. to gather in very large numbers that then comb through and strip an area of everything edible before they move on, en masse. A prime advantage in mass-feeding is gaining access to a resource while predators are effectively intimidated, an imposition that is assisted by the physical size and leonine, masked heads of ♂♂ in both species.

The striking ecological success of *Papio*, the limited contemporary range of *Mandrillus*, and the abundance of baboon-like fossils from savanna habitats over the entire Plio-Pleistocene, all suggest that *Mandrillus* derived from a less forest-adapted type of papionin. None the less, today *Mandrillus* spp. are well adapted members of a rich forest primate community.

The limited range of *Mandrillus* today is of special interest because in some respects it seems relictual, being only viable in the wettest forests. Climatic fluctuations, opening and closing the Cameroon/Gabon 'corridor' provide, in theory, a mechanism for the 'entrapment' of originally non-forest organisms. The location of this corridor immediately adjacent to *Mandrillus* range suggests a possible geographic locus and hints at ecological and climatic conditions that might have facilitated the emergence of a unique genus of 'forest baboons'. The nature and timing of that emergence is currently unknown. If it involved the transfer of a baboon-like ancestor from non-forest into forest, this emergence might have been linked to a warm phase in the mid-Pliocene (3.6 mya) or, just conceivably, to warmer, moister conditions in the very late Miocene (5–6 mya). The timing of such events is crucial for our understanding of *Mandrillus* origins because there are currently fundamental disagreements as to whether *Mandrillus* is the earlier basal type for its close sister group, *Cercocebus*, or whether the relationship between the two genera is reversed (see pp. 165–6 and below).

Mistakenly classed as baboons *Papio* by some authors (Hilzheimer 1906, Elliot 1909b, Haltenorth & Diller 1980), *Mandrillus* has a different genetic profile from *Papio* (Cronin & Sarich 1976, Disotell *et al.* 1992, Goodman *et al.* 1998). C. J. Jolly (pers. comm.) describes the *Lophocebus/Papio/Theropithecus* and *Mandrillus/Cercocebus* stocks as ultimately derived from smallish, moderately long-faced ancestors much like the fossil genera *Parapapio* or *Pliopapio*. A species of this

stock underwent facial retraction, as proposed by Kingdon (1971), that culminated in a common, ancestral mangabey stem. The *Cercocebus* branch of this stem gave rise to the current diversity within the genus, and also to *Mandrillus*. The latter, in Jolly's view, became larger-bodied and longer-faced convergently with *Papio*, itself an offshoot of the other mangabey branch, from which *Lophocebus* and *Theropithecus* also derived.

Kingdon (1971, 1997) agrees with a long-term separation of *Papio* and *Mandrillus* lineages, and also concurs in *M. sphinx*, *M. leucophaeus*, Red-capped Mangabey *Cercocebus torquatus* and Golden-bellied Mangabey *Cercocebus chrysogaster* being closely related but sees them as four divergent lineages that are more conservative than the five shorter-muzzled *Cercocebus* spp. Like Dobroruka & Badalec (1966) and Nakatsukasa (1994a, 1996), Kingdon proposed that shorter-muzzled mangabeys derived from longer-muzzled types. In his view, *Mandrillus* might represent the response of a *Parapapio*-like population to the exceptional humidity (and probable spread of forests) in the later Miocene. From this perspective the *Cercocebus* radiation derived from a once more diverse and more widely distributed *Mandrillus*-like lineage, and Kingdon considers that a number of behavioural, ecological and morphological patterns accord best with this suggestion.

Resolving this issue is of considerable theoretical importance. *Mandrillus* appears to follow an expansive foraging strategy broadly similar to that of *Papio*, which is of demonstrable utility in non-forest habitats. The behavioural and morphological resemblances between *Mandrillus* and *Papio* would, in this instance, derive from a shared ancestry and an adaptive starting point that is relatively early, not late. In the second instance, if this mode of existence evolved independently within the forest, and *Mandrillus* derived from substantially smaller, forest-dwelling mangabey ancestors, then the degree of convergence with baboons invites much closer attention to the morphological details and evolutionary increments behind such an exclusively *intra-forest* transformation. It also invites attention to the particular properties of the forests around the Bight of Bénin to determine what unique features might have favoured this development there and nowhere else. This option necessarily implies that *Mandrillus* is of late, relatively recent evolutionary origin, a conclusion that would tie the evolution of each species to extremely localized conditions. Older origins, in which baboon-like features are more likely retentions (rather than convergences), accords better with what otherwise appears to be a relictual status.

It is interesting that *Mandrillus* shares its range with one of the mangabeys, *C. torquatus*, which, though not itself the most drill-like of these mangabeys (that status belongs to the more robust *C. chrysogaster*), is the largest and longest-faced. Simultaneous field studies on these two sympatric, closely related, semi-terrestrial, hard-object-feeding monkeys should be revealing.

Jonathan Kingdon & Colin P. Groves

Mandrillus sphinx MANDRILL

Fr. Mandrill; Ger. Mandrill

Mandrillus sphinx (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 25. Dja R., Bitye, Cameroon.Mandrill *Mandrillus sphinx* adult male.Mandrill *Mandrillus sphinx* adult female.

Taxonomy Monotypic species. Based on morphological similarities, *Mandrillus sphinx* has often been erroneously referred to as *Papio sphinx*, but compelling genetic and morphological analyses during the 1990s (Disotell 1993, Fleagle & McGraw 1999) show *Mandrillus* to be closer to the terrestrial mangabeys *Cercocebus* spp. than to *Papio*. Synonyms: *burlacei*, *ebolowae*, *escherichi*, *hagenbecki*, *insularis*, *latidens*, *madarogaster*, *maimon*, *mormon*, *pennanti*, *planirostris*, *schreberi*, *suilla*, *tessmanni*, *zenkeri*. Chromosome number: $2n = 42$ (Romagno 2001).

Description Large, stocky, short-tailed, terrestrial monkey with a facial mask of bare red, white and blue skin. Extreme sexual dimorphism, becoming apparent at about four years of age. Fully mature adult ♂♂ (>10 years old) weigh 3–4 times more than adult ♀♀.

Adult ♂: head and neck pelage dark brown with highly contrasting white flashes behind the small brown or pink ears. These flashes are exaggerated by pads of fat on the skull, pushing out the ear and increasing the visibility of the white hair and white skin. Face brightly coloured, with dark red skin covering the prominent brow ridge, nasal ridge and nostrils. Skin around the eyes generally dark brown to black, though in some ♂♂ red colour can spread throughout the face. Eyes hazel-brown with pale skin on the upper lids, highly visible when the animal blinks. Two elongated patches of white skin puckered into 6–10 parallel (paranasal) ridges, run either side of the nose, supported by bony protuberances of the maxillary bone and mimicking a dog-like snarling expression. The troughs of

these paranasal folds are bright blue. White begins to appear on the paranasal ridges at about six years of age. As the paranasal ridges grow, the blue in the troughs is eclipsed by the expanding white ridges. By ten years, the muzzle is completely white, with the blue visible only at the edges of the ridges (i.e. deep within the troughs). When the adult ♂ 'snarls', the blue helps to accentuate the snarl. The blunt muzzle is sparsely haired white, blending into a golden yellow beard and ruff around the face. A triangular crest of erectile hair from the brow ridge to apex of the sagittal crest appears almost black when the animal is agitated. Hair around the face and neck is much longer than the body hair, giving the impression of a disproportionately large head in fully mature ♂♂, and a heavy, 'bear-like' profile. Dorsum and limbs brown to grey. Ventrums white and long-haired. Penis bright red, hairless, not visible in a walking animal though easily visible, and often displayed, in a seated animal. Scrotum bright pink. Perianal skin bright red. Buttocks and upper thighs almost hairless, coloured iridescent blue, blending through purple to pink towards the edges of the hairless patch. Colour intensity and size of bald patch vary among animals. Tail short, 60–100 mm long, held erect, dark brown to black above, sometimes pale grey below. Anal callosities fused in ♂♂; not highly visible in older ♂♂ with full colouration.

Adult ♀: head, neck and body pelage dark brown to mid-grey. No white ear flashes. Skin on face dark blue, occasionally with red in the brow ridge. Paranasal ridges much smaller and less prominent than in the ♂ and generally dark blue with occasional red mottling. Paranasal ridges of the ♀ gradually fade back to blackish-grey as she ages. Faces of old ♀♀ have a 'faded' look but there is no exact age at which this begins. Some adult ♀♀ never have much blue on the paranasal ridges. No white on face, though full cheek pouches can give the temporary impression of a white ruff around the throat. Dorsum and limbs brown to grey. Ventrums light brown to pale grey. Perianal skin red. Adult ♀♀ display a red sexual tumescence around

the vulva during ovulatory cycles. Some ♀♀ have slight thinning of the hair and a pale bluish colouration of the skin on the buttocks. This trait is highly variable, though ♀♀ never attain the iridescent blue colouration of ♂♂, nor develop red colouration on the buttocks. Anal callosities on buttocks unfused and easily visible from behind.

Infants and juveniles: born with pink faces, darkening to black masks and crowns around 2–4 months of age. Large pink ears and face, and white hair on the limbs, easily visible when carried ventrally. Pelage darkens at 5–13 weeks of age to olive and this colour is typical of juveniles under three years old. Head, neck and back pelage relatively thick. Prominent beard yellow, pointed 'goatee', that diminishes around three years of age. Ventrums pale grey to white. Colouration develops in the face and genitals around three years of age, with full adult characteristics in ♀♀ at around four years, and in ♂♂ at around ten years of age. From 3–5 years the paranasal ridges are bluish in both sexes. Unless the penis (red) is seen, the sexes are indistinguishable until 5 years.

Geographic Variation No subspecies recognized although recent phylogeographic analyses show a genetic divergence between populations north and south of the Ogooué R., Gabon (Telfer *et al.* 2003). Individuals from these populations show no reproductive isolation when brought into contact in captivity (Wickings *et al.* 1993).

Similar Species

Mandrillus leucophaeus. Allopatric at Sanaga R., Cameroon. Black facial mask with well-defined edge contrasting with white skin. Beard absent.

Distribution Endemic to western central Africa. Rainforest BZ. Confined to the rainforests of Gabon west of the Ivindo and Ogooué Rivers upstream of their confluence, Cameroon south of the Sanaga R., Equatorial Guinea and coastal Congo, north of Pointe Noire.

Lateral, palatal and dorsal views of skull of Mandrill *Mandrillus sphinx* adult male.

Probably absent from the Ogooué Delta and Lagoons region of coastal Gabon.

Habitat Confined to closed canopy rainforests, Mandrill groups only cross open habitat for short distances (<200 m), though lone ♂♂ sometimes venture farther. Long grass savannas are avoided. Within forest, preference for mature and riparian forest types with clear understorey. Avoids dense herbaceous ground cover, such as in 'Marantaceae' forest. The entire range of the Mandrill is characterized by fairly high rainfall (1500–4000 mm/year) and the occurrence of two wet and two dry seasons per year, each of roughly three months duration. The timing of these seasons is, however, different in the parts of the range north and south of the Equator.

Abundance No reliable population estimates are available. Simple extrapolation from the only accurately measured mean group size of 620 ± 167 (325–845, $n = 6$) and home-range size of ca. 89 km², gives a density of 7.0 ind/km² (6.5–11.2) for the Lopé N. P., Gabon, in the centre of the species' range (Abernethy *et al.* 2001, 2002, White 2007). This mean group size has remained stable at Lopé over 11 years of study. Densities are likely lower outside protected areas.

Adaptations Diurnal and mainly terrestrial. Modified canines and premolars allow efficient shearing of tough pods and seeds. Premolars of the lower jaw are extended and have a modified labial edge forming a flat plate for shearing seeds against the lingual surface of the long upper canines. A well-developed sagittal crest anchors strong jaw musculature, increasing bite force and ability to crack

hard seeds. Upper canines in ♂♂ have an extremely sharp caudal edge and measure 3–5 cm long. All canines are deeply grooved on the rostral surface, possibly to reduce weight whilst maintaining strength in such large teeth. Bite wounds received during male–male fights in the breeding season are common and can be fatal (W. Karesh pers. comm.).

Extreme sexual dimorphism, and the evolution of bright coloured skin patches and specialized vocalizations in breeding ♂♂ may be display adaptations to avoid costly direct conflict during intense competition between ♂♂ (Wickings & Dixon 1992, Abernethy *et al.* 2002). Adult ♂♂ have highly vascularized bony protrusions of the maxillary bones running parallel to the nasal bone. These uplift and exaggerate the visibility of the coloured skin of the face. Fatty deposits behind the ears and on the buttocks similarly serve to increase the visibility of coloured skin patches.

Foraging and Food Omnivorous. Opportunistic omnivores, specializing on fruit, seeds and insects. Mandrills have a wide dietary niche. One group used 48 different foods in a ten-day period (Rogers *et al.* 1996). Dung analysis of 3156 samples from two groups over a period of five years in Lopé showed 76 species of plant used, from which fruit pulp (contained in 76% of samples), seeds (52%), leaves (57%) or other fibres (90%) had been consumed, as well as insect matter (88%) and occasional meat from small mammals, reptiles, crustaceans, or fish (<1% in total). These results are broadly similar to those from other areas (Hoshino 1985, Lahm 1986). There is no strong influence of seasonality on the overall composition of the diet, though the species making up the fruit and seed content vary through the year. Diet shifts towards ripe fruit in times of abundance and towards seeds in times of fruit scarcity (White 2007).

Mandrill hordes (large aggregations of animals) travel continuously, moving an average of 4.2 km per day (0.5–11.2, $n = 92$ day ranges over two years). Bouts of relatively stationary foraging are rare, usually confined to early morning (06:00–07:00h) and late afternoon (17:00–18:00h), whilst opportunistic foraging occurs throughout the travel period from around 07:00–17:00h daily. Group spread during foraging can be over 6 ha, but is more usually around 1–2 ha (White 2007, K. Abernethy & L. White pers. obs.). Most time is spent foraging on the ground, often searching extensively through leaf litter, presumably for fallen seeds, fungi, invertebrates and small vertebrates. Mandrill horde trails are easily seen in the dry season as patches of leaves are swept aside across a swathe of forest floor. Mandrills forage arboreally for fruit and seeds, concentrating particularly on small fruited species such as *Uapaca*, *Dialium* and *Diospyros* species, Oil Palm *Elaeis guineensis* nuts and the large unripe seeds of leguminous trees such as *Pentaclethra macrophylla*. Sugary fruit pulps are often actively rejected when feeding on fruits to extract the seeds (White 2007, K. Abernethy & L. White pers. obs.). Crop-raiding is frequently reported, particularly in dry seasons when fruit crops in the forest are poor (Lahm 1993). Root crops, such as manioc or sweet potato, are frequently targeted. Adult ♂♂ leave the hordes outside the breeding season, possibly to reduce feeding competition with ♀♀ and young, but do not appear to have a significantly different diet when solitary.

Mandrill hordes seem to inhabit relatively exclusive home-ranges. In Lopé a horde of 620 animals used an annual home-range of ca. 89 km² of forest, but changed their range slightly each year, to use an area of approximately 182 km² over six years. Home-ranges rarely

overlap the range of a neighbouring horde (White 2007). Aggressive encounters between individuals occur, but there is no clear evidence of defensive territoriality and intergroup aggression has never been documented (K. Abernethy pers. obs.).

Social and Reproductive Behaviour Social. In Lopé N. P., Mandrill ♀♀ and young (♀ offspring under four years and ♂♂ to approximately five years of age) live in very large hordes of 400–850 animals (mean 620 ± 167 , $n = 6$). Group sizes of 400+, similar to those found at Lopé, are reported for the Minkébé, Waka, Ivindo and Moukalaba Doudou National Parks and the Lékédi Sanctuary, Gabon (P. Henschel, M. Starkey, S. Lahm, C. Mbina & P. Peignot pers. comm.). Much smaller group sizes (80–150 ind) reported for areas in the north of the range during the 1970s and 1980s (Jouventin 1975, Hoshino *et al.* 1984). These may, however, have been due to difficulty of observation, or to group reduction through hunting pressure.

Horde composition in Lopé is typically ca. 15% infants under one year old, 35% juveniles of 2–3 years, 30% adult ♀♀ and 20% subadult ♂♂ (4–9 years old). Adult ♂♂ join the group only during the breeding season, in proportion to the numbers of available breeding ♀♀: a maximum of 21 breeding ♂♂ (2.6% of group members) seen in a horde of 804 Mandrills that included 49 ♀♀ showing sexual tumescence and likely to be fertile (Abernethy *et al.* 2002).

The ♀ hordes appear to have a highly flexible structure and may separate into subgroups for periods of a few days to several weeks at any time of the year, though often this is following disturbance by humans or other predators. Thirty-five radio-collars placed in a horde in Lopé N. P. from 1998 to 2007 (ongoing study) show that subgroups have highly flexible sizes and memberships. Subgroups rarely stay separated for more than a few weeks, though the horde may only reunite for a few days before re-splitting into different subgroups, and the entire horde may only travel together for a small part of the year. Subgroup sizes and subgrouping frequencies are spatio-temporally related to ripe fruit abundance. Adult ♂♂ are only seasonally associated with the hordes and, outside the breeding season, live as solitary individuals (Abernethy *et al.* 2002, White 2007).

Horde or subgroup leadership is unclear in wild Mandrills. As adult ♂♂ are not permanent members of the horde, it is unlikely that they play a role in leadership. Observations of travelling hordes have not shown any consistent pattern of leading individuals, although there is a tendency for younger ♂♂ and ♀♀ without offspring to be towards the front of the group, ♀♀ carrying ventral infants towards the middle of the horde, and juveniles bringing up the rear. Although these patterns are very variable, they are clear enough to imply organization of the entire horde as one unit, rather than multiple subunits. Mandrill hordes travel terrestrially. Although they are agile climbers, they are not good jumpers, lacking the balance brought by a long tail. As such, they do not travel arboreally. When alarmed, all Mandrills drop to the ground and run swiftly, bunched together. Hordes can travel several kilometres in less than one hour in order to escape human predators and will usually move in silence during escape flights. Offspring are carried ventrally for all travel during the first 3–5 months of life and, periodically, at moments of stress or fast travel thereafter. Young become fully independent at ca. two years of age, when the next offspring is born. Males play no role in infant care or defence. Juvenile ♀♀ carry infants in the wild, possible orphaned individuals or closely related individuals, but

this behaviour is rare and breeding ‘helpers’ are not used. At around two years of age infants are fully weaned and often travel and forage in juvenile groups of 6–10. When stressed, however, they return to their individual mothers (K. Abernethy pers. obs.).

When adult ♂♂ are with the hordes they are most often following and mate-guarding sexually receptive ♀♀, spread throughout the group. The number of adult ♂♂ within a horde is not related to overall horde size, but highly correlated to the number of sexually receptive ♀♀ present, as defined by visible sexual tumescences (Abernethy *et al.* 2001). Adult ♀♀ move away from adult ♂♂ by climbing on to thin branches inaccessible to the heavier ♂♂, but ♀ ability to freely choose mates seems restricted. Adult ♂♂ may enter and leave the horde several times during a breeding season, travelling with the ♀♀ for between two days and six months, depending on accessibility of sexually receptive ♀♀ and competition with other ♂♂. Male–male competition is fierce and the secondary sexual characters are likely to play a large role in ♂ reproductive success (Setchell & Dixson 2001). Males rejoin the same horde up to four years in succession. Adult ♂♂ can move between neighbouring hordes either within or between breeding years, but this happens infrequently (only two visits to neighbouring groups documented during ten years radio tracking of 21 breeding ♂♂). Male dispersal away from the natal horde likely occurs during the subadult phase of ♂ development, as ♂♂ 6–9 years of age are solitary. No information exists, however, on the behaviour of wild subadult ♂♂ during this period. Females are not known to disperse between hordes, and genetic analyses indicate that ♀♀ within hordes are highly related.

Females vocalize frequently, using a complex repertoire of calls. Most obvious are long, shrill ‘wraaaaahh’ screams, used to maintain contact across large group spreads. The frequency of these calls increases when the horde is travelling, and especially when directional changes are made, or when subgroups are inadvertently separated from the main horde. Female screams may be heard by the human ear over 1 km away across open ground and up to 600 m in the forest. Chuckling or burbling contact calls are not so loud and appear to be used to maintain group cohesion during foraging. Aggressive hissing is often heard between ♀♀ engaged in squabbles over food items. Mature ♂♂ in the horde emit a constant deep grunting throughout the day when in the presence of sexually receptive ♀♀. Breeding ♂♂ begin to vocalize around dawn and continue until group activity stops at dusk. The grunting frequency and volume increase if the animals are agitated in conflict and are thought to serve as a display signal to reduce direct conflict between ♂♂, and possibly also to influence ♀ choice. Males do not grunt when solitary, nor when there are no sexually receptive ♀♀ in the horde. Alarm calls may be given by any group member, although those emitted by juveniles are often ignored by others. The alarm call is a short cough, repeated and developing into an ‘uh-HUH’ as agitation increases. Small, questioning coughs, accompanied by head bobbing are often used to investigate new objects and precede true alarm calls, especially by juveniles (Hoshino 1985, K. Abernethy pers. obs.).

Other primate species often travel with Mandrills as the horde moves through their range, presumably gaining from increased vigilance and predator deterrence by the large horde. As Mandrill diet overlaps in part with that of each of the sympatric primate species, some inter-specific feeding competition is likely, although the nomadic behaviour of the Mandrills serves to reduce the

Mandrill *Mandrillus sphinx* adult males.

intensity of competition with any one other group. Insect-eating birds, particularly White-crested Hornbills *Tropicranus albocristatus*, also follow foraging Mandrills. Although Mandrills eat meat, active hunting of even small mammals is rare. As such, monkeys are commonly seen mingling with Mandrill hordes. At Lopé, Western Grey-cheeked Mangabeys *Lophocebus albigena* move with Mandrill groups during at least 40% of days, and Putty-nosed Monkey *Cercopithecus nictitans*, Moustached Monkey *Cercopithecus cephus* and Crowned Monkey *Cercopithecus pogonias* also often associated with Mandrills. Ogilby's Duiker *Cephalophus ogilbyi*, Peter's Duiker *Cephalophus callipygus*, Blue Duiker *Philantomba monticola* and Red River Hog *Potamochoerus porcus* forage within Mandrill hordes, showing no avoidance of the Mandrills (K. Abernethy pers. obs.).

Adult ♂♂ and adult ♀♀ both have a sternal gland. Adult ♂♂ use this gland to scent-mark tree trunks by rubbing the chest against the bark in a series of upward thrusts from a semi-seated position. The significance of such marks in communication is poorly understood but may have a role in maintaining the exclusivity of home-ranges.

Reproduction and Population Structure Adult ♂♂ have extreme secondary sexual characters; brightly coloured skin on face, genitals and hindquarters, large size (3–4 times the weight of ♀♀) and loud vocalizations used exclusively during the reproductive period. These characters appear costly to evolve and are likely to have been selected through the enhanced reproductive success of individuals with the most extreme characters (Setchell & Dixson 2001, Setchell *et al.* 2001).

Females of a horde have semi-synchronous reproductive seasons, though sexual activity can continue through 5–6 months of the year in a horde of several hundred animals. The breeding season across the southern range of the Mandrill (south of the Ogooué R.) is between late May and early Nov. Breeding is polygynous, with ♂♂ serially guarding receptive ♀♀ in the group throughout the breeding season. Gestation is around 24 weeks (Wickings & Dixson 1992) and births are concentrated in the short dry season, around Dec–Jan in the southern range, though possibly at a different time in the northern

range. A single infant is born, weighing ca. 500–600 g. Sex ratio at birth is 1 : 1 in the semi-free ranging group in Franceville (Wickings & Dixon 1992) and is likely to also be 1:1 in the wild. Inter-birth intervals in the wild appear to be around two years; ♀♀ carrying infants have not been observed with one-year-old offspring, nor with sexual tumescence, indicating that young are not born in successive years. The inter-birth interval, however, may be longer than two years. Young are fully weaned around two years of age, and are sexually mature at four years in ♀♀ and ten years in ♂♂ (Wickings & Dixon 1992, Wickings *et al.* 1993, K. Abernethy & E. Wickings pers. obs.).

Males do not hold harems nor dominate one-male units, but mix through the group, interacting with one ♀ at a time. Genetic analyses of paternity in a captive colony showed extremely skewed reproductive success rates in ♂♂, with dominant individuals fathering almost all offspring in a group (Wickings *et al.* 1993). Whilst differential reproductive success among wild ♂♂ is certain, it is highly improbable that one ♂ maintains exclusive access to a horde of several hundred ♀♀ in the wild.

The different rates and timing of sexual maturity for ♂♂ and ♀♀, and the different ages during which they are sexually active, combined with the breeding system, form an inbreeding avoidance mechanism that is unique to Mandrills (or, possibly, to *Mandrillus*). Females begin to breed at four years, with an inter-birth interval of about two years, up to 12–14 years. Males only breed between 10 and 14 years; thus a father cannot breed with his daughter, who will not have matured before his death. Even the first son of a mother will not breed until after her death at 14 years (when he will be just 10 years). A Mandrill can only have a full-sibling if his/her father manages to survive to breed two (or just possibly four) years later, finds the same horde and breeds with the same ♀. In the rare case that this happens, these siblings could only mate if the older one is ♂ and the younger is ♀ (otherwise she would be too old [post-reproductive] before he is mature). This differential maturation mechanism means that Mandrills (1) do not need to rely on kin recognition to avoid inbreeding and (2) that hordes require only low levels of immigration/emigration to maintain genetic diversity (K. Abernethy pers. obs.).

Maximum longevity in captivity is 31 years and 8 months (Jones 1982). Radio-telemetry studies of wild animals in Lopé indicate a life-span of around 12–14 years in the wild (based on 15 ♂♂ and three ♀♀ collared at >10 years of age; K. Abernethy & L. White pers. obs.).

Predators, Parasites and Diseases Mandrills are known prey of humans, Leopards *Panthera pardus* and Central African Rock Pythons *Python sebae*. Mandrill remains found in 5.6% of forest Leopard scats in their range (3.1% of ingested biomass; n = 196; Henschel 2001; see also Henschel *et al.* 2011). Predation on Mandrills by Leopards shows a significant skew to the Mandrill breeding season, possibly because ♂ calling allows Leopards to track groups more easily at this time. A census of markets selling bushmeat in Gabon, which covers 60% of the Mandrill's range, showed that 2.2% of the wild animals harvested for the commercial meat trade were Mandrills. These data indicate a minimum off-take of 2000 Mandrills per year for human consumption in Gabon (Abernethy *et al.* 2001). Mandrills comprised ca. 3% of bushmeat eaten by villagers at three sites in Gabon (Foerster *et al.* 2011).

Wild Mandrills carry two strains of Mandrill-specific simian immunodeficiency virus (SIV), that are closely related to the human

HIV virus (Souquière *et al.* 2001), and two strains of mandrill specific STLV-1 (Makuwa *et al.* 2004). Neither virus has, however, been shown to develop the auto-immunodeficiency syndrome (AIDS) provoked by the virus in humans. Parasite loads are not known to be high despite living in large social units. Epidemic deaths of Mandrills from disease, including Ebola virus outbreaks in central Africa during 1996, 2000, 2002 and 2006, are not documented. This may be due to lack of research.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix I.

Gabon banned all primate hunting in July 2002 and the Mandrill is nationally protected in Cameroon and Congo. None the less, populations likely to be declining through hunting and through habitat loss. Most of the species' range is currently allocated as commercial timber concession (Global Forest Watch 2009). Management of hunting on sustainably managed and eco-certified logging concessions is becoming more widespread. If hunting were managed over large areas it could markedly reduce one of the greatest current threats to Mandrills. Mandrills are found in at least 14 protected areas in central Africa: Campo Ma'an N. P. in Cameroon, Monté Alén N. P. in Equatorial Guinea, the Minkébé, Monts de Cristal, Lopé, Moukalaba-Doudou, Waka, Mayumba, Ivindo and Mont Birougou National Parks, Wonga-Wongue Presidential Reserve, Lékédi Sanctuary, and Mont Iboundji Sanctuary in Gabon, and the Conquati-Douli N. P. in Congo. These areas cover ca. 13% of the species' range.

Old, climatically stable, clear understorey forests seem to be the most important habitat for Mandrills, as well as large contiguous forest blocks that allow several hordes to be in reproductive contact. Preservation of forest cover and reduction of bushmeat hunting in the Crystal Mountains (Monte Alén N. P., Monts de Cristal N. P.), Massif du Chaillu (Lopé N. P., Waka N. P., Birougou N. P.), and the uplands of Moukalaba-Doudou N. P. are key areas for the long-term conservation of the Mandrill. A research programme on ecology, genetic variation and population trends was initiated in Lopé N. P. in 1998 in order to establish a national conservation plan for the Mandrill and this programme is still under way.

Measurements

Mandrillus sphinx

HB (♂♂): 860 (840–900) mm, n = 12

HB (♀♀): 570 (530–610) mm, n = 6

T (♂♂): 72 (60–100) mm, n = 11

T (♀♀): 47 (40–60) mm, n = 12

HF (♂♂): 223 (210–230) mm, n = 5

HF (♀♀): 163 (150–170) mm, n = 4

E (♂♂): 45 (30–60) mm, n = 8

E (♀♀): 38 (30–50) mm, n = 9

WT (♂♂): 30.4 (25–36) kg, n = 11

WT (♀♀): 8.9 (7–11) kg, n = 10

Lopé N. P., Gabon, 1998–2002 (K. Abernethy, W. Karesh & L. White pers. obs.)

Mandrillus leucophaeus DRILL

Fr. Drill; Ger. Drill

Mandrillus leucophaeus (F. Cuvier, 1807). Ann. Mus. Hist. Nat. Paris 9: 477. Africa.Drill *Mandrillus leucophaeus* adult male.

Taxonomy Polytypic species. Two subspecies recognized: Mainland Drill *Mandrillus leucophaeus leucophaeus* on the African mainland and Bioko Drill *M. l. poensis* on Bioko I. (Napier 1981, Groves 2001, 2005c, Grubb *et al.* 2003). No reliable evidence that Drills occur south of Sanaga R. Thus, *M. l. mundamensis* is a synonym of *M. l. leucophaeus* (Grubb 1973, Harrison 1988b). Formerly placed by some in genus *Papio*, but *Mandrillus* is more closely related to the semi-terrestrial drill-mangabeys *Cercocebus* than to either baboons *Papio* or the arboreal baboon-mangabeys *Lophocebus* (Dutrillaux *et al.* 1982a, Muleris *et al.* 1986, Disotell *et al.* 1992, Disotell 1994, Goodman *et al.* 1998, Fleagle & McGraw 1999, McGraw & Fleagle 2006). Synonyms: *cinerea*, *drill*, *livea*, *mundamensis*, *poensis*, *sylvestris*, *sylvicola*, *?variegata*. Chromosome number: $2n = 42$ (Chiarelli *et al.* 1979b, Romagno 2001).

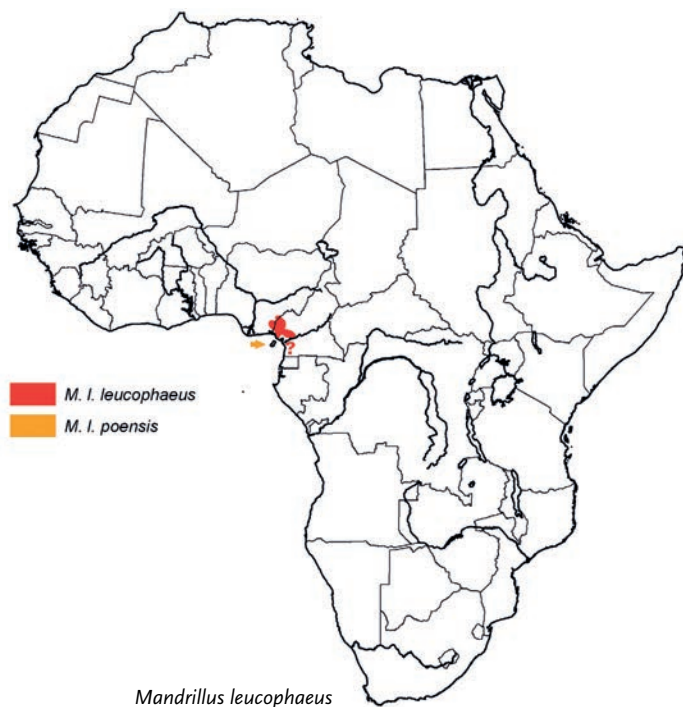

Description Large, robust, short-tailed, semi-terrestrial, highly sexually dimorphic monkey. Adult ♂♂ two-fold (*M. l. poensis*) to three-fold (*M. l. leucophaeus*) heavier than adult ♀♀.

Adult ♂: muzzle elongated, smooth, almost hairless, with single paranasal ridge on either side. Front of muzzle with sparse white whiskers. Lower lip black, marked below with reddish-pink to scarlet strip that may extend 20–30 mm onto chin. Face naked, shiny black, fringed on sides (but not brow) with yellowish-tan fur extending onto chin; hair on chin white only in mature animals. White skin sharply demarcated from black, mask-like face, washed with pink on cheek edge in heavily-coloured ♂♂. Beard absent. Ears naked, black; bare skin behind ears white. Forehead and crown with

Lateral, palatal and dorsal views of skull of Drill *Mandrillus leucophaeus* adult male.

modest, dark brown or blackish medial, semi-erectile crest. Dorsum light brown to greyish-brown with gold overtones (*M. l. leucophaeus*) or blackish-grey (*M. l. poensis*). Dorsal stripe faint, darker brown. Shoulders and upper back with loose mane of longer hair. Hands and feet mixed black and buff. Tail short (<13 cm), with pink skin showing through brown hair; darker tip. Centre of chest between nipples with longer greyish hairs that serve secretions from sternal scent gland. Ventrums and insides of limbs white to greyish-white, more sparsely haired toward rear of body. Skin on inside of thighs and groin reddish-pink to scarlet. Penis sheath scarlet. Penis pink. Scrotum may be pink or lavender, depending on age and condition. Ischial callosities light pink. Skin around anus from tail to callosities deep red. Rump naked, pink grading to blue and lavender. Adult ♂ skin colour varies greatly among individuals, and during the course of life (E. Gadsby pers. obs.).

Adult ♀: like adult ♂ except as noted here. Much smaller (see Measurements below) and without coloured skin, dorsal stripe and elongated hairs on chest or mane. Sternal scent gland less active than in ♂♂. Up to four years of age ♂♂ and ♀♀ look the same. Hair on cheeks yellowish-white. Hair on chin yellowish-white, except in old ♀♀ where it is white. Hair on dorsum same colour in ♀♀ as in ♂♂. Skin on groin pale pink.

Infant: ears, face, hands and feet with white/pink skin. Pelage silvery-grey, with black 'infant cap'. Infant pelage replaced gradually over 3–6 months, to eventually resemble the colour of adult ♀♀. Face darkens to black by 4–6 months (E. Gadsby pers. obs.).

Geographic Variation

M. l. leucophaeus Mainland Drill. Endemic to SE Nigeria and SW Cameroon. Larger than *M. l. poensis*. For adult ♂, HB ca. 12% longer; E ca. 22% longer; HF ca. 14% longer; T ca. 22% longer; WT ca. 60% heavier. Compared to adult ♂ *M. l. poensis*, skull of adult ♂ *M. l. leucophaeus* is longer (192–231 mm); braincase wider (84–102 mm); upper tooththrow longer (54–56 mm). More sexually dimorphic. Adult ♂ about three-fold heavier than adult ♀. See Measurements below. Hairs on sides of crown banded yellow and black. Dorsum greyish-brown.

M. l. poensis Bioko Drill. Endemic to Bioko I., Equatorial Guinea. Smaller than *M. l. leucophaeus* (see above). Compared to adult ♂ *M. l. leucophaeus*, skull of adult ♂ *M. l. poensis* is shorter (186–207 mm); braincase narrower (78–94 mm); tooththrow shorter (45–50 mm). See Measurements below. Less sexually dimorphic. Adult ♂ about two-fold heavier than adult ♀. Hairs on sides of crown yellowish-brown with only the tip black. Dorsum blackish-grey.

Similar Species

Mandrillus sphinx. Allopatric at Sanaga R., Cameroon. Paranasal ridges longitudinally grooved and bluish in adult ♀. Adult ♂ with nasal ridge, nostrils and lips bright red; paranasal ridges longitudinally grooved, white with faint sky-blue troughs. Cheek whiskers and pointed beard yellow to orange.

Distribution Endemic to SE Nigeria, SW Cameroon and Bioko I., Equatorial Guinea. Rainforest BZ. Perhaps the smallest geographic range of any medium-large African mammal. *Mandrillus l. leucophaeus*

occurs from the Cross R., Nigeria as far north-west as 06° 27' N, 08° 57' E (E. Gadsby pers. obs.); as far north-east as 06° 14' N, 09° 33' E, and south-east to the Sanaga R., Cameroon (Grubb 1973, Wolfheim 1983, Dowsett-Lemaire & Dowsett 2001, Oates *et al.* 2004). Range includes forested areas of the Cross R. drainage. Presently confirmed east along Sanaga R. as far as 10° 53' E (B. Morgan pers. comm.) but not farther than the Mbam R. Reports of Drills south of the Sanaga R. probably cases of mistaken identity (Grubb 1973, Harrison 1988b). Historic range <50,000 km² on mainland. Mainland range fragmented into 11 or more habitat islands. With ongoing habitat loss, probably <25,000 km² now available to the Drill, of which the majority lies in Cameroon (Gadsby & Jenkins 1998, E. Gadsby pers. obs.).

On Bioko I. (2017 km²), *M. l. poensis* present on lower slopes of Pico Basile and over much of the southern one-third of the island, including the Gran Caldera Volcánica de Luba (Schaaf *et al.* 1990, Butynski & Koster 1994, González-Kirchner & Sainz de la Maza 1996). Drills on Bioko now believed to be all of the same population. The present extent of occurrence is unlikely to be greater than 800 km² (T. Butynski pers. obs.).

Habitat Primary and mature secondary lowland forest, also mid-altitude, lower montane and occasionally montane forest and associated grasslands. From sea level to ca. 2000 m (Mt Kupe) on mainland (Wild *et al.* 2005) but not reported over 1000 m on Mt Cameroon, the highest peak in Drill range (Gadsby & Jenkins 1992). From sea level to at least 1400 m on Bioko I., but reported by hunters to occur to 1500 m (Butynski & Koster 1994, González-Kirchner & Sainz de la Maza 1996, T. Butynski pers. obs.). Most groups occur at lower altitudes between 0 and 600 m, but may favour higher, more difficult terrain in response to hunting pressure in accessible lowland areas. Within Drill range annual rainfall records include 2690 mm (mean for 1953–63) at Bakundu and 8570 mm at Idenau, Cameroon (Gartlan & Struhsaker 1972); 2790 mm and 3030 mm (means for 2000–05) at Calabar and Afi Mountain, Nigeria, respectively (records from Drill Rehabilitation & Breeding Center, DRBC); ca. 4000 mm on Pico Basile to >10,000 mm on extreme S Bioko I. (Butynski & Koster 1994).

Abundance In 1986, Butynski & Koster (1994) conducted 373 km of primate census on Bioko I. and encountered Drills (seen or heard) at the rate of 0.02 groups/km. In 1990 González-Kirchner (1990) conducted 212 km of primate census on Bioko and encountered Drills at the rate of 0.03 groups/km. Also in 1990, Schaaf *et al.* (1990) conducted 92 km of primate census within the Gran Caldera Volcánica de Luba, SW Bioko, and encountered Drills at the rate of 0.09 groups/km. In 1992, Maté & Colell (1995) conducted 100 km of primate census on SE Bioko and encountered Drills at the rate of 0.02 groups/km. Encounter rate of 0.05 groups/km in 2008 along 44 km of transect in the Gran Caldera de Luba, and 0.08 groups/km in 2009 along 48 km of transect and 0.06 groups/km in 2010 along 50 km of transect at Badja North, SW Bioko (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. obs.). The Gran Caldera de Luba and Badja North are remote sites where hunting is relatively uncommon and where there are no other anthropogenic impacts. As such, the encounter rates at these two sites are likely close to what is expected for an undisturbed population of Drills. Based on field surveys at many sites on Bioko, and on bushmeat market surveys, T. Butynski,

G. Hearn & W. Morra (pers. obs.) estimate the total Drill population on Bioko at 3000–4000 animals.

Drills were once abundant in Korup N. P. (Struhsaker 1972), but are today less common. At one site in north Korup N. P., Drills were encountered at a rate of 0.016 groups/km in 1990 (Edwards 1992). Waltert *et al.* (2002) reported group encounters of 0.01/km at a site ca. 5 km away (in the Korup Support Zone) a decade later. In 2000 Steiner (2001) encountered only one group of Drills during 152 km of census in north Korup N. P. and in the Korup Support Zone (0.007 groups/km). In 2006, however, Astaras *et al.* (2008) encountered 0.015 Drill groups/km during 1346 km of surveys in southern Korup N. P. They estimated density at 1.7 ind/km² within their 63 km² study area and, on this basis, extrapolated the number of drills in Korup N. P. at roughly 1130. About 2500–3000 Drills occur in the Korup region (Astaras 2009).

At the Ebo Forest research site at the eastern edge of the species' range, Drills are seen regularly (B. Morgan pers. comm.). Widespread and relatively common in the Ndokbou Forest (>1000 km²) and Ebo Forest (1400 km²) in the Yabassi region, Cameroon (Dowsett-Lemaire & Dowsett 2001). Within other remaining habitats, such as Takamanda F. R. and Mone F. R., Mt Cameroon, Banyang Mbo Wildlife Sanctuary, Bakossi, Nkwende Hills, Ejagham F. R. (Forbosh *et al.* 2007), Rumpi Hills F. R., Cameroon, and Cross River N. P., Nigeria, Drills are present but infrequently encountered. In five months of foot surveys in Banyang Mbo Wildlife Sanctuary, Drills were heard twice but not seen (Greengrass & Maisels 2007). In 735 km of surveys in the western Oban Hills of Cross River N. P. and adjoining community forest, Birch & Tooze (2006) had five encounters with Drills. While Drills persist across much of their original range where habitat remains, numbers are not evenly distributed. Gadsby & Jenkins (1998) estimated the total number of Drills in Nigeria and Cameroon at 3000–6000 animals.

Adaptations Diurnal and semi-terrestrial. In SW Cameroon, Drills spend more than 50% of time foraging, resting and travelling on or near the ground (Gartlan & Struhsaker 1972). They are agile climbers, younger and lighter animals in particular being capable of making long leaps between outer tree branches (D. Schaaf pers. obs.). Drills ascend trees before dusk to sleep at heights from 8 m to the tree crowns (Astaras 2009, E. Gadsby pers. obs.). They habitually flee from danger on the ground unless pursued by Dogs (Gadsby 1990, Astaras 2009). On Bioko, typically flee into deep, steep-sided canyons where people and Dogs cannot pursue (T. Butynski pers. obs.). They are swift runners, although no estimate of speed is known; also able to swim. The sternal gland of *Mandrillus* spp. is unique among primates (Hill 1970). Drills scent-mark by rubbing this gland against objects such as branches, stones and even food. The Drills' black muzzle serves to make several expressive behaviours appear more conspicuous and species-specific, notably yawns that display canines (associated with mild threats, uncertainty or tension), a mild form of 'lip-smacking' (observed during mutual grooming, and by ♂♂ during copulation; E. Gadsby pers. obs.) and a 'smile' in which the corners of mouth are pulled back to expose the teeth while the head is wagged from side to side (associated with greeting, during play and also seen when ♂♂ court ♀♀).

Foraging and Food Omnivorous. Diet little known. Drills forage in groups, mainly on the ground. About 74% of sightings by Gartlan

& Struhsaker (1972) of feeding Drills in SW Cameroon were on the forest floor. Almost all encounters during daylight hours (except at dusk or dawn at sleeping sites) were of groups foraging on the ground, with only a few individuals at heights of 1–5 m. Feeding groups climb trees to seek shelter during heavy rain (C. Astaras pers. comm.). Gartlan & Struhsaker (1972) found Drills eating fruits of *Musanga cecropioides*, *Oncocalamus wrightianus*, two *Cola* spp. and possibly *Pycnanthus angolensis*. Snails (*Pseudoachatina* and *Lignus* spp.) also eaten. Drill faeces sometimes contained orthopteran (crickets and their allies) and coleopteran (beetles) exoskeletons. Based on analysis of faecal samples in Korup N. P., Astaras (2009) found that fruit and seeds comprised >72% of diet by volume, with pronounced seasonal variations. Fruit and seeds of *M. cecropioides*, *Scottellia klaineana* and *Morinda morindoides*, fruit pulp of *Irvingia gabonensis* and seeds of *Oncoba glauca*, *Pentadesma butyracea* and *Treculia obovoidea* eaten. *Irvingia gabonensis* present in 96% of faecal samples in May and often accounted for the bulk of a sample, but entirely absent in the previous three months (study period Feb–Jun 2006). *Musanga cecropioides* eaten throughout the study period, but occurred at higher rate in 75% of samples in Mar. Further observations in the 2007 rainy season (C. Astaras pers. comm.) identified fruits of eight *Cola* spp., ten *Diospyros* spp., five *Landolphia* spp. and five *Strychnos* spp. as main sources of food during the major fruiting season (Jul–Sep). Leafy material consisted mainly of grass blades, less often leaves of trees and forbs. Fungi (mushrooms) in small amounts in 5% of samples. Insect remains occurred in 70% of samples and consisted mainly of ants, termites and orthopterans. While diet probably consists mainly of fruits and seeds, it is varied and also includes nuts, leaves, flowers, pith, roots, tubers, corms, bark, fungi, invertebrates, eggs (including bird, reptile and snail), small vertebrates (e.g. amphibians and fish) and possibly small to medium-sized mammals (Schaaf *et al.* 1990, E. Gadsby pers. obs.). Semi-captive Drills at DRBC eat frogs, lizards, snakes, snails and birds, and kill, but do not eat, small mammals including genets *Genetta* sp. Skillfully catch and eat flying insects by snatching them out of the air (E. Gadsby pers. obs.). See also Astaras & Waltert (2010).

On Bioko I., Drills eat giant land snails (*Achatina* sp.) (Butynski & Koster 1994), freshwater crabs, ripe fruits of *Xylopia aethiopica* (T. Butynski pers. obs.), *Hunteria umbellata* (Q. Luke pers. comm.), and Oil Palm *Elaeis guineensis*, Coconuts *Cocos nucifera* (Schaaf *et al.* 1990, González-Kirchner & Sainz de la Maza 1996) and termites (Schaaf *et al.* 1990). They dig up and eat marine turtle eggs on the southern beaches (Butynski & Koster 1989). González-Kirchner & Sainz de la Maza (1996) estimate the following for the diet, based on four stomach samples: 58% fruit, 25% insects, 16% other plant foods (e.g. leaves, stems, pith), 1% other invertebrates. Hunters on Bioko I. imitate distress calls of Ogilby's Duiker *Cephalophus ogilbyi* and Blue Duiker *Philantomba monticola* to lure Drills within shotgun range, suggesting that Drills may kill and eat large prey (Schaaf *et al.* 1990, Butynski & Koster 1994, González-Kirchner & Sainz de la Maza 1996). Under other circumstances, Drills and duikers forage peacefully in close proximity (C. Astaras & D. Schaaf pers. obs.).

Foraging includes sifting through leaves and detritus on the ground, digging, turning over stones and wood, breaking open rotten wood and climbing trees for fruit and other foods. Readily enter shallow water to cross streams and forage for aquatic foods such as crabs, turning over small and large stones in the process.

There are no data on the size of Drill home-ranges. Ukizintambara (2006) reports Mandrill *Mandrillus sphinx* home-ranges in Gabon of

100 km², and Drill home-ranges on the mainland may be of similar size. Home-ranges of at least some groups on Bioko are unlikely to be greater than 30 km² (T. Butynski pers. obs.).

Social and Reproductive Behaviour Highly social. Group size variable, with ratio of fully adult ♂♂ to other group members estimated at 1 : 20 (Gartlan 1970). Astaras (2009) reported groups of 25–77 in Korup N. P. (mean 43.3, S.D. = 18.4, n = 8), with multiple large ♂♂ in some of the larger groups. Group size averaged 23.3 individuals (9–55, n = 12) in SW Cameroon, where groups larger than about 20 contained adult ♂♂ in ratio of less than 1 : 20 (Struhsaker 1969). Gartlan (1970) estimated average group size in SW Cameroon at 63.5 (14–179, n = 11). Gadsby (1990) reported mean group size of 28 (5–50, n = 58) based on hunter interviews in Nigeria. Group size estimates collected over 32 years (1970–2002) in Bakossiland, Cameroon, range 5–400 (mean 93.1, n = 105; Wild *et al.* 2005). Wild *et al.* (2005) found no correlation between group size and seasonality, habitat type, or altitude. Abernethy *et al.* (2002) suggest that, in absence of total counts, Mandrill groups may be underestimated by as much as 40%; Drill groups may be similarly underestimated. Groups larger than about 20 individuals may be aggregations of two or more ‘one-male-units’. Larger aggregations (or ‘super-groups’ or ‘hordes’) may form when smaller units congregate. Super-groups are reported as increasingly rare as Drill populations decline (Gadsby 1990).

On Bioko I. groups range in size from 2 to 20 individuals (González-Kirchner & Sainz de la Maza 1996). Hunters indicate that group size is usually around 20 animals, rarely 25, and that only one adult ♂ is present (González-Kirchner 1990, Butynski & Koster 1994). Super-groups never reported for Bioko.

Solitary animals are always adult ♂♂. Of 15 ‘reliable’ Drill counts in Bakundu F. R., only two (13%) were of solitary adult ♂♂ (Gartlan 1970). In Korup N. P. only 2 of 33 visual encounters (6%) were of solitary adult ♂♂ (Astaras 2009). Solitary ♂♂ may be more common on Bioko than on the mainland. Of 11 encounters with Drills by González-Kirchner (1990), four (36%) were solitary ♂♂. González-Kirchner & Sainz de la Maza (1996) reported that 29% of encounters on Bioko I. were with solitary ♂♂. Of solitary ♂♂, 83% were on the ground and 17% in trees. In another study on Bioko, four of 12 encounters (33%) with Drills were with probable solitary individuals (Butynski & Koster 1994, T. Butynski pers. obs.).

There is no indication that Drills are territorial. In some areas they may be semi-nomadic seasonally, based on hunter reports that they are not permanent residents of a given forest area but appear at regular times of the year (Gadsby 1990). On the western edge of the Oban Hills, researchers recorded Drills only in rainy season months (D. Birch pers. comm.). In Korup N. P., Astaras (2009) found Drills in the study area year-round.

Gartlan & Struhsaker (1972) found associations of Drills and other primate species infrequent and transient, more so than polyspecific associations among some *Cercopithecus* spp. They reported three associations in SW Cameroon (Idenau and Bakundu) involving Drills and Putty-nosed Monkeys *Cercopithecus nictitans*, Red-eared Monkeys *Cercopithecus erythrotis*, Crowned Monkeys *Cercopithecus pogonias* and Mona Monkeys *Cercopithecus mona*. In Korup N. P., Drills showed highest association with Red-capped Mangabeys *Cercocebus torquatus*, being present in 10% of all mangabey encounters, but *C. nictitans*

was present in 39% of all drill encounters (Astaras 2009). Drills also associated with all other diurnal primates in Korup (Preuss’s Red Colobus *Procolobus preussi*, Putty-nosed Monkeys, Red-eared Monkeys, Crowned Monkeys and Mona Monkeys) except Robust Chimpanzees *Pan troglodytes*, but these associations were often transient. Monkeys in association with Drills on 50% of 44 encounters (Astaras *et al.* 2011). Among hunter groups interviewed in Nigeria, 59% (n = 67; Gadsby 1990) reported that Drills associate with other primates at fruiting sites, with Drills foraging on fruit dropped by guenons. Some of these also indicated Drills forage on the ground with Red-capped Mangabeys. Of groups interviewed, 3% said Drills associate similarly with Robust Chimpanzees. E. Gadsby (pers. obs.) notes that Mona Monkeys pass through Drill enclosures at DRBC, and feed in trees with Drills.

Associations between Drills and other species of monkeys on Bioko I. are uncommon. González-Kirchner & Sainz de la Maza (1996) observed Drills in association with other primates three times over an 18-month period; once with Black Colobus *Colobus satanas*, once with Crowned Monkeys and once with Red-eared Monkeys. Of 12 encounters by T. Butynski (pers. obs.) with Drills on Bioko, only twice (17%) were the Drills close to another species of monkey; <50 m from a group of Crowned Monkeys and <35 m from a group of Black Colobus.

Gartlan (1970) described Drill vocalizations heard in Bakundu F. R. ‘Alarm barks’ (or ‘pant-threats’) given when immediate danger is detected. This is a two-note, ‘staccato bark’, with the second note higher than the first. ‘Crowing’ contact calls given when individuals or groups are separated and seeking to reunite, and mutually by young and their mothers when separated. Deep, ‘two phase grunts’ or ‘roars’ (called ‘type A’ by Gartlan) given only by adult ♂♂ to mobilize groups, and maintain contact during travel and foraging. Lower intensity ‘two-phase huffing grunt’ (Gartlan’s ‘type B’) is a series of rapid or slowly modulated grunts or pants given by adult ♂♂. In multimale groups at DRBC the two-phase huffing grunt can be heard for hours when two or more adult ♂♂ sit in close proximity to one another (E. Gadsby pers. obs.). Wood (2007) described ‘directed screech,’ which is high-pitched and continuous, most often given by adult ♀♀ or juveniles, and directed toward another individual. By screeching and glancing toward other group members, the ‘aggrieved’ individual draws attention to the ‘transgressor’, toward whom aggression may then be directed by the group. The ‘directed screech’ (Wood 2007) and ‘yell’ described by Feistner (1989) for Mandrills are likely to be the same. Females of all ages ‘coo’ with lips pursed to form a ‘placating face’, as do infants seeking or receiving comfort. All sexes and ages make a sharp version of the staccato grunt, which is repeated continuously to intimidate or signal aggressive intent (E. Gadsby pers. obs.).

Adult ♂♂ grind their teeth at times of extreme agitation, typically when they cannot gain access to a rival (Feistner 1989, E. Gadsby pers. obs.). During altercations, adult ♂♂ may perform a ‘tooth-gnashing’ visual and auditory display, during which the upper canines grind against the anterior premolars, sharpening the canines (Every 1970, Wood 2007). Some of the calls described above (e.g. the crow) are probably unique to *Mandrillus* spp. Despite a rich vocal repertoire, Drills do not have a characteristic adult ♂ ‘loud-call’ as do most cercopithecids. The crow is probably the loudest and most far-reaching. The crow can be heard to >500 m, depending on terrain (C. Astaras pers. comm.).

Facial geometry of Drill *Mandrillus leucophaeus* adult male.

Behaviour of Drills in the wild is not well documented. Semi-captive Drills of both sexes, immature as well as adult, but especially adult ♂♂, scent-mark by rubbing the sternal gland against branches and tree trunks. Novel objects, like sticks, stones and food items, may also be marked. Usually an object is picked up, sniffed and dragged down under the chin and across the centre of the chest one or more times. This activity, seen frequently at DRBC, may be accompanied by salivation (Hill 1970, K. Wood pers. comm.). Adult ♂♂ scent-mark trees by rubbing the chest in upward motion against the object one or more times; more than one individual may mark the same spot (K. Wood pers. comm.). In the wild, scent-marking may aid in orientation, prevent groups from meeting and aid in reunion when animals are dispersed. Scent-marking is not thought to demarcate territory (Jouventin 1975), except in a short-term, localized way, as when two or more ♂♂ meet.

Although subadult ♂♂ may act as sentinels, there is no evidence that adult or subadult ♂♂ defend the group against predators; indeed, they are often the first to flee (Struhsaker 1969, Gartlan 1970). Dominant adult ♂♂ may initiate group movement but do not lead; instead, they usually stay in the middle or rear of the group when on the move (Gadsby 1990). Gartlan (1970) observed herding of group members, enforcement of group cohesion (by subadult and adult ♂♂) and initiation of group movement by adult ♂♂. He concluded that there are relatively high rates of aggression among Drills. However, in semi-captivity at DRBC, affiliative behaviours are more frequent than aggressive behaviours for all group members. Aggression rates by ♀♀ and ♂♂ are equal, but adult ♂♂ are more likely to exhibit aggression toward other adult or subadult ♂♂, often in proximity to an oestrous ♀. Females most often initiate aggression with other ♀♀ (Wood 2007). Herding was never seen at DRBC in 770 h of observation; this, in contrast to Gartlan's (1970) observations, may be due to the wild animals' perception of an observer as a threat, or may be a behavioural deficit occasioned by semi-captivity and the constant proximity of humans.

Aggression is expressed in several ways both by ♂♂ and ♀♀: 'head bobbing', staring at opponent and jerking head forward and down; 'threat rush', a rapid quadrupedal charge ending without physical contact; 'threat jerk', head and upper trunk suddenly thrust forward, eyes wide open, medial crest raised, and lips generally compressed and pushed slightly forward; and 'branch-shaking', jumping onto a branch and shaking it sharply up and down several times (Gartlan 1970). Subadult and adult ♂♂ yawn to display canines as a mild threat, or to show uncertainty or tension.

Affiliative behaviour includes a mild form of 'lip-smacking', observed during mutual grooming, and sometimes exhibited by ♂♂ during copulation (E. Gadsby pers. obs.). Almost any group member may groom another, but the dominant ♂ performs the least grooming and is only groomed by adult ♀♀ (K. Wood pers. comm.). Females at DRBC are more likely to groom related ♀♀ than unrelated ♀♀ and ♂♂ (Wood 2007). High-ranking ♀♀ may monopolize grooming opportunities with high-ranking ♂♂ (K. Wood pers. comm.). The 'smile' involves pulling corners of mouth back to expose canines and premolars, while the head may be moved slowly from side to side; it is thought to function as a greeting and to signal amicability. Use of the smile as affiliative behaviour is unique to *Mandrillus* spp. in that higher-ranking animals may display it to lower-ranking individuals, and vice versa. Infants and juveniles often 'smile' when initiating play bouts, as do ♂♂ courting oestrous ♀♀.

The following description of courtship and mating is based on observations of semi-captive animals at DRBC (where large social groups of Drills live in 0.5–7.0 ha enclosures of native forest habitat), and may not be typical of Drills in the wild. Drill ♀♀ in oestrus exhibit prominent sexual swellings. The dominant ♂ attempts to monitor all swollen ♀♀ in the group, while other ♂♂ may attempt to mate opportunistically, especially with lower-ranking or younger ♀♀. Dominant ♂♂ show preference for high-ranking and mature ♀♀ when several ♀♀ are swollen

simultaneously. A high-ranking ♀ may also attempt to follow and maintain proximity to the dominant ♂, thereby excluding other ♀♀ access. Courtship involves ♂ following ♀ with maximal swelling, sometimes for several days (K. Wood pers. comm.). Target ♀ frequently monopolizes courting male's time by leading him in extended pursuit until eventually allowing him to mount. Female may stand or crouch while ♂ grasps her ankles with his feet, or she may kneel while ♂ stands on her calves, placing hands on her hips during intromission. Male may occasionally take scruff of female's neck in his teeth. During mating, ♀ frequently glances back over her shoulder at ♂, who may lip-smack. *Mandrillus* spp. are single-mount ejaculators (Caldecott *et al.* 1996). See also Marty *et al.* (2009).

Reproduction and Population Structure Except as noted, information on reproduction is based on data gathered during 1994–2005 from $n = 197$ live births involving 56 ♀♀ at DRBC (Wood 2007). Gestation range 161–197 days, mean gestation 176 days ($n = 125$). Seymour (1998) found mean gestation of 176 days for the five years 1993–97. During 2000–05, 72% of births occurred during May–Sep with nearly half of all births occurring in Jun and Jul, showing a strong correlation to peak rainfall months. Only 7% of all births occurred during Dec–Feb, the driest months. Birth peak in wild populations is believed to be the same as that seen in DRBC animals, as evidenced by estimated age of incoming wild-born infants (E. Gadsby pers. obs.).

Males are capable of reproduction at five years, but believed to be suppressed by dominant animals. Females exhibit first perineal (sexual) swelling at 2.7 years (1.6–4.6, $n = 47$) and first birth at 4.5 years (3.1–7.4, $n = 56$). The mean cycle length for ♀♀ is 33 days ($n = 124$ cycles; Seymour 1998). Birth-weight 400–650 g (E. Gadsby pers. obs.). One infant is born at a time. Only one set of twins (0.4%) among >220 births at DRBC. Inter-birth interval variable (mean = 473 days, 209–991 days, $n = 140$). Inter-birth interval significantly shorter after an infant death (Wood 2007). Many ♀♀ reproduce annually. As breeding is seasonal at DRBC, infants are born into ready-made peer groups (Wood 2007). Drill mothers do not actively wean their young; as infants become less dependent on their mothers they still nurse opportunistically until the next offspring is born. Juveniles spend most of their time in playgroups. With the onset of puberty at three years ♀♀ begin to break away from playgroups and join adult society. While sexually mature ♂♂ do not reach their full size, including expression of secondary sexual characteristics until 8–10 years. No observations reported on social structure or reproductive parameters of wild Drills. At DRBC, family members, particularly ♀♀, maintain lifelong affiliations. There is one dominant ♂, and other adult ♂♂ are either group-associated or solitary. Group-associated ♂♂ interact with other group members, but may be aggressively pursued by the dominant ♂ when attempting to mate. Solitary ♂♂ appear to avoid group contact, leaving an area when a group approaches (Wood 2007).

DRBC ♂♂ show signs of aging by 14 years and sometimes as early as 11 years, and typically die of 'old age' without specific pathology at 16–19 years (E. Gadsby pers. obs.). Probably die earlier in the wild. Mortality of wild-born ♂♂ in all age classes at DRBC is significantly higher than for ♀♀. At 20 years, oldest ♀ at DRBC continues to

cycle and bear young. Longevity record in captivity is 28 years for ♂♂ and 37 years for ♀♀ (Jones 1962, Knieriem & Cox 2002).

Predators, Parasites and Diseases Few data. Leopards *Panthera pardus* are probably predators on the mainland. Leopards absent from Bioko. Central African Rock Pythons *Python sebae* are probably a predator both on the mainland and on Bioko. Humans are the major predator of the Drill, both on the mainland and on Bioko (see Conservation below). Parasites found in wild Drill faeces from Afi Mountain, Nigeria are: *Balantidium coli*, *Blastocystis hominis*, *Endolimax nana*, *Entamoeba chattoni*, *E. coli*, *E. hartmanni*, *E. histolytica dispar*, *Enteromonas hominis*, hookworm sp., *Iodamoeba buetschlii* and *Trichomonas* sp. (J. Lewis pers. comm.). Drills have their own simian immunodeficiency virus (SIVdrl) (Clewley *et al.* 1998) found asymptotically in about 20% of incoming wild Drills at DRBC. Other species-specific viruses isolated from wild-born Drills at DRBC are cytomegalovirus (DrCMV) and foamy virus (SFV-drl) (Blewett *et al.* 2003).

Conservation IUCN Category (2012): Endangered. CITES (2012): Appendix I.

The Drill is the African primate with highest conservation priority (Oates 1996a). Populations reduced throughout small historic range and eliminated from much of range due to commercial bushmeat hunting and habitat loss (Wolfheim 1983, Lee *et al.* 1988, Gadsby 1990, Oates 1996a). In the early 1980s commercial hunting for bushmeat became the greatest threat for the Drill. Both on the mainland (Gadsby *et al.* 1994) and on Bioko I. (Butynski & Koster 1994, Hearn *et al.* 2006), Drill is a preferred bushmeat and hunting is widespread and often intense. Drills are hunted at all sites with shotguns and sometimes with dogs. Dogs hold a group at bay in trees while one or more hunters massacre the animals in the group (Gadsby *et al.* 1994, Waltert *et al.* 2002); without dogs, hunters are unlikely to kill more than two or three Drills during an encounter. In Korup hunters claim to kill from 2 to 25 Drills during these encounters, with a mean of 7.2 taken (Steiner *et al.* 2003). In many areas commercial hunters work from semi-permanent camps in the forest, periodically carrying out head-loads of smoked or fresh meat to traders who transport it to urban markets. As a result of widespread and intensive hunting, Drill super-groups have rarely been seen since the mid-1980s in Nigeria but still occurred, albeit at lower frequency, or with smaller-sized super-groups, in Cameroon (Gadsby & Jenkins 1998, Wild *et al.* 2005). According to Gadsby *et al.* (1994: 443): 'The relentless persecution reduces group size, lowers density, increasingly isolates groups of Drills, and may also be affecting behavioural and ecological strategies. It is becoming apparent that the formation of super-groups, which may play a crucial role in transfer of individuals, and thus genetic material, is occurring with decreasing frequency.'

In Nigeria, >60% of remaining Drill habitat lies within Cross River N. P. (3440 km² in two discontinuous divisions). In Cameroon, Korup N. P. (1259 km²) supports Drills and has a 17 km common boundary with Cross River N. P. On Bioko I. Drills occur both in the Pico Basile N. P. (330 km²) and in the Gran Caldera and Southern Highlands Scientific Reserve (510 km²). In none of these 'protected areas', however, is protection effectively enforced, and Drill subpopulations in all areas are probably in decline (Gadsby *et al.* 1994, Waltert *et al.* 2002, Steiner *et al.* 2003, Hearn *et al.* 2006). There is meaningful protection for Drills in Afi Mountain Wildlife Sanctuary,

a small (ca. 100 km²) out-lying habitat at the north-west edge of Drill range (see below). However, the global population of Drills may be losing viability as subpopulations become smaller and increasingly isolated by habitat fragmentation (Gadsby & Jenkins 1998). Habitat loss and hunting continue to drive population decline. With reduced and scattered subpopulations, large aggregations of Drills (hordes or super-groups) that may facilitate both the exploitation of seasonally abundant fruit and the transfer of genetic material are increasingly rare. See also Ting *et al.* (2012).

On Bioko I., Drills are sympatric with four other threatened species of primate (IUCN 2010); Red-eared Monkey (Vulnerable), Preuss's Monkey *Allochrocebus preussi* (Endangered), Pennant's Red Colobus *Procolobus pennantii* (Critically Endangered) and Black Colobus (Vulnerable). In addition, seven of Bioko's 11 species of primate are listed as 'Endangered' at the subspecies level (Butynski & Koster 1994, Hearn *et al.* 2006, IUCN 2010). Six subspecies of primate are endemic to Bioko. No place in Africa, perhaps no place in the world, has so many threatened endemic taxa of primate in such a small area (2017 km²). None the less, hunting of all seven of Bioko's monkey species for the commercial bushmeat trade continues unabated, driving all species closer to extinction on the island (Fa *et al.* 1993, Colell *et al.* 1994, Hearn *et al.* 2006).

Drill group encounter rates during primate census on Bioko declined ca. 33% during the 20 years from 1986 to 2006 (Hearn *et al.* 2006). Bushmeat surveys were conducted at the Malabo bushmeat market for 5–6 days/week from Oct 1997–Sep 2007. During this period, 2366 Drill carcasses were tallied. The total number is certainly greater as the market surveyor was not present all day every day. Island-wide questionnaire surveys were used to assess the percentage of Drill carcasses brought to this market; results indicated that ca. 60% of the Drills killed on Bioko are sold at the Malabo bushmeat market. If so, the total number of Drills killed on Bioko by hunters during this period is estimated at ca. 3940 (W. Morra & G. Hearn pers. comm.). In 1998, 226 Drills were counted at the Malabo bushmeat market during 283 days of survey. In 2006, 544 Drills were counted at the same market during 304 days of survey. Of these, 243 (45%) were adult ♂♂, 198 (36%) were adult ♀♀, 96 (18%) were immature and 7 (1%) had no age/sex data recorded (W. Morra & G. Hearn pers. comm.). If 544 Drills is 60% of the number killed, then roughly 900 Drills were killed by hunters on Bioko in 2006.

Continued rapid decline in Drill distribution and abundance on Bioko indicates that this level of exploitation is far from sustainable. The mean price paid per adult ♂ Drill at the Malabo bushmeat market changed from ca. US\$31 in 1997 to ca. US\$142 in 2007, a more than four-fold increase (Reid *et al.* 2005, W. Morra & G. Hearn pers. comm.). Less than 0.1% of the people of Bioko hunt monkeys. Monkey hunting accounts for <0.002% of Equatorial Guinea's gross domestic product (Reid *et al.* 2005, W. Morra pers. comm.). Monkey meat fulfils <1% of the minimum protein requirements of the urban population, and costs twice as much as beef or chicken (W. Morra pers. comm., T. Butynski pers. obs.). As summarized by W. Morra in Reid *et al.* (2005: 14): 'The primates of Bioko are on their way to extinction, driven by market forces. The decline in supply, coupled with inelastic demand as well as rising income and population, represents a recipe for an ecological catastrophe. And yet, the economic, employment and nutritional gains brought by

monkey hunting are negligible. In other words, Equatorial Guinea risks losing unique national assets and receiving almost no economic gain in return.' On Bioko there is ample primary and secondary forest for all 11 species of primate. Shotgun hunting is the only significant threat, accounting for 99% of monkey kills (Reid *et al.* 2005). As such, the primary conservation action required to conserve Bioko's monkeys is a complete ban on shotgun hunting (Hearn *et al.* 2006).

Critical sites for long-term conservation of the Drill on Bioko are Pico Basile N. P. and the Gran Caldera and Southern Highlands Scientific Reserve.

On the mainland, Drills are sympatric with six other threatened species of primate (IUCN 2010); Preuss's Red Colobus (Critically Endangered), Red-capped Mangabey (Vulnerable), Preuss's Monkey (Endangered), Red-eared Monkey (Vulnerable), Western Gorilla *Gorilla gorilla* (Critically Endangered) and Robust Chimpanzee (Endangered). As such, efforts to conserve the Drill will benefit all six of these species. In Nigeria critical sites for the long-term conservation of these six threatened species are the two divisions of the Cross River N. P., Okwangwo (640 km²) and Oban (2800 km², the largest protected area of Drill habitat), the Afi Mountain Wildlife Sanctuary (ca. 100 km²) and Mbe Mountains community forest (85 km²). Korup N. P. is currently the only Drill habitat in Cameroon where hunting is technically banned; the Banyang Mbo Wildlife Sanctuary (667 km²) allows limited hunting. Proposed protected areas in Cameroon include Takamanda N. P. (675 km²), Mount Cameroon N. P. (646 km²), Bakossi N. P. (ca. 800 km²) and Ebo N. P. (ca. 1100 km²). Legal creation of these protected areas is important for long-term survival of the species, but all new areas, as well as existing protected areas, require tremendous resources and commitment to sustain meaningful protection. Additionally, preserving and restoring habitat corridors to maintain larger protected landscapes will address further fragmentation of subpopulations. Key habitat blocks include: (1) the proposed Takamanda N. P. contiguous with Mone F. R. in Cameroon, Okwangwo Division and Mbe Mts in Nigeria; (2) Banyang Mbo Wildlife Sanctuary and the proposed Bakossi N. P., including Mt Kupé and Mt Manengouba; (3) the largest area and core of Drill habitat, the Oban Division (Nigeria) contiguous with Korup N. P. and its support zone, Ejagham F. R., Rumpi Hills F. R., Nkwende Hills and Nta Ali F. R., all in Cameroon (transboundary cooperation will be required); and (4) the ca. 12 km long forest corridor that connects Pico Basile N. P. and the Gran Caldera and Southern Highlands Scientific Reserve on Bioko. At present this corridor is under threat from agriculture, settlement and road construction, and is heavily hunted (T. Butynski pers. obs.).

In 2007, there were only 67 Drills in European, American and Japanese zoos; this managed population is descended from just six founders (A. Knieriem pers. comm.). At the DRBC, Nigeria, in 2009, there are 302 Drills in seven reproductive groups (wild born, F1, F2, F3) with 54 founders and 22 potential founders. At the Limbe Wildlife Centre, Cameroon, a breeding group of 59 is maintained. Breeding loans from these centres will be required to sustain a viable zoo population into the future. As of 2009, DRBC is planning release of a Drill group in the Afi Mountain Wildlife Sanctuary to reinforce the wild Drill population there (Gadsby 2002, 2006). Drills may be monitored with satellite telemetry. If methods prove successful, additional groups will be released to restock other habitats where Drills are now rare (if adequate protection is realized in those areas).

Measurements*Mandrillus leucophaeus**M. l. leucophaeus*

HB (♂ ♂): 720, 830 mm, n = 2

HB (♀ ♀): 455, 500 mm, n = 2

T (♂ ♂): 108 (86–125) mm, n = 10

T (♀ ♀): 75 (50–94) mm, n = 11

HF (♂ ♂): 211 (196–239) mm, n = 10

HF (♀ ♀): 177 (152–195) mm, n = 12

E (♂ ♂): 45, 47 mm, n = 2

E (♀ ♀): 41, 45 mm, n = 2

WT (♂ ♂): 32.9 (19.8–45.0) kg, n = 12

WT (♀ ♀): 11.6 (7.2–20.5) kg, n = 13

From wild-born Drills at DRBC (E. Gadsby pers. obs.)

HB (♂ ♂): 754 (580–1080) mm, n = 8

T (♂ ♂): 99 (81–126) mm, n = 7

HF (♂ ♂): 202 (158–220) mm, n = 7

E (♂ ♂): 45 (41–50) mm, n = 4

WT (♂ ♂): 20 kg, n = 1

GENUS *Lophocebus***Baboon-mangabeys (Grey-cheeked Mangabeys, Black Mangabeys)***Lophocebus* Palmer, 1903. Science, n.s. 17: 873.

Formerly lumped within *Cercocebus*, the species *albigena* and *aterrimus* have been recognized as distinct from other mangabeys since Barnicot & Hewett-Emmett (1972) showed that they were closer to *Papio* than to *Cercocebus* species. This affinity confirmed by Cronin & Sarich (1976) and by Groves (1978), who revived the generic name *Lophocebus*. Molecular studies (Goodman *et al.* 1998, Disotell 2000) further support this assessment. The vernacular name for *Lophocebus*, ‘baboon-mangabeys’, recognizes the relatively close phylogenetic relationship between *Papio* and *Lophocebus*. Molecular

study puts the time of divergence between *Mandrillus/Cercocebus* and *Papio/Lophocebus* at 6.7 mya (late Miocene) and between *Papio* and *Lophocebus* at 4.1 mya (mid-Pliocene; Perelman *et al.* 2011).

In 2003 and 2004, two small and isolated populations of similar mangabeys were discovered in SC Tanzania. On the basis of visual observations, vocalizations and photographs alone, they were allocated to *Lophocebus* as *L. kipunji* and given the vernacular ‘Kipunji’ (Jones *et al.* 2005). In 2006, with a juvenile specimen to hand and a molecular study, this monkey was allocated a new genus, *Rungwecebus*

Uganda Grey-cheeked Mangabey *Lophocebus ugandae* showing cheek-pouches.

(Davenport *et al.* 2006). That Kipunji does not belong in *Lophocebus* is supported by more recent molecular findings (Zinner *et al.* 2009a).

Lophocebus is distinct in the following respects: scapula long and narrow, deltoid plane on humerus narrow, brachialis flange on humerus narrow, supinator crest restricted, elbow joint broad, ilium constricted at base, lateral lip of patellar groove prominent, tibial shaft compressed, premolars not enlarged. In all these features, *Lophocebus* differs from *Cercocebus* and from *Mandrillus*, and closely resembles *Papio* and *Theropithecus*, to which it is closely related according to molecular data (see above). In addition, *Lophocebus* differs from *Cercocebus* in the following external features: eyelids not pale, a primitive feature among Old World monkeys; hairs solid toned with no medulla, a unique feature of the genus; crown hair raised, often crested, another unique feature among Cercopithecinae; tail long, flexible, another primitive feature but emphasized in this genus, to the extent that it has been referred to as 'semi-prehensile', though this is not entirely accurate, although tails are often looped over branches in an idiosyncratic way. These mangabeys sit sprawled, their limbs spread-eagled, giving them a sort of untidy, 'loose-limbed' appearance. All taxa within *Lophocebus* are arboreal, forest-dependent and confined to equatorial Africa.

Chromosome 10 is of standard papionin type, whereas the banding pattern is modified in *Cercocebus*. Unlike in *Cercocebus* there is no heterochromatic region on chromosome 12. *Lophocebus* is not as widespread as *Cercocebus*, as they do not occur west of the Cross R. in Nigeria, barely reach NW Tanzania, and are absent from Kenya. They are, however, common in the forests of the Congo Basin and SW Uganda.

Traditionally, two species recognized: *Lophocebus albigena*, from east, north and west of the Congo–Lualaba River System, and *L. aterritus* from south of the Grand Cuvette. Groves (1978), operating on an extreme interpretation of the Biological Species Concept, united these two into one species, citing certain features suggesting gene-flow across the Lualaba R. Later, however, he not only separated them again but raised a third taxon, *L. opdenboschi*, to species rank

(Groves 2001). Most recently the same author divides *L. albigena* into four species: Western Grey-cheeked Mangabey *L. albigena* (coastal and riverine forests of the west–central African region), Osman Hill's Grey-cheeked Mangabey *L. osmani* (plateau forests of Cameroon, west to the Cross R.), Johnston's Grey-cheeked Mangabey *L. johnstoni* (forests of N and NE DR Congo, Rwanda, Burundi and Semliki Forest, extreme W Uganda) and Uganda Grey-cheeked Mangabey *L. ugandae* (confined to the forests of SW Uganda and the shores of L. Victoria, including Minziro Forest in extreme NW Tanzania) (Groves 2007a). Here, as almost nothing is known about *L. johnstoni* or *L. albigena*, and little about *L. osmani* (all long-term field studies have been on *L. ugandae*), we continue to treat these four species under the heading of the earliest-described of them, *L. albigena*. Similarly, while recognizing that the Southern Black Mangabey *L. opdenboschi* is as different from the Northern Black Mangabey *L. aterritus* as the latter is from the *L. (albigena)* Group, both are treated under *L. aterritus*, about which little is known in the wild.

Brief characterizations of the six species/forms are as follows:

- 1 pelage long, loose, with a paler mane (= cape = mantle) on shoulders; cheek-whiskers long, thin, pale; a short, partially upright tuft or pair of tufts on crown;
- 2 *albigena*: mane light grey; underside brown; cheeks creamy-white;
- 3 *osmani*: mane red-tinged brown; underside yellowish; cheeks bright greyish-white or golden-white; no long crown-tufts;
- 4 *johnstoni*: mane dark brown; underside dark brown; cheeks light greyish-brown;
- 5 *ugandae*: resembles *johnstoni* but much smaller, with relatively large teeth and jaws; no mane; cheek-whiskers thick, not pale; crown-tuft tidy, not 'scruffy';
- 6 *aterimus*: pelage short, coarse; cheek-whiskers long, swept back with a slight outward curve, grey; crown-tuft tall, upright, thin, coconut-like;
- 7 *opdenboschi*: pelage long, lax; cheek-whiskers short, black; crown-tuft broad, pyramidal, lying back.

Lophocebus albigena (also *L. osmani*, *L. johnstoni*, *L. ugandae*) GREY-CHEEKED MANGABEY

Fr. Mangabé à joues grises; Ger. Grauwangenmangabe

Lophocebus albigena (Gray, 1850). Proc. Zool. Soc. Lond. 1850: 77. Mayombe, DR Congo.Western Grey-cheeked Mangabey *Lophocebus albigena*.

Taxonomy Monotypic species. Originally *Presbytis albigena*. Formerly included in *Cercocebus*. Considered a distinct genus (*Lophocebus*) by Groves (1978). Number of subspecies is debated. Groves (2001) suggested three *albigena* subspecies: *L. a. albigena*, *L. a. johnstoni* and *L. a. osmani*. Subsequently, Groves (2007a) elevated all three to species and added a fourth, *L. ugandae*. Kingdon (1997) recognizes *L. albigena zenkeri*. Grubb *et al.* (2003) and Oates (2011) consider all subspecific distinctions to be uncertain. Gautier-Hion *et al.* (1999) do not recognize the Black Mangabey *Lophocebus aterrimus* as specifically distinct from *L. albigena*.

Separation among taxa is based mostly on similarities in shape and colour of the mane (= cape = mantle), colour of the ventrum and cheeks, and shape of the crown-tuft(s) (Gautier-Hion *et al.* 1999, Groves 2001). There are also well-marked, consistent, craniometric differences that, according to Groves (2007a), enable them to be distinguished at the specific level. For example, *L. osmani* is extremely sexually dimorphic in size (♀♀ have smaller skulls than ♀♀ of other taxa, while ♂♂ have larger skulls but relatively smaller teeth), whereas *L. ugandae* is distinguished by a smaller skull, reduced sexual dimorphism and relatively large masticatory apparatus. Groves (2007a) places these four species in the '*Lophocebus (albigena) Group*'. This is the taxonomy adopted here. *Lophocebus ugandae* is relatively well-studied in the field, and there is some information for *L. albigena*. *Lophocebus osmani* and *L. johnstoni* remain poorly known. Therefore, for convenience, this profile treats these four taxa together as the *Lophocebus (albigena) Group* with most of the information presented here coming from field research on *L. ugandae*.

Nuclear DNA sequences indicate that *Lophocebus* forms a clade with *Papio* and perhaps *Theropithecus*, and is less closely related

Lateral and palatal views of skull of Uganda Grey-cheeked Mangabey *Lophocebus ugandae* adult male.

to terrestrial mangabeys; in particular, gamma-globulin intron sequences suggest that *Lophocebus* diverged from *Cercocebus* ca. 5 mya (early Pliocene), but from *Papio* and *Theropithecus* 4 mya (mid-Pliocene; Disotell 1994, Harris 2000, Page & Goodman 2001). The diphyletic origin of mangabeys is further supported by cranial and postcranial skeletal features (Nakatsukasa 1996, Fleagle & McGraw 1999). Synonyms: see Geographic Variation. Chromosome number: $2n = 42$ (Romagno 2001).

Description Lanky, blackish, medium-sized, arboreal monkeys. One of the largest arboreal cercopithecines. Sexes similar in colour but adult ♀♀ smaller than adult ♂♂. In *L. ugandae*, adult ♀♀ weigh ca. 70% as much as adult ♂♂. Eyelids black. Pelage long, loose, blackish-brown. Hair may form a short, partially upright tuft on crown or pair of tufts above eyebrows. Mane of longer, paler pelage over shoulders (light grey, greyish-brown, yellowish-brown or rusty-brown depending on species). Mane more prominent in ♂, continuous with thin, pale cheek-whiskers (Groves 2001). Tail long, often held in a distinctive arch over the back. Skin is bare over the ischial callosities. Callosities are pronounced, 'C'-shaped and continuous in ♂♂, but broken at the middle in ♀♀ to form two comma-shaped protrusions. Face, palms, soles and perianal area pink in newborns, turning to grey and eventually black by age nine months (Deputte 1992).

Geographic Variation The species of the *Lophocebus (albigena) Group*, according to Groves (2007a), are:

***L. albigena* Western Grey-cheeked Mangabey** (synonyms: *weynsi*, *zenkeri*). Most of western central Africa, west of the Congo R., including all of Congo, Gabon, mainland Equatorial Guinea (i.e. Rio Muni) and coastal S Cameroon. Mane light grey, sometimes with faint straw tones.

***L. osmani* Groves, 1978: Osman Hill's Grey-cheeked Mangabey.** Batouri District, Cameroon, west to Cross R. into SE Nigeria. Mane rusty-brown.

***L. johnstoni* Lydekker, 1990: Johnston's Grey-cheeked Mangabey** (synonyms: *ituricus*, *jamrachi*, *mawambicus*). Burundi, Rwanda, N and NE DR Congo (north of Congo R. and east of Lualaba R.), and Semliki Forest in far W Uganda. Mane usually dark brown, but sometimes pale whitish-grey or chocolate.

***L. ugandae* Matshiei, 1913: Uganda Grey-cheeked Mangabey.** SW and C Uganda and extreme NW Tanzania in Minziro F. R. Mane short, contrastingly yellowish-brown or greyish-brown; skull small.

Similar Species

Cercocebus agilis. Broadly sympatric with *L. albigena* and *L. johnstoni*. Semi-terrestrial. Pelage brownish-grey, short, fine and agouti-banded. Eyelids pale grey.

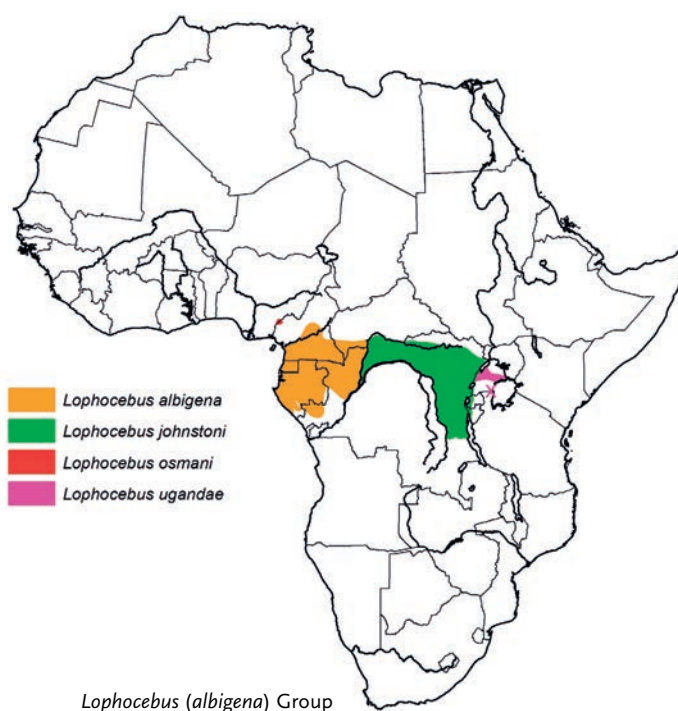

Lophocebus aterrimus. Allopatric with *L. albigena* along Congo/Lualaba R., and with *L. johnstoni* along lower Congo R. On right bank. Black; cheek-whiskers brown and greyish-brown; crest conical.

Distribution Endemic to equatorial Africa. Rainforest BZ. Ranges from Cross R., SE Nigeria, through lowland rainforest of S Cameroon, Equatorial Guinea and Gabon, east to Central African Republic, DR Congo and Congo north of the Congo/Lualaba R. Occurs in East Africa in forest patches through SW Uganda to the Nile R. and into extreme NW Tanzania.

Habitat Grey-cheeked mangabeys inhabit low and medium altitude tropical rainforest. In drier areas they are limited to swamp forest and the immediate environs of water-courses (Kingdon 1971). Almost strictly arboreal, they use the middle and high strata of the forest, including emergent trees. In secondary forests density is low. In forests with mosaics of habitat types they are more commonly found where tree density is high, as in closed canopy swamp and tall forest. Rarely seen foraging on open grasslands and open swamp adjacent to closed canopy forest (W. Olupot pers. obs.). Grey-cheeked mangabeys tend to occur at low density where sympatric with swamp-adapted Red-capped Mangabey *Cercocebus torquatus* (Cashner 1972) or Agile Mangabey *Cercocebus agilis* (Quris 1976). Found from ca. 1600 in Uganda to ca. 2350 m in Nyungwe N. P., Rwanda, and Kahuzi-Biega N. P., DR Congo (Kingdon 1971, Jones *et al.* 2005).

Abundance In Kibale N. P., Uganda, there are 14 ind/km² (Olupot *et al.* 1994) and 0.87–2.41 groups/km² (Chapman *et al.* 2000). Chalmers (1968a) reported 133 ind/km² in forest patches surrounded by recent cultivation in Uganda. In Gabon, L. J. T. White (1992) found 10.0 ± 7.7 ind/km² and 0.2–1.1 groups/km². Cashner (1972) reported 22.1 ± 3.5 ind/km² in Equatorial Guinea.

Adaptations Diurnal and arboreal. Like all cercopithecine species, Grey-cheeked Mangabeys have cheek-pouches in which they store

food when feeding rapidly or on hard seeds. Tail mildly prehensile, a feature most visible in young infants, which wrap their tails around those of their mothers when they are clinging. Like several other forest primates, Grey-cheeked Mangabey ♂♂ possess extralaryngeal air sacs that serve as resonators during the production of the species-typical, stereotyped ♂ loud-call that can be heard from 500–1200 m (Gautier 1971, Waser 1977b). These air sacs are thought to make possible the low pitch of these calls, which allow them to travel long distances with little distortion through the forest canopy. Grey-cheeked Mangabeys have better low frequency hearing than humans (Brown 1989a). Powerful jaws, arms and hands make it possible for them to open and obtain seeds from large, hard fruits (e.g. *Monodora myristica*), and to tear apart dead wood in search of invertebrates. Other African primates of this size (e.g. guenons) do not have this capacity.

Food and Foraging Omnivorous. Grey-cheeked Mangabeys in Kibale forage throughout the day, with peaks at 08:00–09:00h and 14:00–15:00h. Feed on a wide variety of items. Fruit is the most important item in the diet. Feeding on fruit, including pulp, arils and seeds, takes up 58–80% of the feeding time (Waser 1977a, Ham 1994, Poulsen *et al.* 2001, Brugière *et al.* 2002, Shah 2003). Seeds are taken from dehiscent pods, wind-dispersed fruit and immature succulent fruit. Fruits are taken ripe or unripe, depending on the plant species and availability. In Kibale feeding on fruits of *Ficus* spp. comprises a large proportion (16%) of feeding observations. When opening an unripe, insect-infected fig, Grey-cheeked Mangabeys eat the grubs, some seeds and pulp. Other commonly eaten fruits include ripe *Celtis durandii*, *Celtis africana*, *Diospyros abyssinica*, *Uvariopsis congensis*, *Phoenix reclinata* and *Maesopsis eminii*.

May use calls of frugivorous primates and birds, particularly Black-and-white-casqued Hornbills *Bycanistes subcylindricus*, to locate fruit (Olupot *et al.* 1998). Long-term spatial memory suggested to improve foraging efficiency (Janmaat & Chancellor 2010). Fruit sources strongly influence movements. Over a few days group

Uganda Grey-cheeked Mangabey *Lophocebus ugandae*.

movements centre on large fruit patches. After their depletion, the group typically abandons the area for a richer patch. In central Africa seed eating seems to be more common in forests dominated by Caesalpinaceae, which contribute up to 58% of the plant diet (Brugière *et al.* 2002). In Cameroon important food species include *Erythrophloeum suaveolens* and *Enantia chlorantha* (Poulsen *et al.* 2001). In Gabon a total of 75 species of fruit are taken, with seeds of *Pterocarpus soyauxii* being the most selected (Ham 1994).

At all study sites, second to fruit feeding is invertebrate foraging, which takes up 12–31% of the feeding time. Invertebrate foraging includes splitting dead twigs, tearing dead bark, epiphyte masses and liana tangles and searching for and eating objects found there (Waser 1977a). In Gabon 33% of insects are taken from leaves and 17% from flowers; caterpillars and ants comprise 75% of insect-eating (Ham 1994). Leaves (mostly young), flowers and other food items, account for 4–13%, 0–5% and 0–4%, respectively, of feeding time in Kibale, and 4%, 2% and 0.5%, respectively, in Gabon. In Kibale favourite sources of leaves are *Premna angolensis* and *Millettia dura*; in Gabon, *Cryptosepalum staudtii* and *Millettia* sp. Flowers are mostly taken from *M. dura*, *Erythrina* spp., *Symphonia globulifera* and *Monodora myristica* at Kibale and from *Pterocarpus soyauxii* and *Pentaclethra macrophylla* in Gabon. Prominent in the list of ‘other’ items are live bark and pith. Eggs and small vertebrates, including snakes, are infrequently taken (Waser 1977a).

In East Africa home-ranges are 13 ha (Chalmers 1968a) to 410 ha (Waser 1977a), but probably average ca. 250 ha. A home-range of 215 ha was used by one group of 18–23 individuals for one year in Gabon (Ham 1994). Home-range overlap, like home-range size, depends on group density with less overlap in higher density conditions.

Social and Reproductive Behaviour Social. Not territorial. Lives in groups containing several adult ♂♂ and adult ♀♀ and young of various ages. Most groups consist of 10–20 ind (5–30). Small groups may contain only one adult ♂. Group sizes average 18.9 ± 2.3 individuals in Gabon (L. J. T. White 1992). In Kibale weekly counts of six groups over 218 weeks gave an average count of 16.0 ± 2.4 individuals with 3.1 ± 1.2 adult ♂♂, 0.6 ± 0.4 subadult ♂♂, 6.2 ± 0.8 adult ♀♀, 3.6 ± 1.1 juveniles and 2.5 ± 1.3 infants (W. Olupot pers. obs.).

Frequently forms polyspecific associations with other monkeys, rarely with Robust Chimpanzees *Pan troglodytes*. In Gabon the most frequent association is with Crowned Monkeys *Cercopithecus pogonias*; in Uganda, with Red-tail Monkeys *C. ascanius*. These associations may include young of different species playing together and grooming between different species. Grey-cheeked Mangabeyes are highly vocal. Their calls include a variety of ‘grunts’ used in the context of contact, ‘staccato barks’ used in alarm situations, and the adult ♂♂ ‘whoop-gobbles’ loud call (Chalmers 1968b) used for inter-group spacing and coordinating group movements (Waser 1977b, Olupot *et al.* 1998). Adult ♀♀ have a call similar to the whoop-gobble of the adult ♂♂ but this call is rarely given (R. Kaserengenyu & C. Kaganzi pers. comm.). Grey-cheeked Mangabey groups usually avoid one another, but occasionally groups fuse. While groups are mixed, some level of aggression may occur among members of different groups, usually involving adult ♂♂ and adult ♀♀. Large groups can fission temporarily or permanently (Janmaat *et al.* 2009). Stable dominance hierarchy among ♀♀ (Chancellor & Isbell 2009). Infant carrying by ♀♀ other than mothers occurs. Adult ♂♂ also sometimes carry infants, especially when the group is disturbed. Intergroup transfer primarily by adult ♂♂ (Olupot & Waser 2005, Chancellor *et al.* 2011) though it is possible that ♀♀ also transfer between groups (W. Olupot pers. obs.). Mortality rate for transferring ♂♂ is higher than for ♂♂ in groups (Olupot & Waser 2001a).

Reproduction and Population Structure Breeding and birth occur throughout the year. There is no obvious relationship between the timing of breeding or births and rainfall, food availability or food quality. In captivity ♂♂ begin to exceed ♀♀ in weight at 3–4 years (Deputte 1992). In Kibale ♂♂ reach maturity at ca. 7.5 kg at 6–7 years (Olupot 2000b). Testes descend and canines emerge at 4–5 years of age (Deputte 1992). In captivity ♀♀ exhibit their first sexual swelling at 3–4 years of age at a weight of ca. 5 kg, after which their growth rate slows. Cycles (average of 31 days) are initially long and irregular, suggesting a period of adolescent infertility (Deputte 1992). In Kibale the ratio of adult ♂♂ to adult ♀♀ is 1 : 2; adult to young ratio is 1 : 1.4. Birth rate is 0.4 per adult ♀/year (W. Olupot pers. obs.). Gestation is 175 days (Deputte 1991). One infant is born at a time. No cases of twinning reported. In captivity infants weigh ca. 425 g at birth (Ross 1991).

Number of adult ♂♂ in a group is strongly related to the number of oestrous ♀♀ (Olupot & Waser 2001b). A ♀ in oestrus develops a sexual swelling at the genitalia. Most mating occurs at the peak of the swelling (Wallis 1983). Mating is promiscuous. Complete copulation between a ♂ Ashy Red Colobus Monkey *Procolobus rufomitratu* *tephrosceles* and cycling ♀ Grey-cheeked Mangabeyes observed at Kibale on at least four occasions (T. Struhsaker & T. Butynski pers. comm., R. Kaserengenyu pers. comm.).

One ♂ usually dominates matings, but the ♀♀ also mate with other ♂♂, including old juveniles (Arlet *et al.* 2008). Male–female interactions often resemble mate guarding or consortships in baboons *Papio* spp. Each ♂ attempts to maintain close spatial association with the ♀ and tries to prevent other ♂♂ from getting close to her. Exclusive consortships of one ♂ with a ♀ occasionally continue over an entire oestrous period. As in baboons, there are sometimes high levels of aggressive competition for the ♀ and several ♂♂ mate during the oestrous cycle. Mating is followed by post-copulatory grunts by the ♀.

Uganda Grey-cheeked Mangabey *Lophocebus ugandae* showing suborbital indentations.

In captivity, longevity of at least 32 years, 8 months recorded (Jones 1982).

Predators, Parasites and Diseases African Crowned Eagles *Stephanoaetus coronatus* and Robust Chimpanzees are suspected to be the main non-human predators. Solitary ♂♂ are believed to be particularly vulnerable to attacks by *S. coronatus*. Robust Chimpanzees observed to kill an infant Grey-cheeked Mangabey in Kibale (R. Kaserengenyu pers. comm.). *Stephanoaetus coronatus* observed to kill a subadult ♂ in Central African Republic (N. Shah pers. comm.). Circumstances surrounding the death of several radiotracked ♂♂ in Kibale strongly suggest predation by *S. coronatus* (Olupot & Waser 2001a). Male responses to *S. coronatus* attacks are rank-dependent and elevate faecal cortisol (Arlet & Isbell 2009). Grey-cheeked Mangabey bones found under *S. coronatus* nests (Mitani *et al.* 2001) in Kibale and in Leopard *Panthera pardus* scats in Gabon (Henschel *et al.* 2005, 2011).

Conservation IUCN Category (2012): Least Concern as *L. albigena*. *L. johnstoni*, *L. osmani* and *L. ugandae* not assessed. CITES (2012): Appendix II.

Grey-cheeked Mangabeys are sensitive to heavy logging (Skorupa 1988, Kambale Saambili 1998, Olupot 2000a) and forest clearing for agriculture and settlement. In central and West Africa they are also threatened by the bushmeat trade. No records of crop-raiding recorded anywhere but in the Lwamunda Forest, Uganda (Chalmers 1968a).

Measurements

Lophocebus ugandae

HB (♂♂): 520 (470–600) mm, n = 31

T (♂♂): 810 (570–890) mm, n = 31

HF (♂♂): 170 (150–180) mm, n = 31

WT (♂♂): 8.7 (7.5–11.0) kg, n = 31

Kibale Forest, Uganda (Olupot 2000a, b)

Lophocebus johnstoni

HB (♂♂): 580 (540–620) mm, n = 16

HB (♀♀): 510 (440–640) mm, n = 15

T (♂♂): 890 (820–940) mm, n = 16

T (♀♀): 820 (740–900) mm, n = 15

WT (♂): 8.2 kg, n = 1

WT (♂): 6.1 kg, n = 1

From several sites in Zaire (Allen, 1925. Added to this sample are one ♂ and one ♀ from Ituri Forest, Zaire, housed at PCM; C. P. Groves pers. comm.). Sample may include one or more immature individuals.

Lophocebus albigena

WT (♂♂): 9.0 kg, n = 5

WT (♀♀): 6.4 kg, n = 6

Gabon (Gautier-Hion & Gautier 1976)

HB (♂♂): 630 (570–750) mm, n = 9

HB (♀♀): 550 (540–560) mm, n = 4

T (♂♂): 900 (750–1010) mm, n = 9

T (♀♀): 830 (750–880) mm, n = 4

WT (♂♂): 9.2 (8.5–10.0) kg, n = 5

WT (♀♀): 6.0 (6.0–6.0) kg, n = 2

Uganda Grey-cheeked Mangabey *Lophocebus ugandae*.

Lophocebus aterrimus (also *L. opdenboschi*) **BLACK MANGABEY**

Fr. Mangabé noir; Ger. Schopfmangabe

Lophocebus aterrimus (Oudemans, 1890). Der Zoologische Garten 31: 267. Stanley Falls, DR Congo.Northern Black Mangabey *Lophocebus aterrimus* adult male.

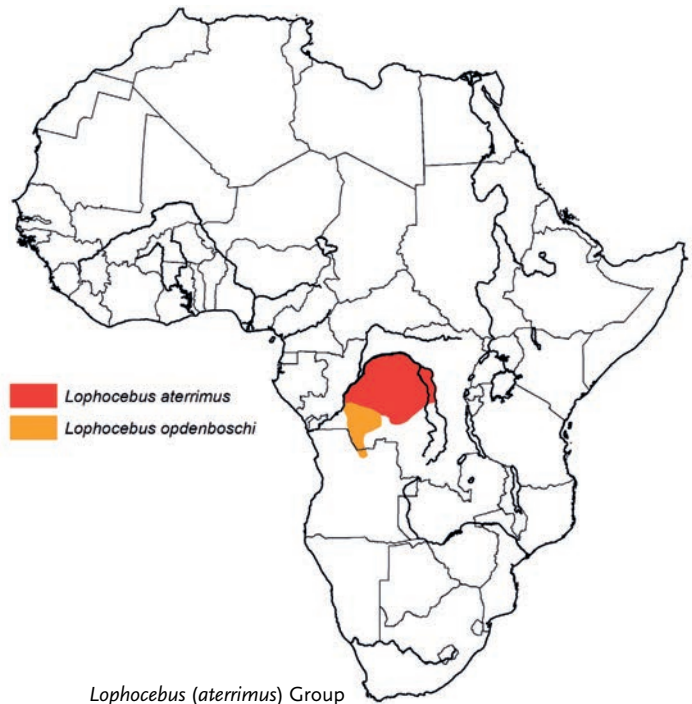

Taxonomy Monotypic species. Described as a full species (Schouteden 1944b), then reduced to a subspecies of the Grey-cheeked Mangabey *Lophocebus albigena* (Schouteden 1948, Groves 1978, Horn 1987a). Re-evaluated as a full species with two subspecies *L. a. aterrimus* and *L. a. opdenboschi* (Kingdon 1997) and this taxonomy was adopted by Grubb *et al.* (2003). Groves (2001, 2007a) has since argued for full species designation for both *aterrimus* and *opdenboschi*, the taxonomy adopted here. *Lophocebus aterrimus* is relatively poorly known, and *L. opdenboschi* is even less studied in the field. Therefore, for convenience, this profile treats these two species together as the ‘*Lophocebus* (*aterrimus*) Group’ with almost all of the information presented here coming from field research on *L. aterrimus*. Synonyms: see Geographic Variation. Chromosome number: $2n = 42$ (Dutrillaux *et al.* 1979).

Description Slender, medium-size, black, arboreal monkeys. Sexes alike in colour. Weight of adult ♀ ca. 70% that of adult ♂. Entirely glossy black fur except for the long curled cheek-whiskers. Albinistic and leucistic individuals not uncommon (Groves 1978, Eppley *et al.* 2010). No eyebrow tufts. Upstanding crest in the centre of the crown (up to 80 mm long). Long sparse fur, up to 150–200 mm on the shoulders forming a mane (= mantle = cape). Long tail and long limbs. Females have red sexual swellings. Total or partial albinism is frequent in *L. aterrimus* (Schouteden 1948, Horn 1987a). Young similar in colour to adults.

Geographic Variation The species of the *Lophocebus* (*aterrimus*) Group, according to Groves (2001, 2007a), are:

***L. aterrimus* Northern Black Mangabey** (synonyms: *coelognathus*, *congicus*, *hamlyni*, *opdenboschi*, *rothschildi*). C Congo Basin, between left bank of Lualaba R. to ca. 4°S in east and to right bank of Kasai R. in west. Cheek-whiskers brown and greyish-brown; crest conical (Schouteden 1944b).

***L. opdenboschi* Schouteden, 1944: Southern Black Mangabey.** W Congo Basin (south of Kasai R.) and NE Angola to ca. 17°05' E, 09°S (Schouteden 1948, Machado 1969, Gautier-Hion *et al.* 1999). Cheek-whiskers black; crest ridged (Schouteden 1944b).

*Lophocebus* (*aterrimus*) Group**Similar Species**

Lophocebus albigena. Allopatric with *L. aterrimus* along Congo/Lualaba R. On right bank. Mane light grey. Ventrums brown. Cheeks creamy white. Crown hair long and scruffy, often forming two small tufts above brows.

Lophocebus johnstoni. Allopatric with *L. aterrimus* along lower Congo R. On right bank. Mane (= mantle = cape) and ventrum dark brown. Cheeks greyish-brown.

Distribution Endemic to Congo Basin. Rainforest BZ. Forested areas of Congo Basin south of the Congo R to NE Angola. See Geographic Variation.

Habitat Moist forest. Data only available for *L. a. aterrimus* studied in the L. Tumba region (Horn 1987b), in the Lomako Forest (McGraw 1994) and in Salonga N. P. (Gautier-Hion & Maisels 1994, Gautier-Hion pers. obs.). Mostly inhabits primary rainforest; frequently in swamp forests at Salonga (but not at Lomako); avoids secondary forest. Known altitudinal range ca. 100–400 m. Annual rainfall 1700 mm–>2100 mm (Ergo & de Halleux 1979).

Abundance The most abundant primate at Lomako with 73 ind/km² and a biomass of 585 kg/km² (McGraw 1994). A comparable density (69 ind/km²) deduced from one group's home-range at Tumba L. (Horn 1987b). Common in the Salonga N. P.

Adaptations Diurnal and arboreal. In the absence of colour markings, even on the face, body postures exhibiting the black silhouettes of

the monkey should be the most important longer-range visual signals. Gives facial grimaces at close quarters. The rich vocal repertoire of *L. aterrimus* may offset a narrower range of visual communication (Kingdon 1997). Inflation of large vocal sacs allows adult ♂♂ to produce a loud 'whoop-gobble' call that can be heard to at least 500 m.

Foraging and Food Omnivorous. Forages extensively in the middle and upper canopy. Often forages in subgroups (Horn 1987b, Gautier-Hion pers. obs.). Home-ranges of two groups were 48 ha and 70 ha with range overlaps with other groups of *L. aterrimus* of 60% and 75%, respectively. When licking nectar from flowers in the canopy along a river bank, one group of ten animals often divided into three subgroups separated by up to 400 m. Adult ♂♂ sometimes forage alone (Gautier-Hion & Maisels 1994). Diet at L. Tumba includes fruits (57%), seeds (30%), flowers (4%), immature leaves (3%) and insects (2%) (Horn 1987b). Thirty-three plant species used at Salonga N. P. where the diet is dominated by arils (32%) and seeds (30%) and includes a small amount of fruit pulp (4%). Flowers (including nectar of *Daniellia pynaertii*; Caesalpiniaceae) comprise 18% of the diet, and leaves 16% (Gautier-Hion & Maisels 1994, A. Gautier-Hion & F. Maisels pers. obs.). At this site most animal prey (insect larvae and ants) are found by searching under bark. Bark and palm shoots also consumed. Strong seasonal dietary variations reflect food availability. During a year-round study, the diet was successively dominated by nectar and leaves (monthly maxima of 50% and 40%, respectively, in Feb), then by arils (mainly from Annonaceae and Myristicaceae with monthly maximum of 73% in May), finally by seeds (mainly from legumes with monthly maximum of 65% in Sep; Gautier-Hion pers. obs.).

Social and Reproductive Behaviour Social. Multile, multi-female groups, with a mean of 10–11 members (Lomako, McGraw 1994; Salonga, Gautier-Hion pers. obs.) numbering up to 19 individuals (Horn 1987b). Two groups, both of 19 individuals, each included three adult ♂♂ and five adult ♀♀. Subgroups and single adult ♂♂ occur. Single adult ♂♂ of a group may visit oestrous ♀♀ in neighbouring groups, but rejoin their own group by nightfall. No territorial defence observed (Horn 1987b). Courtship and mating behaviour, as well as development of the young has not been studied. *Lophocebus aterrimus* frequently engages in polyspecific association (ca. 80% of the time at Salonga, 59% at Lomako), mainly with Wolf's Monkey *Cercopithecus wolffi* (70–90% of bi-specific groups), and with *C. wolffi* and Red-tailed

Monkey *Cercopithecus ascanius* (80% of tri-specific groups). At Salonga *L. aterrimus* occasionally found with Red Colobus *Procolobus rufomitratus* and Angola Colobus *Colobus angolensis* in the presence of *C. wolffi*. The vocal repertoire of *L. aterrimus* is very similar to that of *L. albigena*: includes the 'whoop-gobble' call of adult ♂♂, which serves inter-group spacing and intra-group rallying, and the 'karaou' call that is given by adult and subadult ♂♂ and adult and subadult ♀♀ during alarming situations. A variety of grunts are exchanged at short inter-individual distances (Gautier-Hion pers. obs.).

Reproduction and Population Structure This is one of Africa's least studied monkeys. Few data available on life history parameters or on population structure. Probably very similar to *L. albigena* and *L. johnstoni*. Sexual swellings in adult ♀♀. Ratio ♂ : ♀ about 1 : 1.5.

Predators, Parasites and Diseases No data. Like other monkeys, *L. aterrimus* responds with warning calls to presence of African Crowned Eagles *Stephanoaetus coronatus*.

Conservation IUCN Category (2012): Near Threatened. Near Threatened for *L. a. aterrimus*. Data Deficient for *L. a. opdenboschi*. CITES (2012): Appendix II.

Contemporary status insufficiently known. Salonga N. P. appears to be the most important area for long-term conservation of *L. aterrimus*. Both species are too poorly known to make recommendations for their long-term conservation.

Measurements

Lophocebus aterrimus

HB (♀): 530 mm, n = 1

T (♀): 750 mm, n = 1

Unknown origin (Napier 1981)

WT (♂): 7.9 kg, n = 1

WT (♀♀): 5.6 (4.5–6.7) kg, n = 4

DR Congo (Colyn 1994)

GENUS *Rungwecebus*

Kipunji

Rungwecebus Davenport, Stanley, Sargis, De Luca, Mpunga, Machaga & Olson, 2006. Science 312: 1379.

Rungwecebus is a monotypic genus endemic to two areas of forest in SC Tanzania, the Southern Highlands and the Udzungwa Mts (Davenport 2005a, Jones *et al.* 2005, Davenport *et al.* 2006, 2008). The main characteristics are given in the profile for the Kipunji *Rungwecebus kipunji*. Initially described as belonging to the mangabey genus *Lophocebus* (Jones *et al.* 2005), molecular phylogenetic analyses demonstrate that *R. kipunji* is closer to *Papio* than to *Lophocebus*, *Theropithecus*, *Cercocebus* or *Mandrillus*. Morphological data revealed distinct differences from *Papio*, thus necessitating the description of

a new genus, *Rungwecebus* (Davenport *et al.* 2006). The validity of *Rungwecebus* was questioned (Ehardt & Butynski 2006b, C. P. Groves pers. comm. to von Buol 2006), but evidence from additional molecular markers support Kipunji's current taxonomic status (Olson *et al.* 2008). Zinner *et al.* (2009a) accepted that Kipunji does not belong within *Lophocebus*, but, based on an analysis of mitochondrial sequences from the individual studied by Davenport *et al.* (2006), raised the question of whether *Rungwecebus* is a sister taxon to, or a member of, *Papio*. Morphometric analyses of a subadult

Kipunji *Rungwecebus kipunji* adult.

skull, however, show that whilst possibly more similar to *Lophocebus* than to *Papio* (Gilbert *et al.* 2011), *Rungwecebus* is morphologically distinct from both (Singleton 2009). Burrell *et al.* (2009) suggest that *Rungwecebus* originated by hybridization between Yellow Baboon *Papio cynocephalus* ♀♀ and *Lophocebus* sp. ♂♂. More recently, Roberts *et al.* (2010) provided the first DNA sequences of *Rungwecebus* from Ndundulu, as well as two additional sequences from Mt Rungwe-Kitulo. These data result in consistent topologies with respect to the unique placement of *Rungwecebus* and also demonstrate, as originally suggested by Olson *et al.* (2008), that local introgression by *Papio* ♀♀ only in Rungwe-Kitulo, and not hybrid origin, explains mitochondrial DNA variation in *R. kipunji*.

Rungwecebus differs from *Lophocebus* in having a light to medium greyish-brown pelage, an off-white centre of ventrum and distal half of tail, and crown with long, broad, erect crest of hair. *Rungwecebus* usually holds its tail curved up and backward, but rarely vertical or arched forward. *Rungwecebus* gives a distinctive 'honk-bark' when conspecific groups meet (Jones *et al.* 2005) and when threatened. The 'honk-bark' bears some structural similarity to the *Papio* 'roar-grunt'. *Rungwecebus* does not emit the 'whoop-gobble' loud-call characteristic of *Lophocebus* and *Cercocebus*. *Rungwecebus* differs from *Papio*, *Theropithecus* and *Mandrillus* in lacking the long rostrum and deep mandibular fossae characteristic of these genera. *Rungwecebus* possesses deep suborbital fossae on the maxillae similar to *Lophocebus* and *Cercocebus*, but these are distinct from the deep maxillary fossae present on the rostrum of *Papio*, *Theropithecus* and *Mandrillus*. *Rungwecebus* is much smaller in body size and far more arboreal than *Papio*, *Theropithecus* and *Mandrillus* (Davenport *et al.* 2006).

Discovery and description of this new genus challenges some assumptions about papionine evolution. For example, the molecular data demonstrate that *Rungwecebus* evolved from a *Papio*-like ancestor (Davenport *et al.* 2006), thus casting doubt on the assumption that baboons became more successful by becoming less arboreal. Indeed, it would seem that successful terrestrial primates may have given rise to arboreal species. *Rungwecebus* implies support for the theory posed by Kingdon (1971) that African arboreal monkeys evolved from larger, less arboreal ancestors that resembled baboons. Alternatively

Rungwecebus might represent a stabilized hybrid between *Papio* and a now extinct ancestral *Lophocebus* (C. J. Jolly pers. comm.).

Another important question raised by the discovery of *Rungwecebus* centres on how the suborbital fossa is interpreted. In this respect, the superficial similarity with *Lophocebus* influenced the initial allocation of *kipunji* to the latter genus. It was subsequently revealed that the Kipunji's molecular profile is sufficiently different from *Lophocebus* to merit its separation as a new genus. Instead, *Rungwecebus* has proved to be genetically close to *Papio*, implying that suborbital fossae may simply be evolutionary artefacts deriving from phylogenetic reduction and retraction of mandibles under crania. If this is so, it raises the interesting possibility that extended muzzles in the separate ancestors of *Lophocebus*, *Cercocebus* and *Rungwecebus* shrank and migrated backwards, independently, in the three lineages. In each case J. Kingdon (pers. comm.) suggests derivation from long-faced, mainly terrestrial ancestors. He suggests that during favourable climatic periods in seasonal, non-forest habitats these terrestrial ancestors evolved an ecological strategy that was 'expansive' and relied on large groups ranging far and wide over varied landscapes (much as baboons do today). This is consistent with the evolution of multimale social systems where large, long-muzzled ♂♂ effectively diminish risk from both predation and competition.

The cercopithecine (guenon) radiation demonstrates that an intensive use of arboreal resources by a suite of smaller-bodied monkeys in smaller, more localized groups is generally easier to sustain in forests, where food is relatively scarce on the ground and smaller bodies are better suited to exploit varied vegetation, fruit and invertebrates in the canopy. Kingdon therefore argues that wherever and whenever climatic changes (and/or competitors) diminished the resources available to large groups of terrestrial foragers, their large ♂♂ and heavy, large muzzles became redundant as their expansive strategy ceases to be viable. During the climatic fluctuations of the early Pliocene (5 mya), diverse and widely scattered populations of large-muzzled papionines presumably faced this situation many times. Kingdon suggests that rapid selection for diminished muzzles might help explain the independent evolution of this feature in three lineages, with the evolution of *R. kipunji*, as a sister-group to *Papio*, presumably the most recent.

Great interest is also attached to the biogeography of *Rungwecebus*. The two localities in which *Rungwecebus* has been found can, with confidence, be described as vestiges of a formerly more extensive range. What cannot be determined at present is how wide-ranging this genus once was, nor when its distribution was more or most extensive. None the less, the occurrence of *Rungwecebus* east of a major biogeographic divide (the Somali-Kalahari Arid Corridor) suggests that *Rungwecebus* might have been essentially a south-eastern genus. Benefit (1999) shows that the fossil record makes a southern African origin for *Papio* (and probably most other long-faced papionines) likely. This is consistent also with the biogeography of other restricted-range faunal taxa with an epicentre in the Southern Highlands and a northern limit in the Udzungwas (Davenport 2004, 2005b). J. Kingdon (pers. comm.) agrees that the restriction of *Rungwecebus* to S Tanzania is consistent with isolation of an early *Papio* or *Papio*-like population in this formerly well-forested region. The vulnerability of *Rungwecebus* may therefore be partly connected with widespread deforestation but its precarious hold on existence might be influenced by its evolution before the arrival of arboreal *Cercopithecus* monkeys from western central Africa.

Tim R. B. Davenport

***Rungwecebus kipunji* KIPUNJI**

Fr. Kipunji; Ger. Kipunji

Rungwecebus kipunji (Ehardt, Butynski, Jones & Davenport, 2005). In: Jones, Ehardt, Butynski, Davenport, Mpunga, Machaga & De Luca. 2005. Science 308: 1162. Rungwe-Livingstone (09° 07' –09° 11' S; 33° 40' –33° 55' E), Southern Highlands, SW Tanzania.

Kipunji *Rungwecebus kipunji* adult.

Taxonomy Monotypic species. Originally allocated to *Lophocebus* (Jones *et al.* 2005) based on the non-contrasting black eyelids and arboreal nature, but later placed in a new monotypic genus *Rungwecebus* (Davenport *et al.* 2006) on the basis of molecular and morphological data acquired from a voucher specimen. The genus to which the Kipunji belongs has been questioned (Ehardt & Butynski 2006b, C. P. Groves pers. comm. to von Buol 2006, Zinner *et al.* 2009a) but additional molecular evidence and morphometric analysis supports the phylogenetic position and taxonomic status of *Rungwecebus* (Olson *et al.* 2008, Burrell *et al.* 2009, Singleton, 2009, Roberts *et al.* 2010, Gilbert *et al.* 2011). Synonyms: none. Chromosome number: not known.

Description A mostly brown, medium-sized, long-tailed, arboreal monkey. Sexes similar in colour. Little sexual dimorphism;

adult ♀♀ estimated to be 90–95% the weight of adult ♂♂. No adult body weights available but estimates range 8–16 kg (T. Davenport pers. obs.). Facial skin, including eyelids, black. Muzzle bare, relatively elongated, black. Suborbital fossa pronounced. Eyes brown. Cheek-whiskers long, extending laterally and curving downward. Crown with prominent, long, broad, erect crest of dark greyish-brown hair. Shoulder mane (= mantle = cape) of adult ♂♂ variable in colour and length; typically of long, straight, cinnamon-brown hairs. Dorsum light to medium greyish-brown over distal half. Tail dusky-brown over proximal half and off-white with interspersed darker hairs over distal half. Tail pelage smooth, not shaggy or lax. Tail longer than HB. Forelimbs dark greyish-brown. Upper hindlimbs dark rufous-brown. Lower hindlimbs cinnamon. Hands and feet black. Ventrums off-white. Patch on upper chest that

Lateral, palatal and frontal views of skull of Kipunji *Rungwecebus kipunji* juvenile.

is close to cinnamon. Individual hairs long and straight, without banding or speckling (Davenport *et al.* 2006). Ischial callosities pink; fused in ♂ and unfused in ♀. Tail carried loosely and parallel to, or below, the plane of the back, curving downward to the level of the feet during locomotion. Tail not held arched over the back when standing, nor held vertically, except as a semi-prehensile support (Jones *et al.* 2005, Davenport *et al.* 2006). Infants less hirsute with a reddish tinge to pelage.

Geographic Variation Two isolated populations known, but no subspecies described. Ventrum off-white and sharply demarcated from the brown of rest of body in some Ndundulu Forest animals, but lighter and not sharply demarcated in Rungwe–Kitulo animals. Ndundulu animals seem less vocal than Rungwe–Kitulo counterparts.

Similar Species None that is sympatric or parapatric.

Distribution Afromontane–Afroalpine BZ. Endemic to S Tanzania; known only from two populations separated by ca. 350 km of largely non-forested land. One (fragmented) population occurs at 1750–2450 m in 12.4 km² of Rungwe–Kitulo Forest in the Southern Highlands of SW Tanzania (09° 07′–09° 11′ S, 33° 40′–33° 55′ E; Davenport *et al.* 2008). The Rungwe–Kitulo Forest includes Mt

Rungwecebus kipunji

Rungwe F. R. (150 km²) and Livingstone Forest (191 km²), which lies within Kitulo N. P. (412 km²) (Davenport & Bytebier 2004, Davenport *et al.* 2008). Mt Rungwe F. R. and Livingstone Forest are connected by the Bujingijila Corridor, a narrow (<2 km wide) swathe of degraded and encroached-upon forest. *Rungwecebus kipunji* inhabits the wetter forest of south Mt Rungwe and isolated groups are scattered in the north and south of Livingstone Forest (Davenport 2005a, 2006b, Jones *et al.* 2005, Davenport *et al.* 2006, 2008). Area of occupancy in Mt Rungwe and Livingstone Forest is 6.72 and 4.08 km², respectively. Extent of occurrence in Mt Rungwe and Livingstone is 8.15 and 4.25 km², respectively. Anecdotal evidence from interviews points to the historic presence of *R. kipunji* in other Southern Highland forests, though this is unconfirmed, and recent extensive searches have found no new subpopulations in other forests (Davenport *et al.* 2008).

The other population of *R. kipunji* ranges 1300–1750 m in altitude in the Vikongwa Valley, Ndundulu Forest (07° 40′–07° 51′ S, 35° 10′–36° 50′ E; ca. 180 km of closed forest), in the Kilombero Nature Reserve in the Udzungwa Mts, S Tanzania (Jones *et al.* 2005). The area of occupancy of *R. kipunji* in the Ndundulu Forest is 1.98 km² and the extent of occurrence 5.28 km² (Davenport *et al.* 2008). Research to date in Ndundulu Forest, and the lack of independent knowledge of the species among local villagers, indicate that *R. kipunji* is absent from large parts of this forest (Jones 2006, Davenport *et al.* 2008).

Habitat Habitat ranges from degraded montane and upper montane forest from 1350–2450 m in Rungwe–Kitulo, to pristine submontane forest from 1300–1750 m in Ndundulu (Davenport *et al.* 2006, 2008, 2010). In Rungwe–Kitulo the canopy is often broken and at 10–30 m with emergents to 35 m. *Rungwecebus kipunji* prefers steep-sided gullies and valley edges, and is often found near streams (T. Davenport, N. Mpunga & S. Machaga pers. obs.). Ridges and open areas are usually avoided. The most common trees in

Rungwe–Kitulo include *Agauria salicifolia*, *Allophylus chaunostachys*, *Aphloia theiformis*, *Bersama abyssinica*, *Casearia battiscombei*, *Cassipourea gummiflua*, *Cassipourea malosana*, *Chrysophyllum gorungosanum*, *Clausena anisata*, *Cornus volkensii*, *Diospyros whyteana*, *Ekebergia capensis*, *Ficalhoa laurifolia*, *Ficus sur*, *Ficus thonningii*, *Garcinia buehneri*, *Hagenia abyssinica*, *Macaranga capensis*, *Macaranga kilimandscharica*, *Maesa lanceolata*, *Maytenus acuminata*, *Neoboutonia macrocalyx*, *Nuxia congata*, *Olinia rochetiana*, *Peddiea fischeri*, *Syzygium guineense*, *Tabernaemontana angolensis*, *Trichocladus ellipticus*. The numbers of *Albizia gummifera*, *C. battiscombei*, *Entandrophragma* sp., *M. kilimandscharica*, *Ocotea usambarensis*, *Olea capensis*, *Parinari excelsa*, *Podocarpus latifolius* and *Prunus africana* have all been greatly reduced by logging (Lovett 1986, McKone & Walzem 1994, Davenport 2005b, 2006a). Thick undergrowth is typical, with the tree fern *Cyathea manniana*, wild banana *Ensete ventricosum* and large stands of bamboo *Sinarundinaria alpina* common in the south and south-east of Mt Rungwe and in the north-west of Livingstone (T. Davenport pers. obs.). *Rungwecebus kipunji* rarely frequents the bamboo, and leaves the forest only to raid nearby crops (see below), especially in Feb–Apr (T. Davenport, N. Mpunga & S. Machaga pers. obs.). In areas inhabited by *R. kipunji*, annual rainfall ca. 1850–2500 mm (T. Davenport pers. obs.). Mean annual rainfall from 1968–2008 was 2133 mm. Wet season is Nov–May and dry (colder) season is Jun–Oct (Davenport *et al.* 2010).

In Ndundulu, the primary *P. excelsa*-dominant forest is undisturbed and the canopy is unbroken, reaching a height of 40–50 m with emergents to 60 m (Jones 2006). Other trees (and shrubs) present include *B. abyssinica*, *C. gummiflua*, *Cola stelecantha*, *Craterospermum longipedunculatum*, *Dicranolepis usambarica*, *Ixora scheffleri*, *Myrianthus* sp., *Oxyanthus speciosus*, *Polyscias fulva*, *Psychotria* sp., *Strombosia scheffleri*, *Strychnos* sp., *Tarenna pavettoides*, *Tarenna quadrangularis*, *Uvariopsis* sp., *Vitex amaniensis* and *Zanthoxylum gillettii* (Ehardt & Butynski 2006b).

Abundance Following 2864 h of surveys, 772 h of simultaneous multi-group observational monitoring events and 209 group counts, the total *R. kipunji* population is estimated to be 1117 animals in 38 groups. Of these, 1042 individuals are estimated to occur in Rungwe–Kitulo in 34 groups, and 75 individuals in Ndundulu in four groups. Initial density estimates are 83.9 ind/km² in Rungwe–Kitulo, and 14.2 ind/km² in Ndundulu, with the total species density, excluding home-range overlaps, being 63.1 ind/km² (Davenport *et al.* 2008).

Adaptations Diurnal and arboreal, mainly >10 m above the ground, although occasional feeding on the ground observed in both populations. Moves to ground to cross degraded forest patches and to avoid intra-group conflict and predators (Davenport *et al.* 2006). Tolerant of low temperatures; temperatures in parts of Rungwe–Kitulo can drop to –3 °C during Jun–Aug. Sleep high (usually >30 m) in branches of trees such as *B. abyssinica*, *H. abyssinica*, *M. lanceolata* and *S. guineense*. Typically rests in the middle of the day for 30–60 min. Most active 08:00–11:30h and 15:00–18:00h (T. Davenport, N. Mpunga, D. De Luca & S. Machaga pers. obs.). Able to open large, hard fruits and break dead wood in search of grubs.

Foraging and Food Omnivorous. Groups in Rungwe–Kitulo travel a mean of 1.29 km/day (S.E. = 0.15, 0.99–1.71, n = 235

days) (De Luca *et al.* 2009) and group members usually remain within 300 m of each other, except when disturbed (T. Davenport, D. De Luca, N. Mpunga, S. Machaga & C. Bracebridge pers. obs.). Using fixed kernel density, estimation calculated using the ‘reference’ method as a smoothing parameter, mean home-range size of *R. kipunji* in Mt Rungwe is 3.06 km² (S.E. = 0.67, 1.16–4.30, n = 4 groups) (De Luca *et al.* 2009).

During 9498 h of observation of 34 groups in the Southern Highlands, 122 food plants were recorded from 60 families (64 tree species, 30 herbs, 9 climbers, 7 shrubs, 6 liana, 3 grasses and 3 ferns). Diet comprised mature leaves (22%), unripe fruits (14%), ripe fruits (13%), young leaves (12%), bark (11%), stalks (9%), flowers (9%), pith (7%), insects (2%) and seed pods, rhizomes, shoots, tubers, epiphytes, ground herbs, climbers, moss, fungi and lichen (2%). Soil eaten on two occasions. Raids maize, bean, pea, sweet potato and banana fields, and granaries if close to the forest edge. Most frequently eaten plant was *M. capensis*. Other commonly eaten plants were *Ilex mitis*, *Psydrax parviflora*, *C. gorungosanum*, *B. abyssinica*, *Myrianthus holstii*, *Tabernaemontana stapfiana*, *Landolphia buehneri*, *Ureia hypselodendron*, *T. pavettoides*, *C. gummiflua*, *Allophylus abyssinicus*, *P. excelsa*, *Entandrophragma excelsum*, *F. thonningii*, *P. fulva* and *Multidentia crassa*. *Kipunji* appears to be more folivorous during the dry season and more frugivorous during the wet season (Davenport *et al.* 2010, Bracebridge *et al.* 2012). Most foraging occurs in early morning and late afternoon (Davenport *et al.* 2006).

Social and Reproductive Behaviour Social. Not territorial (De Luca *et al.* 2009). Groups comprise several adult ♂♂ and several adult ♀♀. Size estimates for Rungwe–Kitulo groups 25–39 ind/group (mean 30.6, S.E. = 0.62, n = 34) and in Ndundulu from 15 to 25 ind/group (mean 18.8, S.E. = 2.39, n = 4). For *R. kipunji* as a whole, groups number 15–39 animals (mean 29.4, S.E. = 0.85, n = 38; Davenport *et al.* 2008). In 34 groups closely observed in Rungwe–Kitulo, there was a maximum of two clinging infants/group (Davenport *et al.* 2008). There is no evidence that solitary animals occur (Davenport *et al.* 2006). In Rungwe–Kitulo groups form polyspecific associations with Peter’s Angola Colobus *Colobus angolensis palliatus* and Sykes’s Monkey *Cercopithecus mitis*, especially early in the morning and late in the afternoon, and the three species often sleep in neighbouring trees (Davenport *et al.* 2006). *Rungwecebus kipunji* groups at Ndundulu form polyspecific associations with *C. a. palliatus*, *C. mitis* and Udzungwa Red Colobus *Procolobus gordonorum* (Davenport *et al.* 2005, 2006).

Four copulations observed in Rungwe–Kitulo in late Sep. One pair moved ca. 200 m from the main group, copulated twice in 10 min and again after a further 45 min. No ♀ post-copulatory vocalizations heard. Copulation lasted 3–7 sec (T. Davenport, N. Mpunga & S. Machaga pers. obs.). Infants carried beneath ♀. Instances of ‘kidnapping’ observed in Ndundulu accompanied by loud screams, a chase and one animal falling to the ground (T. Davenport & T. Jones pers. obs.) and in Mt Rungwe (C. Bracebridge pers. comm.). Grooming observed most often in early afternoons. Oestrous ♀♀ often groomed by young ♂♂, though female–female, female–male, and adult–juvenile grooming also observed (T. Davenport, T. Jones, N. Mpunga, C. Bracebridge & R. Starkey pers. obs.).

Inter-group territorial displays occur where ranges overlap. Disputes often highly vocal in Rungwe–Kitulo, usually involving

adult ♂♂, but sometimes ♀♀ and juveniles also calling. No inter-group physical contact observed in over 772 h of direct observation (Davenport *et al.* 2008).

In the Rungwe–Kitulo population adult ♂♂ emit a distinctive, loud, low-pitched ‘honk-bark’, most evident when conspecific groups meet, and when threatened or disturbed (Jones *et al.* 2005). Adult ♀♀ also give this call but less often than adult ♂♂ (T. Davenport pers. obs.). Honk-barks can be heard by the human ear to 1 km and are used as a group-spacing mechanism. Honk-barks given throughout the day but most often in early morning and late afternoon. A call similar to the honk-bark has been heard at Ndundulu but this remains unanalysed (T. Jones pers. comm.). The characteristic ‘whoop-gobble’ of *Lophocebus* and *Cercocebus* mangabeys (Waser 1977b) is not known in *R. kipunji*. The honk-bark is qualitatively and quantifiably different from the whoop-gobble (Jones *et al.* 2005) and exhibits some structural congruence to the ‘roar-grunt’ of *Papio* (Davenport *et al.* 2006). At least six other call types have been identified (T. Davenport, C. Bracebridge & T. Jones pers. obs.). Contact ‘grunts’ given. High-pitched, sharp ‘chirrup’ given in alarm at African Crowned Eagles *Stephanoaetus coronatus*. ‘Screams’ given during intra-group agonistic encounters (Davenport *et al.* 2005). ‘Chutters’ emitted within groups when foraging. High-pitched ‘squeals’ also given (Davenport *et al.* 2005, Ehardt & Butynski 2006b).

Reproduction and Population Structure Genital swelling in oestrous ♀♀. Singletons born ($n = >38$). Twins not observed. No evidence of a birth season, with infants born throughout the year (T. Davenport & N. Mpunga pers. obs.).

Predators, Parasites and Diseases Main predators are African Crowned Eagles and humans (Davenport 2005a). On seeing an eagle, adult *R. kipunji* emit a series of alarm ‘chirrup’ (N. Mpunga & T. Davenport pers. obs.) that can last up to 15 min (Ehardt & Butynski 2006b). On hearing an eagle, individuals drop into thick vegetation and the entire group is silent. When the eagle has passed, the *R. kipunji* emit a few low ‘grunts’, although they do not move immediately, on one occasion remaining still for a further 14 min. Hunted by humans but primarily as retribution for crop-raiding and as a by-catch when hunting *C. mitis*. No longer targeted for meat as was once the case (Davenport *et al.* 2006). *Rungwecebus kipunji* emits one or several loud, sharp, alarm ‘chirrup’ on seeing a human (T. Davenport & T. Jones pers. obs.) and there is an accompanying vigorous head shake directed towards the threat (Davenport 2005a). One or two subadults often act as sentinels, watching the threat and diverting it by lagging behind as the main group escapes. Sentinels can become separated from the group by >500 m in such instances (T. Davenport, N. Mpunga & S. Machaga pers. obs.). Leopards *Panthera pardus* also eat primates in the Southern Highlands (D. De Luca & N. Mpunga pers. comm.) and probably take *R. kipunji* in both Rungwe–Kitulo and Ndundulu.

Conservation IUCN Category (2012): Critically Endangered. CITES (2012): Appendix II.

Known world population fragmented and comprised of ca. 1117 individuals over an area of ca. 20 km² (Davenport *et al.* 2008). *Rungwecebus kipunji* is among Africa’s most threatened animals (Davenport *et al.* 2008, Davenport 2009) and one of the world’s 25

most threatened primates (Ehardt *et al.* 2007, Davenport *et al.* 2009). The threats to *R. kipunji* are considerable. The Rungwe–Kitulo forests are severely degraded; logging, charcoal-making, illegal hunting and unmanaged resource extraction are common (Davenport 2003, 2005b, 2006a, Machaga *et al.* 2005). The narrow Bujingijila Corridor linking Mt Rungwe to Livingstone Forest, and the corridors joining the northern and southern sections of Livingstone, are encroached by farmers and degraded (Davenport 2005b). Without immediate conservation intervention these forests will be fragmented, resulting in isolated *R. kipunji* subpopulations some of which are unlikely to be viable over the long-term (Davenport *et al.* 2008). Protecting these corridors is of the highest priority for the conservation of this genus/species (Bracebridge *et al.* 2011, De Jong & Butynski 2012). *Rungwecebus kipunji* is hunted by local people, especially on farms. The more disturbed the forest is, the more this happens (Davenport *et al.* 2006). Mount Rungwe, while nominally a Forest Reserve, remains largely unmanaged and unprotected, although it was upgraded to Nature Reserve status in June 2009 (T. Davenport pers. obs.). The smaller Livingstone Forest population is within Kitulo N. P. but swift and effective conservation action is needed in both areas.

Although Ndundulu Forest is in excellent condition, and largely undisturbed, *R. kipunji* is present in very low numbers. The reasons for this are unclear and whether this population is viable in the long-term is debatable (Davenport & Jones 2005, Davenport *et al.* 2008). It is hoped that the gazettelement in August 2007 of Kilombero Nature Reserve incorporating Matundu, Iyondo and West Kilombero Scarp Forest Reserves, will serve to further protect *R. kipunji* in Ndundulu. The forests of the Southern Highlands and of the Udzungwas Mts are rich in endemic and threatened taxa of plants and animals (Rodgers & Homewood 1982, Fjeldså & Lovett 1997, Davenport 2002, 2003, 2004, 2005b, 2009, Burgess *et al.* 2004a, 2007, Davenport & Bytebier 2004, Rovero & De Luca 2007). Within the Udzungwa Mts, the Ndundulu Forest is especially important for the long-term survival not only of *R. kipunji* but also of several taxa that are either endemic to the Udzungwas, or to the Udzungwas and one or more nearby montane forests. These include the ‘Endangered’ Udzungwa Forest-partridge *Xenoperdix udzungwensis* (a monotypic genus endemic to the region), the ‘Vulnerable’ Rufous-winged Sunbird *Nectarina rufipennis*, the ‘Vulnerable’ Udzungwa Red Colobus, the recently discovered Phillips’s Congo Shrew *Congosorex phillipsorum* (Stanley *et al.* 2005) and Grey-faced Giant Sengi *Rhynchocyon udzungwensis* (Rovero *et al.* 2008). Ndundulu is the only known site in Tanzania for the Cassin’s Hawk-eagle *Spizaetus africanus* (Jones 2007). As the largest, most charismatic and rarest of these species, *R. kipunji* is now serving as a ‘flagship’ genus/species for the enhanced conservation of the biodiversity both of the Udzungwa Mts and the Southern Highlands (Davenport *et al.* 2005, Davenport 2006b, Jones 2006, von Buol 2006).

The presence of *R. kipunji* in both sites further supports the notion that the Southern Highlands are zoologically more aligned to the Eastern Arc Mts than has usually been thought (Davenport 2004, 2005b, Carleton & Stanley 2005, Davenport & Jones 2005, Davenport *et al.* 2006) and that both regions remain refugia for relict populations of ancient lineages whose closest relatives are geographically very distant (Fjeldså & Lovett 1997, Davenport 2004, Stanley *et al.* 2005).

Measurements

Rungwecebus kipunji

No adult body measurements available. HB of adult ♂ estimated at 850–900 mm. WT of adult ♂ estimated at 10–16 kg (Jones *et al.* 2005). Measurements of one subadult ♂: HB 370 mm; T 499 mm; HF 128 mm; E 35 mm; WT ca. 4.0 kg; GLS 96 mm; GWS 66 mm (Davenport *et al.* 2006).

Key References Davenport 2005a; Davenport *et al.* 2005, 2006, 2008, 2009; Davenport & Jones, 2008; Ehardt & Butynski 2006b; Jones *et al.* 2005.

GENUS *Papio*

Baboons

Papio Erxleben, 1777. Systema Regni Animalis, 1, Mammalia, 15.

Olive Baboon *Papio anubis* adult male.

Papio is a polytypic genus endemic to sub-Saharan Africa and Arabia. This account follows Groves (2001, 2005c) and Grubb *et al.* (2003) in recognizing five extant species of *Papio*: Hamadryas Baboon *Papio hamadryas*, Yellow Baboon *Papio cynocephalus*, Chacma Baboon *Papio ursinus*, Olive Baboon *Papio anubis* and Guinea Baboon *Papio papio*. Collectively, their non-overlapping but often contiguous ranges occupy most of Africa south of the Sahara (from sea level to >3300 m), in any habitat, from evergreen forest to semi-desert, that affords food, a night refuge on rock faces or in tall trees, and surface water. *Papio* baboons are, however, notably absent from western central African rainforest areas occupied by Mandrills *Mandrillus sphinx* or Drills *Mandrillus leucophaeus*, and from the central Congo Basin.

Papio exhibits the distinctive features of cercopithecine and papionin monkeys (e.g. buccal pouches, dental traits). They are distinguished from their closest relatives, the other African papionins (*Mandrillus*, Kipunji *Rungwecebus kipunji*, drill-mangabeys *Cercocebus* spp. and, especially, Geladas *Theropithecus gelada* and baboon-mangabeys *Lophocebus* spp.) by the following combination of features, some of which are probably ancestral for the African papionin clade: size large (adult ♂ >14 kg, >20 kg in most populations); muzzle prominent, defined by marked concavity of the ante-orbital

profile, but lacking prominent, longitudinal bosses; suborbital fossa moderate or absent; tail subequal to head and body, neither long and muscular nor extremely reduced; molar teeth not unusually high-crowned or complex; ♀ periovulatory swelling anogenital. Details of postcranial structure show distinct but not extreme adaptations to terrestrial digitigrade posture and locomotion.

Papio spp. are justly renowned for their ecological eclecticism and adaptability, reflected in their present-day wide geographical range

Papio cynocephalus

Chacma Baboon *Papio ursinus*

Skulls of four baboon *Papio* species.

and habitat diversity. The ecological diversity of the genus makes it especially amenable to studies of the interaction between habitat and behaviour – especially social behaviour (e.g. Hill & Dunbar 2002). Most inter-population differences in physique and physiology, however, are not obviously related to ecological adaptation. The one major exception is *P. hamadryas*, whose social system, and correlated features of pelage, development and physiology, can be seen as adapted to the semi-arid environments.

Genetic and palaeontological information suggest that the last common ancestor of the extant *Papio* clade lived in southern Africa ca. 2 mya (Delson 1988, Wildman *et al.* 2004, Burrell *et al.* 2009, Zinner *et al.* 2009b). Baboons seem to have spread rapidly from this base during the Pleistocene, presumably diversifying as their range was dissected by climatically driven changes in habitat distribution. Until the late Pleistocene, however, *Papio* is far rarer in the fossil record than its close relative *Theropithecus*, which is now reduced to a single, relict species. As the species accounts indicate, some populations of *Papio* have been studied in depth for more than 30 years, but these studies divulge but a small fraction of the variation within this ecologically diverse genus. The natural history and behaviour of other populations, including the widespread and distinct Kinda Baboon (regarded here as a subspecies of the Yellow Baboon *P. c. kindae*, but see Zinner *et al.* 2011), remain largely undocumented.

Though the main outlines of intra-generic diversity of *Papio* are relatively clear, the taxonomy of *Papio* is disputed, largely because of conflicting species definitions. Diagnosable geographical 'forms' within the genus have parapatric ranges, and most, perhaps all, interbreed at their boundaries, forming hybrid zones (Jolly 1993, Kingdon 1997). Thus, they might be distinguished as full (phylogenetic) species, or regarded as subspecies of a single, polytypic (biological) species (*Papio hamadryas*) (Jolly 1993, Sarmiento 1998a, b, Groves 2001, Frost *et al.*

2003). The five-species solution, adopted here, is a practical compromise that groups forms of generally similar external appearance. Another configuration, less defensible but commonly adopted (e.g. Smuts *et al.* 1987), separates *P. hamadryas* ('the Desert Baboon') as a distinct species, but groups all others ('the Savanna Baboons') as subspecies of a single species, *P. cynocephalus*. The latter taxon, however, appears not to be monophyletic, and the implication of an ecological and behavioural dichotomy is overly simplistic and even misleading. Regardless of the taxonomy used to express it, diversity within the genus *Papio* includes features hinting at a complex evolutionary history. *Papio papio*, for example, exhibits physical and behavioural traits (Jolly & Phillips-Conroy 2006) that ally it most closely with the *P. hamadryas*, from which it is currently separated by at least 5500 km of *P. anubis* range. Genetic information suggests a history that includes deep genetic introgression between species ('mitochondrial capture'), and possibly the formation of species by hybridization (Wildman *et al.* 2004, Burrell 2009, Zinner *et al.* 2009a, b, Keller *et al.* 2010, Zinner *et al.* 2011).

The species (and subspecies) within the genus *Papio* are identified primarily by the colour and texture of the pelage (Hill 1970, Jolly 1993, Rowe 1996, Kingdon 1997, Groves 2001). Besides overall colour, important diagnostic features are the extent of development, if any, of a mane (= cape = mantle) of waved hair over the forequarters, or of a fringe of long, straight hairs on the trunk and nape; the extent to which pelage of the cheeks contrasts in colour and/or length with that of the crown; the presence/absence of contrastingly lighter ventral pelage; and the facial profile, especially the projection of the nose. All these diagnostic features are most fully developed in adult ♂♂.

Clifford J. Jolly

Papio papio GUINEA BABOON

Fr. Babouin de Guinée; Ger. Guinea-Pavian

Papio papio (Desmarest, 1820). Encyclopédie Méthodique, Mammalogie 1: 69. 'Coast of Guinea'.

Taxonomy Monotypic species. Individuals of appearance intermediate between *Papio papio* and Olive Baboon *Papio anubis*

Guinea Baboon *Papio papio* adult male.

occur in Mali (Pollock in Sharman 1981) but little is known about this hybrid zone (Sarmiento 1998a). See molecular information in Zinner *et al.* (2011). Synonyms: *olivaceus*, *rubescens*, *sphinx*. Chromosome number: 2n = 42 (Romagno 2001).

Description Medium sized, uniformly grizzled reddish-brown baboon. Female like ♂, but smaller, with barely half the body weight of the ♂. Face dark pinkish-purple. Male with distinct mane (= cape = mane) on shoulders. Tail arched; not 'kinked' or 'broken'. Perineum varies from bluish-grey to mottled. Female has largest oestrous swelling of any monkey. Pelage changes from black to brown, skin from pink to black, by seven months of age. Whitish individuals (albinos?) occur (Dupuy & Gaillard 1970, A. Galat-Luong pers. obs.).

Geographic Variation None recorded.

Similar Species

Papio anubis. Closely adjoining and probably parapatric range in Mali and perhaps Guinea. Said to be sympatric in Sierra Leone (T. S.

Jones in Booth 1958b). Larger, with darker, greyish-brown pelage; mane of adult ♂ less pronounced; tail 'broken'.

Distribution Endemic to West Africa. Sudan Savanna and Northern Rainforest–Savanna Mosaic BZs. Atlantic coast eastwards to ca. 12°W, ca. 11–18°N.

Historical Distribution Booth (1958b) set the historic northern limit in Mauritania, whereas Dupuy (1971) set the north-western limit at St Louis and Podor, Senegal. One ecological limit is the absence of broad-leaved trees and the dominance of *Acacia nilotica* (A. Galat-Luong pers. obs.). Northern limit has moved south due to decreasing rainfall (Verschuren 1982). Some fragmented populations may still occur in Casamance, Senegal (13°05'N, 16°20'W; Galat-Luong *et al.* 2006). Tahiri-Zagret (1976) noted that the Edinburgh Zoo, UK, received two *P. papio* from Ghana and speculated about the presence of the two species in Côte d'Ivoire. There are, however, no confirmed records for Ghana and G. Galat & A. Galat-Luong (pers. obs.) only found *P. anubis* in Côte d'Ivoire during nine years of fieldwork.

Current Distribution S Mauritania south-east through Senegal, Gambia, Mali, Guinea-Bissau, Guinea into Sierra Leone; an area of >200,000 km². Range of reintroduced individuals in Saloum, Senegal, is expanding (G. Galat & A. Galat-Luong pers. obs.).

Habitat In all types of savannas. Preferred habitats include Sudanese shrubby wooded savannas and sub-Guinean mosaic woodlands (400–1200 mm annual rainfall). In Niokolo Koba N. P., Senegal, a representative area of the preferred habitat, time spent in scrub about 40%, in open woodland 29%, in forest 21%, in grass 6%, in bush 4% and in gallery forest <1% (Sharman 1981). Of 506 group encounters in this area, 49% were in shrubby savanna, 35% in tree savanna, 8% in bamboo, 4% in open grassland, 2% in Ronier Palm *Borassus aethiopium* areas and 2% in forest (G. Galat & A. Galat-Luong pers. obs.). Also found in Sahelian steppe (200–400 mm annual rainfall) and, in the southern part of its distribution, in secondary high forest (1200–1400 mm annual rainfall). Will enter mangrove swamps (Galat-Luong *et al.* 2006). Not found in Sahelian acacia forests. Guinea Baboons present at altitudes from 0 to >1000 m (Fouta Djallon, Guinea) and over the temperature range ca. 20–50°C. In Niokolo Koba N. P. they sleep in tall trees, including *Ceiba pentandra* (85% of the sleeping trees, n = 52), *Cola cordifolia*, *Erythrophleum suaveolens*, *Azelia africana* (Sharman 1981), *Anogeissus leiocarpus*, *Antiaris africana* (Ndiaye 1983) and *B. aethiopium*, near stream beds or on branches overhanging rivers (Sharman 1981, Adie *et al.* 1997). The same sleeping sites are often used (92 of 133 observation nights; Anderson & McGrew 1984). Daytime sleeping sites are located in the shadow of large trees, thickets, cliffs and caves (A. Galat-Luong pers. obs.). Guinea Baboons require surface water and typically drink at least once per day.

Abundance In Niokolo Koba N. P., Sharman (1981) estimated 5.5–8.7 ind/km² (n = 2 groups), Verschuren (1982), Galat *et al.* (1998a, b) 6.3 ind/km² in 1990–93 (n = 305 group encounters), and 7.3 ind/km² in 1994–98 (n = 237 group encounters), while the densities of the ungulates were decreasing. In this National Park, density near water was higher, up to 19 ind/km² (n = 365 group

encounters; Lavocat 1997). In Upper Niger N. P., Guinea, Touré *et al.* (1997) estimated 46 ind/km². Verschuren (1982) estimated 100,000 Guinea Baboons for an 8000 km² area (12.5 ind/km²) in Senegal that included Niokolo Koba N. P. He rejected estimations of 200,000–300,000 baboons made for this same area in 1977.

Adaptations Diurnal and semi-terrestrial. In Senegal, although water is still available at the end of the dry season in river beds, Guinea Baboons (and Robust Chimpanzees *Pan troglodytes*) dig holes in sand near stagnant, putrid water. Thus, they drink sand-filtered water, cleaned of pathogenic microbes (Galat-Luong & Galat 2000).

Foraging and Food Omnivorous. In Niokolo Koba N. P., Guinea Baboons spend 24% of time feeding and 37% of time moving (Sharman 1981). Locomotion and feeding peaks occur 09:00–11:30h and 15:30–18:00h (Boese 1973). Water pool use showed two peaks, 07:00–10:00h and 16:00–18:00h (Galat *et al.* 1997, Lavocat 1997). Moving also occurs during two periods, 08:00–09:00h and 16:00–17:00h (Galat *et al.* 1997). In Niokolo Koba N. P. they feed on fruits (60% of feeding records), mainly of *Adamsonia digitata*, *Saba senegalensis*, *Lannea acida*, *Vitex madiensis*, *Spondias mombin* and *B. aethiopicus*. Also eaten are the shoots of *Oxytenanthera abyssinica*, seeds (17% of *B. aethiopicus* and *Combretum* spp.), various parts of *C. pentandra*, as well as buds, flowers, new leaves, roots, fungi, invertebrates, eggs and small vertebrates (n = 2024 feeding records, 58 food species; Sharman 1981). Other foods include the fruits of *Mangifera indica*, *Parkia biglobosa*, *Borassus flabellifer*, *Parinari macrophylla* and *Bombax costatum* (Ndiaye 1983), and the flowers of *Mitragyna inermis* and leaves of *Andropogon* sp. (Lavocat 1997). Feed on floating water plants while wading in the Gambia R. (A. Galat-Luong pers. obs.).

Guinea Baboons open termitariums of *Cubitermes* sp., roll over laterite boulders (Fady 1972, Sharman 1981, A. Galat-Luong pers.

obs.), and follow fire in order to catch invertebrates and small vertebrates to eat (Ndiaye 1983, A. Galat-Luong pers. obs.). They 'fish' for oysters *Etheria* sp. (Ndiaye 1983); also feed on grasshoppers and Agama Lizards *Agama agama*; occasionally hunt Scrub Hares *Lepus saxatilis*, Bushbucks *Tragelaphus scriptus* and Red-flanked Duikers *Cephalophus rufilatus* (McGrew *et al.* 1978, Sharman 1981). Guinea Baboons enter mangrove swamps to feed on Fiddler Crabs *Uca tangeri* (A. Galat-Luong pers. obs.), raid crops, steal stored grain in villages and food left out at field camps. Local people say Guinea Baboons feed on the rumen and the intestines of recently dead cattle. They dig in the ground to reach salt (A. Galat-Luong pers. obs.). Day range is 4–13 km (mean 8, $n = 49$; Sharman 1981). Home-ranges of two neighbouring groups were 19 km² and 43 km², with 9 km² overlap (Sharman 1981).

Social and Reproductive Behaviour Social. In Niokolo Koba N. P., Guinea Baboons show a multi-level group structure (Galat-Luong *et al.* 2006). First-level social unit is a 'one-male unit' (OMU) (Stammbach 1987), which is probably a matrilineal kin group (Sharman 1981). The OMU is best seen during feeding, foraging and sleeping periods. While moving, OMUs are led by an adult ♂. While resting, a subadult ♂ assumes vigilance (Boese 1973).

OMUs (Boese 1973) join with larger subgroups (second-level subgroups) to form a 'troop' before they begin to move or while sleeping at night (A. Galat-Luong pers. obs.). Multimale troops (Dunbar & Nathan 1972, Boese 1975) move in long columns (Bert *et al.* 1967a, b, Boese 1973) where the OMU (Boese 1973) and the second-level subgroups are still identifiable (A. Galat-Luong pers. obs.). Juveniles occasionally move from one OMU to another within these larger subgroups. At night the second-level subgroups sleep separately (Anderson & McGrew 1984) or together (Dunbar 1972). Several troops may join forming sleeping aggregations (Sharman 1981). In Niokolo Koba N. P. mean size of troops varies with climatic conditions between years (Boese *et al.* 1982). Mean number of instantaneously visible individuals in groups changes: 14 in 1990, 15 in 1991, 10 in 1992, 6 in 1993, 9 in 1994, 8 in 1995, 11 in 1998 ($n = 539$ group encounters, same transects, Feb.) (G. Galat & A. Galat-Luong pers. obs.). Size of troops declines in the dry season (50–90 individuals, $n = 2$ troops) and increases during the wet season (135–250 individuals, $n = 2$ troops; Sharman 1981). Mean number of visible individuals in groups also varies with time of day: 8 at 07:00h, 12 at 08:00–11:00h, 15 at 17:00h, 8 at 18:00h ($n = 96$ group encounters; G. Galat & A. Galat-Luong pers. obs.).

In Niokolo Koba N. P. mean sizes of the different categories of groups are:

First-level social unit: mean ca. 8 individuals (1 adult ♂, 3–4 adult ♀ and their young; Dekeyser 1956); 10 individuals (3–23, $n = 30$, 1 adult ♂, 3 adult ♀, 1 subadult ♂, 3 juveniles and 3 infants; Boese 1973).

Second-level moving and day rest subgroups: mean 19 individuals (5–65, $n = 45$; Galat-Luong *et al.* 2006), second-level sleeping subgroups median 20–24 individuals (8–65, $n = 92$; Anderson & McGrew 1984).

Third-level troops: mean 64 individuals (10–200, $n = 10$; Boese 1973); 193 individuals (135–250, $n = 2$; median = 55 individuals, $n = 16$;

Sharman 1981); 91 individuals (13–223, $n = 19$; Boese *et al.* 1982); 100 individuals (63–122, $n = 3$; Galat *et al.* 1998a, b); 62 individuals (22–249, $n = 111$; Galat-Luong *et al.* 2006).

To the south-east outside the Niokolo Koba N. P. group size is 72 individuals (24–200, $n = 14$; Galat-Luong *et al.* 2006); to the west (Saloum), 51 individuals (30–80, $n = 7$; A. Galat-Luong pers. obs.). In Upper Niger N. P. the distribution of group size was: 1–20 individuals, 20%; 21–50, 27%; 51–100, 47%; >100, 7% ($n = 871$ individuals; Touré *et al.* 1997). Sleeping aggregations number up to 630 individuals (Sharman 1981).

Separate behaviours described total 35: seven friendly, five agonistic, six sexual, six subgroup-specific, 11 mother–infant relations (Boese 1973). 'Noisy branch shaking', for example in Ronier Palms, and 'prancing' are frequent during agonistic displays. 'Kick press', recorded in captivity, has not been seen in the wild (Boese 1973). Spacing behaviour described (Boese 1973); territorial behaviour not observed. Guinea Baboons spend 19% of their time in social activities and 21% resting (Sharman 1981). Inter-subgroup herding (Galat-Luong *et al.* 2006) and intra-subgroup sexual herding occur (Boese 1973). Young are carried ventrally for up to four months and then in the jockey position (Boese 1973). Young are cared for by mother, sisters and aunts. Infant care and carrying by adult ♂♂ occurs (Boese 1973). One mother carried her dead newborn for three days (A. Galat-Luong pers. obs.). Few vocalizations are described. Boese (1973) and Byrne (1981) postulate an inter-group spacing role to the adult male's loud two-syllable 'wahoo' bark. Muffled grunt-like vocalization given by ♀♀ in 39% of the copulations, but is not specific to copulation only (Boese 1973).

Green Monkeys *Chlorocebus sabaeus* chase Guinea Baboons from trees and water pools. Guinea Baboons and Robust Chimpanzees avoid each other (A. Galat-Luong pers. obs.).

Reproduction and Population Structure First oestrous cycle at 3.5–4.5 years. First large perineal swelling at 4.5 years (Boese 1973). Mean age at sexual maturity for ♀♀ is 3 years 8 months, and first pregnancy at 4 years, 3 months (Gauthier 1994). Length of gestation is 26 weeks (Rowell 1967). A birth peak during Jan–Mar at Niokolo Koba (Dunbar 1974). Male to ♀ ratio 1 : 1.4 (1 : 1 and 1 : 1.5, $n = 2$ groups; Boese 1973). Group composition: 23% adult ♂♂, 32% adult ♀♀, 45–47% immatures (Boese 1973, Sharman 1981). Longevity >23 years of age for two wild-born ♀♀ living in the Parc Zoologique de Paris (MNHN).

Predators, Parasites and Diseases Humans, Leopards *Panthera pardus* (one Leopard for one troop of baboons; Verschuren 1982), Central African Rock Pythons *Python sebae*, Spotted Hyaenas *Crocuta crocuta* and African Wild Dogs *Lycaon pictus* are the main predators. Attacks observed by Nile Crocodiles *Crocodylus niloticus*, Leopards (five dead baboons found at a sleeping site after a nocturnal attack; Ndiaye 1983) and Spotted Hyena (three hyenas chasing a group of 80 baboons fleeing and climbing vertical cliffs; A. Galat-Luong pers. obs.). Since 1994, attacks by Lions *Panthera leo* have increased in Niokolo Koba N. P. due to reduced numbers of large ungulates (A. Galat-Luong pers. obs.). Side-striped Jackals *Canis adustus*, Caracals *Felis caracal*, Servals *Felis serval* and large eagles, like the Martial Eagle *Polemaetus bellicosus*, perhaps prey on young.

Walker & Spooner (1960) noted *Histoplasma* infections. Identified intestinal parasites and the percentage of animals infected are: Niokolo Koba – 98%: *Entamoeba coli* (30%), Nematoda (68%), Strongylidae (33%), *Strongyloides stercoralis* (22%), *Trichuris trichura* (30%), *Ascaris lumbricoides* (21%) (n = 63; Pourrut *et al.* 1997). Assirick, Senegal – Nematoda: *Strongyloides* sp. (26%), *Necator* sp. (38%), *Physaloptera* sp. (31%), *Trichuris* sp. (28%), *Streptophargus* sp. (23%), Trematoda *Schistosoma mansoni* (23%), *Stringoidea* sp. (44%); Protozoa: *Balantidium coli* (72%), *E. coli* (87%), *Iodamoeba butschilli* (38%) (n = 39; McGrew *et al.* 1989a). See Howells *et al.* (2010) for infection rates at Fongoli, Senegal. Susceptible to malaria, filariasis, tuberculosis; healthy carriers of amari virus. Particularly susceptible to epilepsy, thus, sleep and encephaloelectrophysiology has been studied in the wild (Bert *et al.* 1967a, b, Bert 1971, Balzamo *et al.* 1975, 1982). No simian immunodeficiency virus detected (n = 484; Durand *et al.* 1990).

Conservation IUCN Category (2012): Near Threatened. CITES (2012): Appendix II.

Habitat degradation and loss due to expanding agriculture and livestock grazing have led to significant population declines outside the national parks (Galat *et al.* 2000). Hunted for meat and to stop crop-raiding. Mean number traded per year (1989–93) was 131 (118 from Senegal) (Butynski 1996). Guinea Baboons still common in large protected areas in Senegal, Mali and Guinea.

Measurements

Papio papio

Papio hamadryas HAMADRYAS BABOON (SACRED BABOON)

Fr. Babouin Hamadryas; Ger. Mantelpavian

Papio hamadryas (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 27. Egypt.

Taxonomy Monotypic species. Mitochondrial evidence suggests that populations of Hamadryas in the Arabian peninsula have been separated from those in the Horn of Africa for at least 37,000 years. The time of separation is estimated at 37,000–74,000 years ago by Wildman *et al.* (2004) and at 85,000–119,000 years ago by Winney *et al.* (2004). Synonyms: *aegyptiaca*, *arabicus*, *brockmani*, *chaeropithecus*, *cynamoligus*, *nedjo*, *wagleri*. Chromosome number 2n = 42 (www.snprc.org/baboon/baboonGenomics.html, Romagno 2001).

Description Distinguished from other *Papio* spp. by lighter pelage, lighter and redder faces, and large greyish-white mane (= mantle = cape) on adult ♂. Face skin and ears pink to reddish-grey to dark greyish-black. Muzzle prognathic. Perineum pink in both ♂♂ and ♀♀, tail medium-length and held in gentle arch. Sexes differ in colour of pelage. Adult ♀♀ about 59% of the weight of adult ♂♂. Adult ♂: pelage light greyish-brown to greyish-white with short hair on crown of head, forelimbs below elbows, hindlimbs, posterior torso and tail. Mane large, formed by long, thick hair on shoulders, anterior torso, cheeks and sides of head, ranging from dark greyish-brown to silvery grey to off-white. Large, prominent areas of bare skin, usually bright pink, lateral to ischial callosities and extending to sides of buttocks. Ischial callosities not separated. Tail has tuft at tip. Adult ♀: more

Hamadryas Baboon *Papio hamadryas* adult male.

uniform in colour, golden brown, no mane, smaller body size and smaller area of paracallosal skin. Paracallosal skin pale to bright pink depending on reproductive state (colour of face immediately around eyes may also vary from grey to pink depending on reproductive state). Ischial callosities separated. Tail lacks tuft at tip. Infant pelage black until 6–12 months of age, when it turns brown.

Geographic Variation No consistent morphological differences among regional populations. Among Horn of Africa populations, pelage and skin are darker in colour in more western parts of range (near areas of hybridization with Anubis Baboon *Papio anubis*) and lighter (with whiter mane in adult ♂♂) in eastern parts of range (Kummer 1968, Kummer *et al.* 1985, Jolly 1993). African and Arabian populations distinguished by mitochondrial haplotypes (Wildman *et al.* 2004).

Similar Species

Papio anubis. Parapatric or narrowly sympatric above ca. 500 m on eastern edge of range in Ethiopia and Eritrea. Sympatric at Debre Libanos (ca. 2000 m; C. Jolly pers. comm.). Olive-brown to olive-grey pelage. Mane short to medium and same colour as rest of pelage. Face purple-black. Perineum black. Tail kinked (i.e. 'broken').

Theropithecus gelada. Sympatric in highlands of N Ethiopia above 1700 m, but usually above 2400 m. Dark to light brown pelage. Face skin dark brown to black. Less prognathic. Mane of adult ♂ brown instead of grey as in Hamadryas. Mane extends to below elbows. Patch of naked pink skin on upper chest in both sexes.

Distribution Endemic to arid zone of Horn of Africa and SW Arabian Peninsula. Sudan Savanna and Afromontane–Afroalpine BZs. Throughout N, C and E Ethiopia. Also in NE Sudan, Eritrea, Djibouti, N Somalia, SW Saudi Arabia and SW Yemen. It is not clear how Hamadryas originally dispersed to the Arabian Peninsula, nor whether they speciated from other *Papio* spp. on the Arabian Peninsula or in the Horn of Africa. Mitochondrial data suggest two Pleistocene invasions

of Arabia by African Hamadryas, one in the early late Pleistocene and again sometime between 37,000 and 119,000 years ago (Wildman *et al.* 2004, Winney *et al.* 2004), though Kummer (1995) regards such a lengthy separation to be unlikely. Hamadryas distribution meets that of *P. anubis*, with which they hybridize (Phillips-Conroy *et al.* 1991, 1992), in Awash N. P. and elsewhere in Ethiopia and in Eritrea.

Habitat Usually in arid semi-desert dominated by *Acacia* spp. trees and shrubs, *Grewia* spp. and *Dobera glabra* (Kummer 1968), but also occur where annual rainfall is >900 mm (Zinner *et al.* 2001a). Found from sea level up to 3300 m in the Simien Mts, NC Ethiopia (Crook & Aldrich-Blake 1968, Yalden *et al.* 1996) and up to 3000 m in Eritrea (Zinner *et al.* 2001a); also in highland regions of SW Saudi Arabia and Yemen (Biquand *et al.* 1992, Al-Safadi 1994). Important components of the habitat are permanent sources of drinking water and vertical rock faces on which to sleep.

Abundance Population density ranges from 1.8 ind/km² in the Erer Gota region of Ethiopia (Kummer 1968) to 23.9 ind/km² in the Durfo region of Eritrea (Zinner *et al.* 2001a).

Adaptations Diurnal and terrestrial. Well adapted to dry habitats and widely dispersed, scarce resources. Hamadryas sleep on cliffs throughout range and in Doum Palms *Hyphaene thebaica* at one location where cliffs are not available (Schreier & Swedell 2008). Compared with Olive Baboons, Yellow Baboons *Papio cynocephalus*, Rhesus Macaques *Macaca mulatta* and humans, Hamadryas are able to maintain their blood plasma volume when dehydrated by reducing evaporative water loss and urine flow and thus appear to be physiologically better-adapted to water scarcity (Zurovsky & Shkolnik 1993).

Foraging and Food Omnivorous. Larger home-ranges and longer daily travel distances than most other *Papio* spp. (Sigg & Stolba 1981, Sigg 1986, Swedell 2002b, Schreier 2010). Home-range size for two well-studied bands in Ethiopia was 28 km² (Sigg & Stolba 1981) and 38 km² (Schreier 2009); but 9 km² for a commensal population in Saudi Arabia (Boug *et al.* 1994). No territorial behaviour occurs other than occasional inter-band aggression over access to sleeping sites. Hamadryas travel up to 19 km/day, leaving sleeping cliffs in early to mid-morning and returning (to the same or a different sleeping cliff) before dusk (Kummer 1968). Mean daily travel distance 6.5–13.2 km at three sites in C Ethiopia (Kummer 1968, Nagel 1973, Sigg & Stolba 1981, Swedell 2002b, 2006, Schreier 2010). Approximately 57% of daytime spent travelling and foraging, and 43% resting and grooming (Schreier 2009).

Relies mainly on plant foods. Common food items include flowers, leaves and seeds of *Acacia* spp. trees and shrubs, *Grewia* spp. berries, and grasses such as *Cyperus rotundus* and *Seddera bagshawei* (Kummer 1968, Al-Safadi 1994, Swedell *et al.* 2008, Schreier 2010). They feed opportunistically on insects, small mammals such as Abyssinian Hares *Lepus habessinicus*, agricultural crops and refuse from yards or garbage dumps. Foods that constitute a sizable portion of diet in limited parts of their range include the fruits of *H. thebaica* in the Awash region of C Ethiopia (Swedell *et al.* 2008) and the fruit and young shoots of Prickly Pear *Opuntia* spp. in Ethiopia (Kummer 1968) and Eritrea (Zinner *et al.* 2001a). The latter may be an important source of water, as its water content is over 96% (Zinner *et al.* 2001a). Diet

Papio hamadryas

varies seasonally, with flowers and young leaves constituting a greater portion of the diet during the long rains of Jul–Aug (Schreier 2010). There are no reported sex differences in foraging behaviour or diet.

Social and Reproductive Behaviour Social, with a complex, multi-level social structure. Smallest stable social unit is the one-male unit (OMU), comprising one adult ‘leader’ ♂, 1–9 ♀♀, dependent offspring and sometimes one or more ‘follower’ ♂♂. Cohesion of OMUs maintained by aggressive herding of the leader ♂, who threatens and bites ♀♀ to condition them to stay near him (Swedell & Schreier 2009). Several OMUs comprise a ‘band’ (the social unit analogous to the ‘group’ or ‘troop’ of other papionins) whose members coordinate their movements. Size of bands varies from about 30 to over 400 individuals. Bands are larger in areas of greater food abundance: 150–400 individuals (mean 192, $n = 3$; Schreier & Swedell 2012) at Filoha, Ethiopia, where range includes Doum Palm forests, vs. 30–95 at Erer Gota, Ethiopia (Kummer 1968: 30–90; Sigg & Stolba 1981: 62–95; Abegglen 1984: 52–90). Also within bands are ‘solitary’ ♂♂ who, along with older juvenile ♂♂, move freely within the band and interact mainly with other solitary ♂♂ and juveniles (Pines *et al.* 2011). Two or more bands sharing a common sleeping site comprise a ‘troop’, a temporary aggregation that does not function as a consistent social group (Kummer 1968). Abegglen (1984) and Schreier & Swedell (2007, 2009) observed a fourth level of social organization, the ‘clan’: a subset of a band composed of several OMUs whose ♂ leaders share affiliative relationships and may be related. Unlike other baboons, Hamadryas are more ‘male-bonded’ than ‘female-bonded’. Social relationships among ♂♂ may take the form of grooming (among solitary ♂♂) or ritualized ‘notifications’ (among leader ♂♂ or between leaders and followers) whereby one ♂ approaches, looks at, presents his buttocks to and quickly leaves another ♂. In general, Hamadryas social organization is based largely on competition among ♂♂ over exclusive access to and control of ♀♀, but ♀ choice and relationships among ♀♀ appear to play a role as well (Kummer 1968, Bachmann & Kummer 1980,

Abegglen 1984, Colmenares 1992, Colmenares *et al.* 1994, Swedell 2002a, 2006, Pines & Swedell 2011, Pines *et al.* 2011).

Current evidence suggests composition of Hamadryas bands is quite stable over time compared with other baboons (Sigg *et al.* 1982, Swedell *et al.* 2011). Males at least occasionally disperse among bands, probably to gain reproductive access to ♀♀ (Phillips-Conroy *et al.* 1991, 1992), and ♀♀ are forcibly transferred among OMUs, clans and (less often) bands by leader ♂♂ during takeovers (Kummer 1968, Sigg *et al.* 1982, Abegglen 1984, Swedell 2000, Swedell & Schreier 2009, Swedell *et al.* 2011). Genetic data from Eritrean and Saudi Arabian populations support a pattern of transfer among bands mainly by ♀♀ (Hapke *et al.* 2001, Hammond *et al.* 2006), while microsatellite data from an Ethiopian population suggest high levels of relatedness among all individuals in a band, suggesting relatively little gene flow overall (Woolley-Barker 1999, Swedell & Woolley-Barker 2001).

Copulations occur almost exclusively between ♀♀ and their leader ♂♂. Subadult follower and solitary ♂♂ occasionally gain sexual access to ♀♀, but fully adult non-leader ♂♂ rarely copulate and appear to be waiting for future reproductive opportunities (Kummer 1995, Swedell 2006, Swedell & Saunders 2006, Pines *et al.* 2011). Copulations occur, on average, about once an hour for oestrous ♀♀. Most copulations involve multiple mounts, averaging 7.5 thrusts per mount (1–14, $n = 66$), five minutes between mounts (1–17, $n = 8$), and one ejaculation per four mounts (Swedell 2006). Juveniles remain in natal OMU until 2–3 years of age, by which point ♂♂ spend most of their time in play groups and ♀♀ have been incorporated into another OMU. Infants and juveniles sometimes carried by adult and subadult ♂♂ in addition to their mothers (Kummer 1968, Swedell 2006).

Vocalizations are similar to other *Papio* spp. ‘Grunts’ given during affiliative interactions and at onset of group movement. ‘Alarm barks’ emitted in response to predators. ‘Contact barks’ given when ♀♀ or juveniles lose contact with other group members. ‘Wahoo barks’ given by adult ♂♂ during inter-band encounters, aggressive interactions,

♀ herding, and loss of contact with group. 'Kecks' or 'staccato-coughs' (♀ ♀ only) and 'screams' (all age and sex classes) given during agonistic interactions and in response to aggression or threat. 'Copulation calls' given by some ♀ ♀ during and/or after copulation (Swedell 2006, Swedell & Saunders 2006, J. Saunders pers. comm.).

Reproduction and Population Structure Female ovarian cycles average 39 days in the wild (31–52, $n = 17$; Swedell 2006) and 42 days in captivity (33–49, $n = 9$; D. Zinner pers. comm.). Like other baboons, Hamadryas ♀ ♀ undergo pronounced swelling of the perineal region (medial to the ischial callosities) during the periovulatory period. Sexual swelling generally coincides with behavioural oestrus (Caljan *et al.* 1987, Swedell 2006). Reproductive synchrony occurs in some wild populations (Kummer & Kurt 1963, Kummer 1968) but not others (Swedell 2006), and occurs in captivity (Schwibbe *et al.* 1992, Zinner *et al.* 1994). Gestation averages 26 weeks (24.4–27.3, $n = 52$; Kaumanns *et al.* 1989); singleton births are the norm. Twins not reported. Birth weight ca. 900 g ($n = 1$; D. Zinner pers. comm.). Interval between births of surviving infants ranges 18–28 months (mean 22, $n = 12$) at Erer Gota (Sigg *et al.* 1982), though this interval may be shorter (mean 19 months, 15.5–21.5, $n = 3$) in richer habitats (Swedell 2006). In general, no birth seasonality occurs, though Kummer (1968) observed two birth peaks over one year at Erer Gota (however, the timing of these peaks varied among groups in the same area). In the wild, adolescent ♀ ♀ undergo their first oestrous cycles at about four years of age (mean 4.3, $n = 13$) and first birth at about six years of age (mean 6.1, 5.5–7.0, $n = 8$), at which point they have reached adult size (Sigg *et al.* 1982). Female reproductive maturation occurs more than a year earlier in captivity (Caljan *et al.* 1987, Kaumanns *et al.* 1989). Adolescent ♂ ♂ reach the size of an adult ♀ at about five years of age, at which point the testes have descended but the mane has not yet developed. By ten years of age, ♂ ♂ have attained adult body size and have a full mane (Sigg *et al.* 1982). Although ♀ ♀ give birth to their first surviving infant by six years of age, ♂ ♂ in the wild probably do not reproduce until they are at least nine years of age (Sigg *et al.* 1982).

The sex ratio within bands is 1.1–2.4 adult and subadult ♀ ♀ per adult and subadult ♂. There are 1.1–1.6 adults and subadults per infant or juvenile (Kummer 1968, Kummer *et al.* 1985, Zinner *et al.* 2001b, Swedell 2006). Birth rates in captivity average 0.6 infants/♀/year, with a peak in ♀ fertility at 9–14 years of age and a sharp reduction in fertility (to zero) after 20 years of age (Caljan *et al.* 1987, Chalyan *et al.* 1994). Infant survival to one year of age is 82% at Erer Gota (Sigg *et al.* 1982) and 87% at Filoha (Swedell pers. obs.). These survival rates are higher than those of many other *Papio* spp. populations, suggesting that the OMU social structure may provide better protection for Hamadryas infants compared with other baboons (Sigg *et al.* 1982). Longevity in the wild is not known, but most Hamadryas in captivity live to an age of about 20 years and few survive beyond 30 years (Lapin *et al.* 1979).

Predators, Parasites and Diseases Potential predators include Lions *Panthera leo*, Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, Spotted Hyenas *Crocuta crocuta*, Striped Hyenas *Hyaena hyaena*, Black-backed Jackals *Canis mesomelas*, Nile Crocodiles *Crocodylus niloticus* and Verreaux's Eagles *Aquila verreauxii*. Over a period of 20 months near

Awash, Lions and Spotted Hyenas (and baboon alarm calls) were heard frequently near the sleeping cliffs at night and snake bites were a suspected cause of at least two deaths (Swedell 2006). In the same region a group of 180 Hamadryas, upon encountering three Spotted Hyenas at dawn at their sleeping cliff, ran faster and farther from the cliff than they had ever been observed to do before, suggesting that Spotted Hyenas are indeed a threat (Swedell 2006). At Erer Gota two Leopards, fresh blood and two dead ♀ Hamadryas were observed at dawn at the base of a sleeping cliff, and body parts of one of the Hamadryas were found in a tree, presumably put there by a Leopard (Kummer 1995). In Eritrea, Verreaux's Eagles observed interacting with Hamadryas in a manner highly suggestive of hunting behaviour, and the Hamadryas responded by giving alarm calls, seeking protective cover and, in the case of adult ♂ ♂, threatening the birds (Zinner & Peláez 1999). Hamadryas are also threatened by farmers and their dogs in Eritrea, but adult ♂ ♂ can successfully repel dogs (Zinner *et al.* 2000). Overall, the vertical cliffs used as sleeping sites (ranging from 10 to over 50 m in height) presumably afford Hamadryas adequate protection against nocturnal terrestrial predators, and Hamadryas do not, in general, appear to be at great risk from predation.

Intestinal parasites such as *Giardia* spp., *Entamoeba* spp., *Balantidium coli*, *Hymenolepis nana*, *Schistosoma mansoni*, *Ascaris* sp., *Enterobius* sp., *Trichuris* sp. and hookworm found in wild and commensal populations in Saudi Arabia (Nasher 1988, Ghandour *et al.* 1995), though few, if any, parasites found in Ethiopian populations. Prevalence of parasites appears to vary depending on proximity to human habitation (Ghandour *et al.* 1995). It is not known what other diseases occur in wild populations of Hamadryas.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Not greatly threatened by the nomadic pastoralists with whom they share most of their range, but by the extension of agriculture into dry river valleys via irrigation (D. Zinner pers. comm.). Not hunted for food, but sometimes shot for skins, for their callosities (which are used in traditional medicine in some parts of Eritrea), or as a result of crop-raiding (Wolfheim 1983, Biquand *et al.* 1992, Zinner *et al.* 2001c). In Eritrea young are used as pets (Zinner *et al.* 2001c). Main threat overall is loss of habitat to agriculture and human settlement.

Measurements

Papio ursinus CHACMA BABOON

Fr. Chacma; Ger. Bärenpavian

Papio ursinus (Kerr, 1792). Animal Kingdom, p. 63. Western Cape Province, Cape of Good Hope, South Africa.Chacma Baboon *Papio ursinus* adult male.*Papio ursinus*

Taxonomy Polytypic species. Treated as a subspecies in a monotypic genus by some authorities (e.g. Skinner & Chimimba 2005). Groves (2001, 2005) recognizes three subspecies within *P. ursinus*. Grubb *et al.* (2003) recognize two subspecies. The taxonomy of Groves (2001, 2005) is followed here. For recent molecular findings, see Sithaldeen *et al.* (2009), Keller *et al.* (2010) and Zinner *et al.* (2011). Synonyms: *capensis*, *chacamensis*, *chobiensis*, *comatus*, *griseipes*, *ngamiensis*, *nigripes*, *occidentalis*, *orientalis*, *porcaria*, *ruacana*, *sphingiola*, *transvaalensis*. Chromosome number: $2n = 42$ (Romagno 2001).

Description Large, robust baboon with ventrum and sides of muzzle noticeably paler than dorsum, and tail 'broken' near base. Adult ♀♀ like adult ♂♂, but much smaller; body weight of adult ♀♀ half that of adult ♂♂. Pelage coarse, blackish, dark brown, or dark yellowish-grey (*griseipes*) above, paler below. Male mane (= cape = mantle) relatively thin, often with back-curling hairs on nape of neck. Skin of face, extremities and around the ischial callosities grey or black. Muzzle long, robust, usually more downwardly-flexed than in other baboons. Nostrils do not protrude beyond plane of upper lip or snout. Tail 'broken': proximal one-third of tail held up, distal two-thirds hangs down at sharp angle.

Geographic Variation Little is known of these subspecies, so the following should be treated as preliminary (Hill 1970, Groves 2001).

P. u. ursinus Southern Chacma. Widespread across S Botswana and South Africa. Black or charcoal grey in western and south-western part of range, but lightens to grey and brown towards the east (although still with dark extremities). Face, hands, feet and tail black.

P. u. griseipes Grey-footed Chacma. SW Zambia, Zimbabwe, N Botswana, Mozambique (south of Zambezi R.) and NE South Africa. Pelage fawn. Hands, feet and tail grey rather than blackish.

P. u. ruacana North-western Chacma. SW Angola and Namibia. Small. Feet black. Crown and back blackish, tending to contrast with lighter flanks and limbs.

Similar Species

Papio cynocephalus. Sympatric or parapatric at southern extreme of range. Smaller with yellow-brown dorsum and off-white ventrum.

Distribution Endemic to southern Africa. Zambezi Woodland, South-West Arid, Highveld, and South-West Cape BZs. Widespread throughout the Southern African Subregion south of Zambezi R. to SW Angola and SW Zambia, southwards through much of Namibia, Zimbabwe and South Africa to the Cape.

Habitat *Papio ursinus* is an adaptable, semi-terrestrial generalist that occurs in most habitats, including desert, savanna grassland and woodland, montane grassland and Cape Fynbos. Limited by the availability of water and safe sleeping sites (tall trees or cliff faces). Occurs from sea level to at least 3000 m where there is often snow and temperatures below freezing (Hall 1966).

Abundance Population density varies substantially among habitats: 1.4 baboons/km² in montane grassland (Whiten *et al.* 1987); 3.2/km² in savanna grassland (Anderson 1981); 5.3/km² in desert oases (Hamilton *et al.* 1976); and 24.0/km² in savanna woodland (Hamilton *et al.* 1976).

Adaptations Diurnal and semi-terrestrial. There is substantial variation in body mass among sites, especially for adult ♂♂ (mean adult ♂ weight 23–31 kg, mean adult ♀ weight 14–16 kg, across 11 sites). This variation related to local patterns of rainfall and temperature; body size tends to be larger in wetter, cooler

habitats, presumably reflecting higher habitat quality (Barrett & Henzi 1997). High temperatures can also cause thermal stress. In response, *P. ursinus* is able to tolerate substantial fluctuation in core body temperature – as much as 5.3 °C – and undertake behavioural actions such as ‘sandbathing’ (Brain & Mitchell 1999). Adaptations shared with other *Papio* spp. include cheek pouches. In *P. ursinus* these are used primarily to accumulate food rapidly when faced with competition from other group members, e.g. when food is limited and when foraging in the centre of the group (Hayes *et al.* 1992).

Foraging and Food Omnivorous. Forage during daylight hours and frequently cover substantial distances over the course of the day, e.g. 4.1 km across a home-range of 14.5 km² (Whiten *et al.* 1987). Travelling and feeding occupy about 30% and 38% of daylight hours, respectively, while the remaining hours are spent resting and grooming (Hill 1999a). Habitats are selected in order to both maximize food intake rates and minimize predation risk. Food-rich habitats avoided if high risk, in favour of safer habitats where food is less abundant (Cowlshaw 1997a). As such, foraging preferentially takes place close to refuges, such as large trees and cliffs, to reduce the risk of predation (Cowlshaw 1997b). Vigilant to predators (Cowlshaw 1998). Foraging ♀♀ adopt similar patterns of anti-predator vigilance across populations (Hill & Cowlshaw 2002).

As in all baboons, diet of *P. ursinus* is diverse and highly flexible. Diet typically includes fruits and pods (including seeds), flowers, leaves and subterranean items (e.g. roots and corms). The predominant foods are usually fruits/pods (Hill 1999a). However, the relative importance of the different dietary constituents varies both among sites and seasons. Animals are also included in the diet; most commonly insects (Hamilton *et al.* 1978), but on occasions tortoises, birds, mammals and fish (Hamilton & Busse 1982, Hamilton & Tilson 1985, Hill 1999b).

Although the diet of *P. ursinus* is broad, it is also selective. Individuals preferentially select foods high in protein and lipid, and avoid foods high in fibre, phenolics and alkaloids (Whiten *et al.* 1991). A comparison between low-altitude and high-altitude montane groups found that individuals in both groups obtained the same nutrient yields despite a high degree of seasonality and different foraging substrates (Byrne *et al.* 1993). During periods of food shortage, adults switch to less-preferred foods, and juveniles learn of these by observation of the adults (Hamilton 1986). Prefer to drink daily, but can go without drinking for 11 days (Brain 1991) or longer (Brain & Mitchell 1999).

Social and Reproductive Behaviour Social. Live in stable social groups, or ‘troops’, of about 22–79 individuals (Henzi *et al.* 1999). The adult sex ratio within these groups is variable, although always female-biased; e.g. 0.15–0.81 ♂♂ per ♀♀ (Henzi *et al.* 1999). Within groups ♀♀ tend to be philopatric whereas ♂♂ disperse to other groups at adulthood, although there are exceptions in both cases (Hamilton & Bulger 1990, Henzi *et al.* 2000b).

Following immigration into new groups and/or the acquisition of high social rank (see below), ♂♂ often attempt to kill infants in the group. This behaviour benefits the ♂ since it leads to the resumption of oestrous cycling by previously lactating ♀♀, thereby

maximizing his own opportunities to father offspring (Palombit *et al.* 2000). In response, ♀♀ often mate with many ♂♂ to confuse paternity (thus reducing the likelihood that any one ♂ will subsequently attempt infanticide), a strategy that may be assisted through both sexual swellings and copulation calls (O’Connell & Cowlshaw 1994). In addition, following conception, ♀♀ often develop and maintain ‘friendships’ with particular ♂♂ with whom they have mated. These ♂ friends help protect the infants, for example by carrying them out of danger (Anderson 1992, Palombit *et al.* 1997, Weingrill 2000).

Competition for limited, but monopolizable, resources within groups leads to the development of dominance hierarchies in which high-ranking individuals benefit most. Amongst ♂♂, dominant individuals monopolize ♀♀ when they are most likely to conceive (through mate-guarding ‘consortships’), and thus achieve the highest mating success (Bulger 1993, Weingrill *et al.* 2000). Amongst ♀♀, dominant individuals may obtain more food, potentially leading to higher birth rates (Bulger & Hamilton 1987). They also occupy positions of greater safety from predators, potentially leading to higher survival rates (Ron *et al.* 1996). In addition, dominant ♀♀ can experience higher infant survival rates (Bulger & Hamilton 1987), possibly as a result of their ability to monopolize access to ♂ friends (Palombit *et al.* 2001). The strength of such rank effects are variable among sites depending upon the local availability of limited resources.

Individuals may elicit tolerance and support from others during competition through grooming them. Grooming can be viewed as a ‘commodity’ that is valuable in itself (it is associated with the release of endorphins into the bloodstream and plays a role in ectoparasite removal), and group members can exchange this commodity for either reciprocal grooming or for tolerance at, and thus access to, limited resources (Barrett *et al.* 1999, 2002). Active coalitionary support, in contrast, appears to be rare in *P. ursinus*, regardless of grooming relationships (Silk *et al.* 1999). Grooming is often, but not always, directed towards kin and high-ranking individuals (Seyfarth 1976, Barrett *et al.* 1999, Silk *et al.* 1999), and typically reflects social bonds between individuals. Social bonds tend to be strongest between ♀♀, although strong bonds also occur between ♂♂ and ♀♀ (including ‘friendships’; see above) (Henzi *et al.* 2000a). Females spend about 12% of their day grooming (Hill 1999a), during which time they strive to groom all other ♀♀ in the group. However, when there is insufficient time to groom everyone, ♀♀ focus on their key social partners (Henzi *et al.* 1997b, Silk *et al.* 1999). Bonds between social partners are also mediated through vocalizations. ‘Soft grunts’ are used by dominant individuals to reassure subordinate animals and to reconcile combatants after fights (Cheney *et al.* 1995, Silk *et al.* 1996).

Even when not socializing, group members tend to stay close to one another. Adults are usually within 5 m of at least one other adult, and rarely more than 25 m away. This probably reflects a response to predation risk (these distances are greater where predators are absent), although spatial proximity within groups appears to be most strongly influenced by ♂ defence of infants (Cowlshaw 1999). When social partners lose sight of one another, loud ‘contact’ barks are used to maintain contact (Cheney *et al.* 1996). Males, similarly, use loud two-syllable ‘wahoo’ calls when they become separated from the group. However, ♂ ‘wahoos’ are primarily used as alarm

calls or as vocal signals of stamina and competitive ability (Fischer *et al.* 2002, Kitchen *et al.* 2003).

Not territorial. Encounters between groups can be infrequent, e.g. once every five days (Cowlshaw 1995). On occasion, groups attempt to monopolize valuable ecological resources (Hamilton *et al.* 1976), but more commonly resource-defence is absent and groups encounters are relatively peaceful (Cowlshaw 1995). Males primarily use inter-group encounters to assess potential mating opportunities in neighbouring groups. The ensuing mate-guarding behaviour by resident ♂♂ leads to aggressive chasing, or 'herding', of ♀♀ away from the approaching group (Cheney & Seyfarth 1977, Henzi *et al.* 1998, Kitchen *et al.* 2004).

Reproduction and Population Structure Gestation averages 187 days (173–193, $n = 14$). Newborn weighs 600–800 g and has black pelage and pink skin (Gilbert & Gillman 1951). Adult ♀♀ give birth to a single infant. Inter-birth interval is 20–38 months (Hill *et al.* 2000). Although births occur throughout the year, birth peaks reported both in the Drakensburg Mts, South Africa, and Okavango Delta, Botswana. These birth peaks most likely reflect improved conception rates following periods of high food abundance (Lycett *et al.* 1999, Cheney *et al.* 2004). At De Hoop, South Africa, infants begin weaning at about 4–5 months, although suckling can continue until 12–13 months (Barrett & Henzi 2000). High maternal dominance rank can increase growth rates in infant and juvenile ♀♀, but the same effect is not seen in ♂ offspring (Johnson 2003).

Population structure is primarily determined by group size (and thus the number of discrete units that comprise the population). Minimum group size is determined by predation risk and the minimal requirements for safety, whereas maximum group size is determined by food abundance and the time available to maintain grooming relationships with other group members. As groups grow in size there is no corresponding increase in time available for grooming additional group members. In fact, the time available for grooming can even decline, due to the demands of foraging time, since feeding competition can intensify as groups grow. Hence ♀♀ find it increasingly difficult to sustain all of their grooming relationships and begin to focus only on their key social partners. As a result, the social coherence of the group is weakened and large groups eventually fission (Henzi *et al.* 1997a, b).

Predators, Parasites and Diseases Leopards *Panthera pardus* are the most important predator of *P. ursinus*. Other predators include Lions *Panthera leo*, Brown Hyenas *Hyaena brunnea*, Spotted Hyena *Crocuta crocuta*, Nile Crocodiles *Crocodylus niloticus* and Southern African Rock Pythons *Python natalensis* (Cowlshaw 1994, Cheney *et al.* 2004). Verreaux's Eagles *Aquila verreauxii* will attack *P. ursinus* to defend their nests, but do not appear to prey on them (Gargett 1990). Adult *P. ursinus* ♂♂, who are least vulnerable to predation (due to their size and ferocity), will often take an active role in group defence against predators – occupying the most dangerous position in the group during travel (Rhine & Tilson 1987) and often retaliating against predators following attack (Cowlshaw 1994).

Papio ursinus is vulnerable to a variety of parasites and pathogens. Patterns of infection with gastrointestinal parasites, primarily

protozoans and helminths, vary both with altitude and habitat (Appleton & Henzi 1993, Appleton & Brain 1995). Ectoparasites are relatively rare, although one case of heavy tick infestation has been recorded (Brain & Bohrmann 1992). In this case, the ticks (genus *Rhipicephalus*) appeared to be directly or indirectly responsible for over half of all infant deaths. An epidemic disease (possibly bacterial yersiniosis, or an unknown haemorrhagic/enteric viral infection) also recorded (Barrett & Henzi 1998). The disease killed 85% of members in one group, and 32% of members in a second group, before heavy rains appeared to terminate the epidemic. Males appeared to be particularly vulnerable to this infection (and facilitated its transmission between the groups).

Patterns of mortality in *P. ursinus* are complex. In the Okavango Delta mortality is highest among infants, and can largely be attributed to infanticide. In contrast, the lower mortality rates seen among juveniles and young adults are driven primarily by predation. Mortality from both sources shows a seasonal peak that occurs when groups are more dispersed and travel along more predictable routes (Cheney *et al.* 2004). The relationship between social rank and mortality is variable across populations. Predation can affect all ♀♀ equally (Cheney *et al.* 2004), or low-ranking ♀♀ in particular (Ron *et al.* 1996). Similarly, infanticide may be most severe among high-ranking and low-ranking ♀♀ (Cheney *et al.* 2004), or infant mortality may be highest among low-ranking ♀♀ (Bulger & Hamilton 1987). Infant mortality can also increase in larger groups (Bulger & Hamilton 1987). As well as infanticide and predation, *P. ursinus* also suffers mortality from disease (see above) and wounds sustained during fights (Brain 1992). In addition, a food and water shortage in a Namib Desert oasis led to widespread mortality from starvation. In this case, adult ♀♀, juveniles and infants were more susceptible to starvation than adult ♂♂ (Hamilton 1985).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The widespread geographic range of *P. ursinus*, together with its ability to survive over a wide range of habitats and to live commensally with people, should ensure its long-term survival. However, *P. ursinus* can experience local persecution as a result of crop-raiding and livestock predation. In addition, *P. ursinus* is subject to trophy hunting and live-trapping for biomedical research, although analyses of the known legal trade in the early 1990s suggested that its impact on wild populations is minimal (Butynski 1996).

Measurements

Papio ursinus ursinus

HB (♂): 720 (670–755) mm, $n = 5$
 HB (♀): 613 (550–681) mm, $n = 15$
 T (♂): 566 (530–605) mm, $n = 5$
 T (♀): 471 (415–515) mm, $n = 15$
 HF (♂): 209 (197–220) mm, $n = 5$
 HF (♀): 176 (170–184) mm, $n = 15$
 E (♂): 59 (55–63) mm, $n = 5$
 E (♀): 48 (45–54) mm, $n = 15$
 WT (♂): 28.3 (26.6–30.0) kg, $n = 5$
 WT (♀): 15.1 (11.1–18.3) kg, $n = 15$
 Tsaobis, Namibia (G. Cowlshaw pers. obs.).

Papio ursinus (probably *ursinus* and *griseipes* combined)

TL (♂♂): 1450 (1320–1570) mm, n = 9

TL (♀♀): 1190 (1080–1160) mm, n = 5

T (♂♂): 725 (598–840) mm, n = 9

T (♀♀): 585 (556–610) mm, n = 5

HF (♂♂): 223 (217–236) mm, n = 9

HF (♀♀): 184 (176–194) mm, n = 5

E (♂♂): 58 (54–65) mm, n = 8

E (♀♀): 50 (44–52) mm, n = 5

WT (♂♂): 31.8 (27.2–43.5) kg, n = 9

WT (♀♀): 15.4 (14.6–17.2) kg, n = 5

Botswana (Smithers 1971). See Skinner & Chimimba (2005) for more WT data.

Papio cynocephalus YELLOW BABOON

Fr. Babouin cynocéphale; Ger. Gelber Pavian

Papio cynocephalus (Linnaeus, 1766). Systema Naturae, 12th edn, 1: 38. Inland from Mombasa, Kenya.

Yellow Baboon *Papio cynocephalus* adult male.

Taxonomy Polytypic species. The Yellow Baboon presently retains its own species designation, *Papio cynocephalus*, with three subspecies – Central *cynocephalus*, Ibean *ibeanus* and Kinda *kindae* (Grubb *et al.* 2003). Some researchers suggest separating baboons into two species, *Papio hamadryas* for the Hamadryas or Sacred Baboon, and *P. cynocephalus* for the Savanna Baboons (Groves 2001). Under this construct, the Yellow Baboon would be a subspecies of Savanna Baboon. Alternatively, Jolly (1993) suggests lumping all baboons under one species, *P. hamadryas*, which would result in at least five subspecies. Synonyms: *antiquorum*, *babouin*, *basiliscus*, *flavidus*, *ibeanus*, *jubilaeus*, *kindae*, *langheldi*, *ochraceus*, *pruinusos*, *?rhodesiae*, *ruhei*, *streptus*, *sublutea*, *thoth*, *?variegata*. Chromosome number 2n = 42 (Romagno 2001).

Description Slender baboon with dorsum light brown to yellowish-brown to pale reddish-brown, contrasting with whitish ventrum. Sexes alike in colour of pelage. Adult ♂♂ weigh about twice as much as adult ♀♀. Adult ♂: skull not flattened behind the supraorbital ridge. Head appears pointed when viewed from the front, sometimes with a crest. Forehead not parallel with the angle of the muzzle (Alberts & Altmann 2001). Muzzle predominantly bare, greyish to black, often with varying amounts of sparse and patchy white pelage. Nostrils set back from the lips. Mane (= cape = mantle) absent or greatly reduced relative to other *Papio* spp. Dorsum, tail and outer limbs range from light brown to yellowish-brown to pale reddish-brown. Ventrums,

inner limbs and cheeks lighter, almost white, and pelage more sparse. Pelage long, especially on sides. Skin grey to black on primarily bare hands and paracallosities, but paracallosities of Kinda can be rosy-pink both on adult ♂♂ and adult ♀♀ (Y. de Jong & T. Butynski pers. comm.). Skin on rest of body, in densely pelaged areas, and in armpits and crotch, ranges from grey to pinkish or almost white, often in a splotchy pattern. Tail tends to be tapered with a sharp bend or hook between a proximal ascending portion and descending, distal one; tail shape is highly individually variable, however, and is useful in individual recognition. Angle of tail becomes more vertical during ontogeny (Hausfater 1977). Scrotum grey. Paracallosal skin fused.

Adult ♀: paracallosal skin split vertically. Nipples pinkish and button-like until ♀ has nursed an infant. Nipples of multiparous ♀♀ are dark, and the two nipples tend to differ considerably in length and often in colouration.

Immatures: infants of Central and Ibean, but not Kinda, have a black natal coat that is characteristic of all other baboon species. According to Groves (2001), Kinda newborns are unique among baboons in that the coat is reddish, not black. Kinda newborns at Mahale N. P., Tanzania, at the north-east corner of the range for this subspecies, have whitish pelage, pink muzzle and ears, but older infants have a reddish-brown coat. Infants in transition between these two pelage colours are pale yellowish-orange (Y. de Jong & T. Butynski pers. comm.). Between 6 and 12 months of age pelage gradually changes to the species-typical coat. Muzzle, ears, ischial callosities, paracallosities and scrotum are pink, and the ischial callosities are split in both sexes. Between 7 and 15 months of age, skin colour, except for scrotum, changes to the grey of adults and the paracallosities of ♂♂ fuse (Altmann *et al.* 1981). Body mass growth is approximately 5 g/day for both sexes through 3–4 years of age, after which ♂♂ experience an adolescent growth spurt (Altmann & Alberts 2005).

Geographic Variation

P. c. cynocephalus Central or Typical Yellow Baboon. South coast of Kenya southwards through most of Tanzania, Malawi, east of the Luangwa R. in Zambia and into N Mozambique. Straight, soft, silky pelage. Mane absent (Jolly 1993, Groves 2001, Zinner *et al.* 2009b). New-born with black pelage.

P. c. ibeanus Ibean Yellow Baboon. Central and S Somalia, SE Ethiopia, and E and SC Kenya. Hill (1970) indicates that *P. c. ibeanus* meets *P. c. cynocephalus* at the Galana-Sabaki R. Wavier and coarser pelage.

Trace of a mane. More like the Olive Baboon *Papio anubis* and Guinea Baboon *Papio papio* (Jolly 1993, Groves 2001, Zinner *et al.* 2009b). Newborn with black pelage.

P. c. kindae Kinda Yellow Baboon. From Cunene R. in S Angola north to the Congo R., then eastward across southern DR Congo to SW L. Tanganyika and C and N Zambia (south to Zambezi R.) (Jolly 1993, Groves 2001, Zinner *et al.* 2009b). Probably also up west side of L. Tanganyika (Mahale Mts) to Malagarasi R. (T. Butynski & Y. de Jong pers. comm.). Straight, soft, silky pelage. Mane absent. Bare skin around eyes pink. Body size is unusually small (Hill 1970, Jolly 1993, Groves 2001). Adults of both sexes can have rosy-pink callosities. Newborn with whitish pelage at Mahale Mts (Y. de Jong & T. Butynski pers. comm.).

Numerous photographs of the three subspecies of *P. cynocephalus* at many sites in Kenya and Tanzania are available at: www.wildsolutions.nl

Similar Species

Papio anubis. Sympatric or parapatric in W Somalia, SE Ethiopia, C and S Kenya, N Tanzania and south-east DR Congo. More robust. Grizzled, olive-brown dorsum. Mane thick over neck and shoulders. Top of head appears flat when viewed from the front. Tail appears 'broken'. Nose not 'upturned'.

Papio ursinus. Sympatric or parapatric in S Angola, SW Zambia and NW Mozambique. More robust. Grey, dark brown, to blackish dorsum.

Distribution Endemic to tropical Africa, mostly south of the equator. Southern Rainforest–Savanna Mosaic, Somalia–Maasai Bushland, Zambezian Woodland and Coastal Forest Mosaic BZs. Widely distributed in south-central and East Africa. Ranges from Angola through south DR Congo to E Kenya, SE Ethiopia and C Somalia through much of Tanzania, Malawi, most of Zambia to the Zambezi R. Valley and into N Mozambique. Whereas Yellow Baboons and Olive Baboons both inhabit the central latitudes of Africa, and their distributions overlap in a number of hybrid zones (Maples & McKern 1967, Jolly 1993, Alberts & Altmann 2001, Zinner *et al.* 2009b), Yellow Baboons typically inhabit low-altitude woodlands and savannas. Their distribution may be correlated more with vegetation than geography (Jolly 1993).

Two areas of Yellow–Olive hybridization are known. One runs through Amboseli N. P., SC Kenya, and the surrounding area, extending north and south of the Amboseli Basin. Genetic models and previous surveys suggest that the hybrid zone is relatively narrow and historically stable through this region, with Olive Baboons to the west of Amboseli and Yellow Baboons to the east (Charpentier *et al.* 2012; see also Maples & McKern 1967, Altmann & Altmann 1970, Samuels & Altmann 1986, Alberts & Altmann 2001).

A second, broad, clinal hybrid zone occurs between the Laikipia Plateau in C Kenya and the Lower Tana R./Indian Ocean. This cline appears to start just to the north-east, east and south-east of Mt Kenya and covers an upper altitudinal range of from roughly 1000 m asl at Mwea National Reserve (to the south of Mt Kenya) to roughly 600 m asl at Meru N. P. (to the north of Mt Kenya). The zone then continues south-eastwards towards the lower Tana R. to at least 30 m asl, perhaps to the Indian Ocean. Baboons in this >200 km wide region are intermediate and cannot be readily allocated to either Olive or Yellow Baboons. As one moves south-eastwards towards the

Papio cynocephalus

Kenya coast, however, the baboons become increasingly Yellow-like in their phenotypes (T. Butynski & Y. de Jong pers. comm.).

A potential Yellow Baboon–Chacma Baboon *Papio ursinus* hybrid zone exists in the Zambezi R. Valley. Some confusion exists as to whether Central or Kinda are in areas of Zambia. In the Zambezi R. Valley the Yellow Baboon range is thought to be only north of the Zambezi R., whereas the predominantly southern range of the Grey-footed Chacma Baboon *P. u. griseipes* extends north of the Zambezi R. as well, perhaps creating a hybrid zone there.

Habitat Primarily in open and woodland savanna. Associated with miombo (*Brachystegia* spp.) woodland over much of the range. In East Africa, Fever Trees *Acacia xanthophloea* and Tortilis Trees *Acacia tortilis* are used as sources of food and shelter. Yellow Baboons use woodland groves for sleeping at night, as well as for sources of shade during hot days. A water source within a day's walk appears to be necessary (Altmann & Altmann 1970). Distribution between wet and dry season lengths varies across the range. Most parts of the range experience one long wet season and one dry season. However, the Amboseli area usually experiences two wet and two dry seasons: one long and one short (Altmann *et al.* 2002). Mean annual rainfall over the range of the Yellow Baboon varies from ca. 320 mm (e.g. Garissa on the Tana R., EC Kenya) to ca. 1200 mm (e.g. Mombasa, SE Kenya; T. Butynski pers. comm.). Mean annual rainfall at two of the main Yellow Baboon study sites is as follows: 348 mm in Amboseli N. P. (over 25 years; Altmann *et al.* 2002); 842 mm in Mikumi N. P., SC Tanzania (over 20 years; Norton *et al.* 1987). Yellow baboons range in altitude from sea level to at least 1800 m (Mahale Mts, WC Tanzania; Kano 1971, T. Butynski & Y. de Jong pers. comm.) and to at least 1900 m in the Udzungwa Mts, SC Tanzania (Rovero *et al.* 2009). Altitude is ca. 1100 m at Amboseli and 450–740 m at Mikumi.

Abundance Abundant in parts of their range, with densities of 10–60 ind/ km² (Wolfheim 1983). Population density in the

Amboseli Basin decreased from 73 to 4 baboons/km² during the 1960s (Altmann *et al.* 1985). Density in the mid-1980s was 1.2 baboons/km² (Samuels & Altmann 1991). Almost two decades later, the density remains similar, although the distribution of groups shifted within the Basin, primarily to the south and west.

Adaptations Diurnal and semi-terrestrial. Behaviour and movement are adjusted to the thermal environment and microhabitats encountered (Stelzner 1988). Sitting position is adjusted relative to wind (Stelzner & Hausfater 1986). Behaviours include huddling for warmth, particularly by mothers with infants, and by young juveniles with each other, and resting on tree limbs or under trees for shade during the day. In Ruaha N. P., Tanzania, sun avoidance behaviour is regulated by temperature in the dry season and by humidity in the wet season (Pochron 2000). Other adaptations are those characteristic of the genus, with Yellow Baboons perhaps exhibiting *Papio*'s ecological and social adaptability to the greatest extent among the species.

Foraging and Food Omnivorous. Yellow Baboons forage throughout the day. Movement patterns are influenced by season and the availability of food. Completely wild-foraging groups spend ca. 70–75% of their time foraging (feeding + walking), and travel as much as 8–10 km/day, whereas groups that exploit garbage dumps reduce their foraging time to ca. 35–40% and travel 2–4 km/day (Muruthi *et al.* 1991, Altmann *et al.* 1993). Less time is spent feeding during the wet seasons and in years of high rainfall (Bronikowski & Altmann 1996, Alberts *et al.* 2005). These differences in foraging time are more pronounced for wild-foraging groups than for those that exploit garbage dumps. Yellow Baboons appear to be obligate drinkers: they drink almost daily and their home-ranges tend to include a water source within a half-day's journey (Altmann 1998). Yellow Baboons are not territorial, but have overlapping home-ranges of approximately 24 km² (for a group of about 40 animals).

Yellow Baboons have a highly diverse diet that incorporates a wide variety of plant and animal species. At the same time, they are extremely selective, as is evident in their differential use of plant parts of high nutritive value and their avoidance of toxic ones (Altmann 1998). Yellow Baboons incorporate new foods as they become available, whether through season or habitat change (Alberts *et al.* 2005). In Mikumi N. P., 85 plant foods are eaten (Norton *et al.* 1987) compared with 277 foods (plant & animal) for Amboseli (Altmann 1998). Foods available or utilized differ seasonally and, to a lesser extent, from year to year. Consequently, the duration, timing of study, and criteria for 'splitting' or 'lumping' food types influences the number of foods reported in the diet.

The numerous foods that Yellow Baboons consume include all or parts of various species of trees (particularly *Acacia* spp.), grasses, sedges and bushes, as well as animal matter, including insects (e.g. grasshoppers, beetles and larvae), and meat of several species of mammals. In Amboseli these include Cape Hare *Lepus capensis*, Thomson's Gazelle *Eudorcas thomsonii* and Grant's Gazelle *Nanger (granti) granti* and, more rarely, Impala *Aepyceros melampus*, Vervet Monkey *Chlorocebus pygerythrus*, Northern Lesser Galago *Galago senegalensis*, birds, reptiles and bird and reptile eggs. The inclusion of meat in the diet is largely opportunistic. Vertebrate prey are caught by juveniles and adults of both sexes, but consumption of larger prey is primarily restricted to adult baboons, particularly adult ♂♂.

Human refuse piles near settlements and tourist lodges are also exploited (Muruthi *et al.* 1991). Availability of these food sources results in less energy expenditure, more rapid juvenile growth, earlier physical maturation, more frequent reproduction, higher infant survival and adults that are larger and obese (Altmann *et al.* 1993, Altmann & Alberts 2005).

Social and Reproductive Behaviour Social. Yellow Baboons typically live in multimale, multifemale groups ranging in size from 18 to 100 individuals. The number of adult ♂♂ in a group is correlated with the number of adult ♀♀. Males tend to leave groups with few reproductive opportunities and join ones with many (Alberts & Altmann 1995a). Single-male groups also exist in Amboseli. These relatively ephemeral single-male groups occasionally join a multimale group; more commonly, additional ♂♂ join and thereby create a multimale group. Groups in Amboseli sometimes fission at approximately 60–70 individuals for wild-foraging groups and at larger sizes for groups with high food availability, but there is no simple relationship between group size and fission.

Females remain in their natal group for life; exceptions occur when a female's natal group fissions or fuses with another group. Females form a linear dominance hierarchy that tends to be stable among matrilineal and across generations. Maternal rank acquisition determines a young female's rank, even in the absence of her mother. Specifically, older juvenile ♀♀ usually attain a rank immediately below their mother, but above their older sisters. The daughters of the family matriarch are therefore ranked in inverse age-order. All long-lived ♀♀ that have adult daughters and that are not members of the top-ranking family lose rank to their adult daughters (Combes & Altmann 2001). Daughters of high-ranking ♀♀ reach maturity earlier and conceive their first offspring earlier than those of low-ranking ♀♀ (Altmann *et al.* 1988), particularly when groups are large.

Males are the dispersing sex. Natal dispersal occurs at ca. 8.5 years of age (6.8–13.4), although recent evidence suggests that Olive ♂♂ and hybrid Yellow–Olive ♂♂ in the Amboseli area disperse earlier than Yellow ♂♂ (Alberts & Altmann 1995b, 2001). Secondary dispersal is common. Group tenure averages 24 months in non-natal groups. Male maturation is also affected by mother's dominance rank. Sons of high-ranking ♀♀ physically mature earlier, as indicated by testicular enlargement, and attain adult dominance rank earlier than sons of low-ranking ♀♀ (Alberts & Altmann 1995b). Males form a linear hierarchy, but one that is much less stable than that of ♀♀ (Hausfater 1975). Fighting ability and age influence a male's rank. Male dominance rank predicts mating success. Mating success and offspring production are coincident with the time a ♂ is high-ranking in a non-natal group (Alberts *et al.* 2006).

Females have prominent oestrous swellings that are closely related to reproductive condition. When the ♀ is in oestrus, ♂♂ and ♀♀ form close associations, called 'consortships'. This form of mate-guarding is characterized by a ♂ following and mating exclusively with the oestrous ♀ for periods ranging from hours to several days (Rasmussen 1985). Fertilization is most likely to occur within the five days prior to the deturgescence of the sexual skin (Hendrickx & Kraemer 1969). Oestrogen levels are highest during this period, and consortships are most likely then, particularly with the highest-ranking ♂ (Gesquiere *et al.* 2007). Males, especially middle- and

lower-ranking ones, sometimes form coalitions in order to take over a consortship. These ♂♂ are usually older and past their prime, and have been resident in the group for a relatively long time (Noë 1992). Approximately half of the ♂♂ in Amboseli commence reproducing (i.e. begin consorting) in their natal group. Maternal siblings are usually strongly avoided as consort partners. Although consortships between paternal siblings do occur, these consort pairs exhibit lower levels of cohesion and sexual behaviour than do non-kin pairs (Alberts 1999).

Aggressive behaviours include lunging, staring, displaying the canines, and/or raising the eyebrows to show the white skin of the eyelids. Submissive gestures include cowering (of the whole body or part of the body), baring teeth while pulling back lips (in a grimace), screaming and raising the tail. Noisy and obvious fights between animals sometimes occur. More common, particularly among ♀♀, are the more subtle threats, displacements and responses to eyebrow-raising. Infant deaths from infanticide or kidnapping occur rarely (J. Altmann & S. Alberts pers. obs.).

Affiliative behaviours include reaching out a hand, huddling, grooming and remaining in close proximity. Grooming is common, and easily identifiable by the groomer's active brushing and searching of another's fur (sometimes removing dead skin flakes and ectoparasites) and by the relaxed posture of the individual being groomed. Adult and juvenile ♀♀ are the most common age/sex classes to engage in grooming. They groom each other, their infants and adult ♂♂. New mothers are particular targets of grooming behaviour by other ♀♀ in the group. Adult ♂♂ groom ♀♀, primarily during consortship. Female infants become more reciprocal groomers with their mothers than ♂ offspring and at a younger age. Females tend to disproportionately groom and stay near certain individuals within their social group; these 'friends' are most commonly, but not exclusively, their close maternal and paternal kin (Smith *et al.* 2003, Silk *et al.* 2006).

Infant Yellow Baboons ride ventrally on their mothers for the first few months and then gradually transition to predominantly ride dorsally or 'jockey' style by eight months. Contact is maintained primarily by the mother during the first month or two; as the infants age, however, they become more responsible for maintaining proximity to or finding their mothers (Altmann 1980). Infants and juveniles of both sexes spend considerable time playing with each other. By four years of age, play behaviour of the two sexes differentiates, and play groups tend to become single-sex; ♂♂ spend more time playing, and the play of ♂♂ becomes more rough (Pereira & Altmann 1985).

The behavioural repertoire includes at least ten vocalizations, including contact calls, 'grunts' and 'screams'. Grunts are given during foraging and may facilitate affiliative interactions and close spatial proximity. 'Lip-smacking' (a rapid movement of the tongue between the lips) is also an affiliative vocalization. Screams occur during agonistic interactions. Alarm calls and contact 'barks' also occur. Both sexes produce almost all of the vocalizations. Males produce a loud bark, a 'wahoo', more frequently than ♀♀ and in more varied contexts, including alarms and aggressive displays. Females produce individually identifiable copulation calls that vary in form over the menstrual cycle (Semple 2001). Specifically, calls are longer and contain more units during matings with higher-ranking ♂♂ (Semple *et al.* 2002). Infants produce a 'coo' distress call that is

Yellow Baboon *Papio cynocephalus* adult male.

virtually never given by adults. This rather mournful-seeming call is usually produced while the infant is crouching, and the call sometimes alternates with higher intensity screeches and 'ikks' (aka 'geckers').

Reproduction and Population Structure Polygynandrous. A single infant is born after a gestation of ca. 180 days. Twinning is rare (twice in 700 births in Amboseli; in one case the twins were stillborn, in the other one infant died after ten days and the other survived). Infants weigh ca. 850 g at birth (Ross 1991). Yellow Baboons are not seasonal breeders; both conceptions and births occur at appreciable frequencies year-round. However, under harsh conditions, such as drought, reproduction is more likely to fail at each stage – cycling, conception and foetal survival (Beehner *et al.* 2006). Weaning is completed between 12 and 18 months of age. Nutritional intake of ♀♀ during their weaning period predicts their lifetime reproductive success (Altmann 1991).

Males reach full adulthood at ca. 7–8 years of age. Although testicular enlargement, which is indicative of sperm production, occurs at a median age of 5.7 years (5.0–6.2, $n = 32$), the transition from subadulthood to adulthood occurs when ♂♂ enter the adult ♂ dominance hierarchy. At this time ♂♂ are large and strong enough to win fights with other adults. Median age of attainment of first adult dominance rank is 7.4 years (6.7–8.4). Adult ♂♂ then quickly rise in rank when young, but usually maintain high-ranking tenure for less than a year; eight months on average in Amboseli (Alberts *et al.* 2003; see Hamilton & Bulger 1990 and Packer *et al.* 2000 for similar patterns in Chacma and Olive Baboons, respectively). Attainment of adult dominance rank always precedes first consortship. Median age of first consortship is 7.9 years (7.4–8.5). High-ranking ♂♂ essentially monopolize consortships and, therefore, infant paternity during their tenure. As a result, age cohorts sometimes represent paternal sibships, although considerable variation exists in the extent to which this is true.

Females mature, as indicated by first sexual swelling, at ca. 4.5 years (Rhine *et al.* 2000, including a table comparing ♂ life-history milestones for Mikumi and Amboseli). Median cycle length is 39 days, including adolescent and immediate postpartum cycles that

are often longer than others (Gesquiere *et al.* 2007). Daughters of high-ranking mothers reach menarche and first conception earlier than those of low-ranking ♀♀. Following a period of adolescent sub-fertility, a ♀ first gives birth at ca. 6.5 years (Rhine *et al.* 2000). Pregnancy is marked by pink colouration around the edge of the callosities, on the paracallosal skin and sometimes by pink under the eyes in late pregnancy. Pregnancy is usually characterized by an absence of sexual swelling. Inter-birth intervals average two years in wild-feeding groups, and as little as one year during times of food abundance or in garbage-feeding groups. If the infant dies, ♀♀ resume cycling within one month of the death and conceive within one or two cycles (Altmann *et al.* 1988). If the infant survives, the mother experiences a postpartum amenorrhoea of 10–12 months and experiences three or four cycles before conceiving.

Sex ratio at birth is 1 : 1. Adult sex ratio is female-biased. In Amboseli wild-feeding groups have, on average, 1.6 adult ♀♀ per adult ♂, and groups with some garbage feeding have 2.5 adult ♀♀ per adult ♂; approximately half the population consists of sexually mature animals (0.61–1.35; Samuels & Altmann 1991). Infant mortality is approximately 30% within the first two years of life (Alberts & Altmann 2003). This is in addition to about 14% of pregnancies resulting in miscarriage (Altmann *et al.* 1988, Beehner *et al.* 2006). After the first two years of life, mortality rates are low until late adulthood. Median adult life-span is approximately 12 years in the wild. Maximum known life-span of wild Yellow Baboons is 27 years (Alberts & Altmann 2003). In captivity they can live into their early 30s (Bronikowski *et al.* 2002).

Predators, Parasites and Diseases Known predators of Yellow Baboons include Leopards *Panthera pardus*, Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta* and Nile Crocodiles *Crocodylus niloticus*. Robust Chimpanzees *Pan troglodytes* communally kill and eat immature Yellow Baboons in Mahale Mountains N. P. (Wrangham & Van Zinnicq Bergmann-Riss 1990, Nishie 2004). Potential predators include Cheetahs *Acinonyx jubatus*, jackals, raptors and pythons. Black-backed Jackal *Canis mesomelas* and raptor predation attempts have been observed on juvenile Yellow Baboons only (Altmann & Altmann 1970). Leopards appear to be particularly adept predators of baboons due to their nocturnal hunting and ability to climb trees, but Spotted Hyenas or Lions may be the predominant predator in some locales or years, depending on abundance. Humans occasionally kill Yellow Baboons as pests.

Starting >30 years ago (Kalter 1973), parasite screening of blood or faeces has occasionally been conducted for laboratory and field populations of various baboon species (see the recent, ongoing public database at www.mammalparasite.org). None the less, prevalence, incidence, temporal changes within populations and extent of pathogenesis remain largely unknown for virtually all parasites and baboon populations. This gap may soon be redressed as a recent surge of interest in primate disease has already resulted in one book (Nunn & Altizer 2006). The malaria-like parasite *Hepatozoon simiae* occurs in Yellow Baboons (Phillips-Conroy *et al.* 1988, Tung *et al.* 2009). In Amboseli screening for gastrointestinal parasites has been conducted several times and most recently reported in Hahn *et al.* (2003). Coxsackie virus type B2, a paralytic disease, has been found in wild populations, including Amboseli (Kalter 1973). SIV has been reported in two Yellow Baboons in

Mikumi N. P. (Kodama *et al.* 1989). In a serum viral screening (M. Isahakia pers. comm.) no SIV was found in approximately 80 animals in the Amboseli area.

Specific causes of death may differ by location and over time even in the same population as predator presence, disease presence and environmental factors change. More than half of the deaths in the Amboseli population are probably due to predation.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Although the Yellow Baboon is not currently threatened, the effects of human encroachment on numbers remain unclear. The baboons' tendency for crop-raiding and foraging in areas of human habitation has caused them to be treated as vermin in many areas, creating a situation that might lead, in the short-term, to local extinction, and in the long-term to more broad endangerment. However, their prevalence in non-farmland areas in Kenya and Tanzania reduces their vulnerability to human–animal conflict.

Habitat changes may also influence population size, density and ranging patterns. Although the cause(s) of decline in the baboon population in Amboseli in the 1960s is unknown, the dependence of Yellow Baboons on woodland savanna, and the degradation of this habitat in the Amboseli area, has caused local changes in range and range use in the decades since then. The woodland loss in Amboseli since the 1970s is associated with temperature increases in the area as a result of global climate change (Altmann *et al.* 2002).

Measurements

Papio cynocephalus

HB (♂♂): 730 (620–840) mm, n = 6
 HB (♀♀): 620 (550–680) mm, n = 4
 T (♂♂): 600 (450–660) mm, n = 6
 T (♀♀): 500 (380–560) mm, n = 4
 WT (♂♂): 24.9 (22.8–28.3) kg, n = 3
 WT (♀♀): 13.6 kg, n = 1
 BMNH, various locations (Napier 1981)

WT (♂♂): 25.8 kg, n = 20

WT (♀♀): 11.9 kg, n = 18

Wild-foraging individuals at Amboseli N. P., Kenya; see source for body measurements for garbage-feeding individuals (Altmann *et al.* 1993)

WT (♂♂): 24.7 (21.6–29.4) kg, n = 33

WT (♀♀): 13.0 (10.5–16.1) kg, n = 43

Wild-foraging individuals at Amboseli N. P., Kenya (2006–08; S. Alberts & J. Altmann pers. obs.)

WT (♂♂): 22.6 (18.6–27.7) kg, n = 35

WT (♀♀): 12.1 (9.1–16.8) kg, n = 35

Wild-foraging individuals at Mikumi N. P., Tanzania (J. Rogers pers. comm.)

Papio anubis OLIVE BABOON (ANUBIS BABOON)

Fr. Babouin Doguera; Ger. Anubispavian

Papio anubis (Lesson, 1827). Manuel de Mammalogie ou Histoire Naturelle des Mammifères, p. 27. Upper Nile.Olive Baboon *Papio anubis* adult male.

Taxonomy Monotypic species. The ‘tangle’ characterizing baboon taxonomy (Groves 2001: 237) has generated at least three classifications for ‘Olive Baboon’: (1) a species, closely allied to Yellow Baboon *Papio cynocephalus*, Guinea Baboon *Papio papio* and Chacma Baboon *Papio ursinus*; or (2) a subspecies of a single species (*P. cynocephalus*) uniting these four forms under the common name ‘Savanna Baboon’; or (3) part of a ‘superspecies’ comprising these four taxa plus the Hamadryas Baboon *Papio hamadryas* (Sarmiento 1998a, b). Mitochondrial data argue compellingly against the second of these taxonomies and underscore the close phylogenetic relationship of Olive Baboons and Yellow Baboons (Newman *et al.* 2004, Zinner *et al.* 2009a, b). Four to seven geographic variants (subspecies) of Olive Baboon have been recognized (Hill 1967, 2000, Napier & Napier 1967). Currently, however, no subspecies are recognized (Groves 2001, 2005c, Grubb *et al.* 2003). Synonyms: *doguera*, *furax*, *graueri*, *heuglini*, *lestes*, *lydekkeri*, *neumanni*, *nigeriae*, *niloticus*, *olivaceus*, *silvestris*, *tessellatum*, *tibestianus*, *vigilis*, *weneri*, *yokoensis*. Chromosome number: $2n = 42$ (Romagno 2001).

Description Large, semi-terrestrial, diurnal monkey. Nares frequently projecting beyond nose (cf. ‘upturned’ nose of Yellow Baboon). Top of head appears flat when viewed from the front. Face naked, dark grey to black, framed by prominent ruffs of hair at cheeks. Ears large, though usually obscured by surrounding pelage. Pelage coarse, varying from dark grey to olive-brown, sometimes grading into olive- or light brown (khaki or grey). Dorsum and ventrum similarly coloured. Pelage of hands and/or feet black in

some populations. Tail well-furred, sometimes bent at acute angle midway (due to fused tail vertebrae), appearing as if ‘broken’. Ischial callosities variable shades of grey. Adult ♂♂ much larger than adult ♀♀ and with heavy, but not large, mane (= cape = mantle). Adult ♀♀ are about 54% the weight of adult ♂♂. Canines of adult ♂♂ long and pointed (worn down or broken in older individuals). Adult ♀ with much less well developed mane and smaller canines than ♂. Fertile ♀♀ undergo monthly cycles of conspicuous swelling of the pink/red perineal sexual skin. Paracallosal skin pink during pregnancy. Infants have black natal coat, pink face and paracallosal region; skin typically changed to black by 10–12 months of age, though maturational change in pelage colouration is more variable. Numerous photographs of *P. anubis* at many sites in Kenya and Tanzania are available at: www.wildsolutions.nl

Geographic Variation Four to eight geographic variants differentiated as subspecies (Hill 1967, Napier & Napier 1967) or even species (Elliot 1913b). Nevertheless, in spite of geographic variation in coat colour, the distribution of black pelage on hands and feet, and cranium size, Jolly (1993: 7) emphasizes how ‘remarkably similar’ Olive Baboons are across their entire distribution. Based on cranial measurements, the forms found in Uganda and DR Congo appear largest, while the smallest are Saharan isolates and populations in Tanzania and Ethiopia where distribution adjoins that of the Yellow Baboon and Hamadryas Baboon, respectively (Jolly 1993). One commonly cited form, the so-called ‘Heuglin’s Baboon’ of S Sudan and SW Ethiopia, is of unclear status: its wavy hair and mane are shared in common with other Olive Baboons, but its lighter colour and pale cheeks and undersides are distinctly different (Sarmiento 1998a).

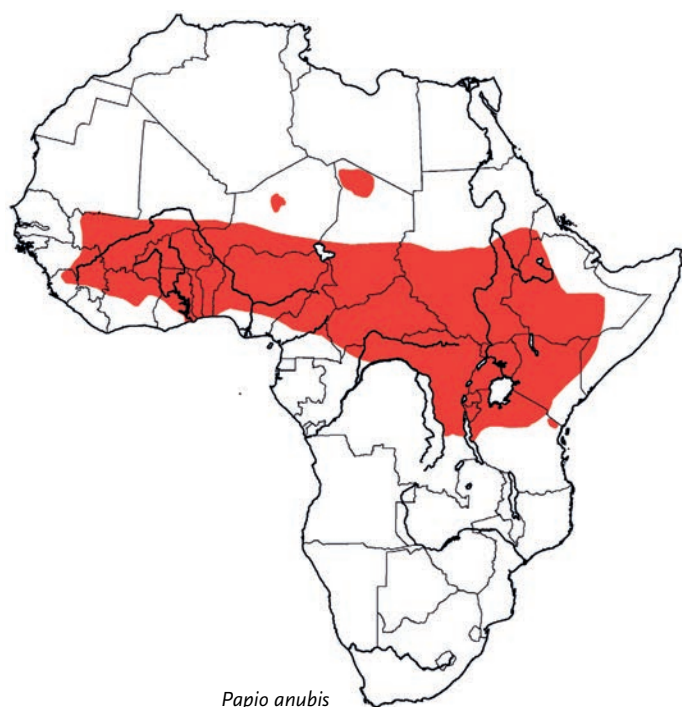

Similar Species

Papio cynocephalus. Sympatric or parapatric in SE Ethiopia, W Somalia, C and S Kenya, N Tanzania and south-east DR Congo. More gracile (slender). Mane of ♂♂ generally absent or much less developed. Dorsum light brown to yellowish-brown. Tail not ‘broken’. Nose ‘upturned’ (see above). Head appears pointed when viewed from the front.

Papio papio. Closely adjoining and probably parapatric in Mali and perhaps Guinea. Said to be sympatric in Sierra Leone (T. S. Jones in Booth 1958b). Smaller, with lighter, uniformly grizzled reddish-brown pelage; mane of adult ♂ more pronounced; tail arched.

Papio hamadryas. Sympatric or parapatric from above ca. 500 m on western edge of range in Ethiopia and Eritrea. Body smaller. Facial skin bright pink to red. Cheek tufts long, laterally projecting and silvery. Tail gently arched at distal end. Mane of adult ♂♂ generally much more prominent (to elbows) and silvery, contrasting with back. Male anogenital area is reddish.

Theropithecus gelada. Sympatric in highlands of N Ethiopia. Altitudinal overlap from ca. 2300–3800 m. Less prognathic. Mane extends to below elbows. Tail not ‘broken’. Patch of naked pink skin on upper chest in both sexes.

*Papio anubis*

Distribution Endemic to tropical Africa, mostly north of the equator. Sudan Savanna, Guinea Savanna, Northern Rainforest–Savanna Mosaic, Eastern Rainforest–Savanna Mosaic, Afromontane–Afroalpine, and Somalia–Masai Bushland BZs. Distribution more extensive than any other baboon; in fact, most African primates generally (only 3 of 64 species have larger latitudinal range; Cowlishaw & Hacker 1997). Straddles circumtropical Africa from Mauritania to N Cameroon eastward to C Ethiopia and SW lowlands of Eritrea, southwards through East Africa as far as SE DR Congo, Burundi and NC Tanzania (Wolfheim 1983). Southern-most population in Tanzania is probably at Mt Hanang ($4^{\circ}28'S$, $35^{\circ}24'E$, 2050 m asl; T. Butynski & Y. de Jong pers. comm.). Isolated populations occupy Tibesti Plateau ($20^{\circ}N$, $16^{\circ}E$) and Air Massif in Saharan Chad. In the wild a broad hybrid zone with Yellow Baboon runs along a north-east/south-west line from at least Meru N. P. in the north, through Tsavo East N. P. to the south-west Amboseli Basin, Kenya, to L. Manyara N. P., Tanzania (Alberts & Altmann 2001, Y. de Jong & T. Butynski pers. comm.). Hybridizes with Hamadryas Baboon in Ethiopia (Nagel 1973), SC Eritrea (Zinner *et al.* 2001c, 2009b), and Somalia (J. Beehner pers. comm.). In one stable hybrid zone along a 20 km stretch of the Awash Valley, C Ethiopia, admixture is maintained by movements of ♂♂ of both parental species, as well as of hybrid stock, among 8–12 groups (Phillips-Conroy *et al.* 1992). Hybridizes with Geladas *Theropithecus gelada* in Ethiopia (Dunbar & Dunbar 1974c, Jolly *et al.* 1997). Hybridization is suspected, though unsubstantiated, where distributions of Olive Baboons and Guinea Baboons presumably abut in Mali (Groves 2001).

Habitat As befitting its wide geographic range, *P. anubis* occupies an enormous variety of vegetation and climatic conditions from lowlands to high mountains. Found near sea level in Ghana (Depew 1983, L. Depew & I. Gordon pers. comm.) and probably also Togo, Bénin and SW Nigeria (Wolfheim 1983, Sarmiento 1998a). Occurs at 500–3300 m in Ethiopia (Yalden *et al.* 1977). Sighted at 3850 m on

Mt Orobó, Ethiopia, which is about 500 m above the treeline (Bolton 1973). Lowest altitude reported for East Africa (where the Yellow Baboon occupies the lower regions) is at 540 m in Meru N. P., C Kenya (Y. de Jong & T. Butynski pers. comm.). Highest altitudes reported for East Africa are 2500 m in the Echuya F. R., SW Uganda (E. E. Sarmiento pers. comm.), 2300 m in the Bwindi Impenetrable N. P., SW Uganda, 2370 m at Nyahururu (Thompson's Fall), C Kenya, and 2550 m at Empakai Crater in the Ngorongoro Conservation Area, NC Tanzania (Y. de Jong & T. Butynski pers. comm.).

Typically an open-country species, and thus common in Sudan and Sahel savannas, grassland, woodlands and rocky hill habitats. Individuals in some populations, however, spend up to 50–60% of their activity period in forest (Rowell 1966); mixed forest-mosaic and mid-altitude and montane forest (e.g. W Uganda, NE DR Congo), and high-altitude bamboo *Arundinaria alpina* forest (DR Congo). When in closed-canopy moist forest, *P. anubis* is seldom found more than 2 km into the forest. *Papio anubis* is nowhere known to live entirely within closed-canopy moist forest (T. Butynski pers. comm.). In the dry montane forest of the Mathews Range, C Kenya, *P. anubis* is common and appears to spend almost all of the time deep within forest, although there is some use of the limited 'open habitats' (cliffs, tallus slopes, burnt sites). Here it is important to note that all other cercopithecines are absent except for De Brazza's Monkey *Cercopithecus neglectus* (which is uncommon here). As such, this might be a case of 'competitive release', perhaps especially in the absence of Sykes's Monkey *Cercopithecus mitis* (De Jong & Butynski 2010a). Also inhabits semi-desert steppe and arid thorn scrub with gallery forest (Ethiopia) (Aldrich-Blake *et al.* 1971, Dunbar & Dunbar 1974b), though may be limited to river beds and gallery forests in these habitats (Zinner *et al.* 2001c). Makes use of mangrove forest in Kenya (T. Butynski & Y. de Jong pers. comm.) and in Ghana (L. Depew & I. Gordon pers. comm.) but does not appear to be able to live solely in this habitat. Habitat selection is limited primarily by availability of water and secure sleeping sites. These baboons require regular access to water, and moisture from subterranean plant parts is important in dry seasons.

Where studied, *P. anubis* inhabits areas with mean annual rainfall of 2022 mm in E Nigeria (Gashaka-Gumti N. P., Higham *et al.* 2009), 1400–1500 mm in SW Uganda (Bwindi Impenetrable N. P., Butynski 1985; Budongo F. R., Plumptre 1996; Kibale N. P., Struhsaker 1997), to 570 mm in Ethiopian semi-desert (J. Beehner pers. comm.), and ca. 300–900 mm in W Eritrea (Zinner *et al.* 2001c), with intervening values elsewhere, such as 710–756 mm in the Eastern Rift Valley, Kenya (Harding 1976) and 550 mm on the Laikipia Plateau, Kenya (Barton *et al.* 1996). Must have access to communally used sleeping refuges providing safety from predators: either large trees (e.g. Fever Trees *Acacia xanthophloea* in gallery forests [R. Palombit pers. obs.], Oil Palms *Elaeis guineensis* along L. Victoria [A. Matsumoto-Oda pers. comm.]) or steep cliff faces or rocky inselbergs ('koppies') [DeVore & Hall 1965]).

Abundance Considered 'abundant or common' in at least eight countries (Wolfheim 1983). Population density varies from 4 ind/km² in arid savanna–woodland habitats (DeVore & Hall 1965), 11–14 ind/km² in moist forests in W and SW Uganda (Rowell 1966, Butynski 1985, Plumptre & Reynolds 1994), to 30–35 ind/km² in moist forests in W Tanzania (Ransom 1981) and WC Uganda (Struhsaker 1997).

Adaptations Diurnal and semi-terrestrial. Primary adaptation is extreme adaptability and flexibility to conditions, as exemplified by ability to exploit foods of many kinds. Digitigrady (body weight borne on volar surfaces of fingers) represents morphological adaptation for increased efficiency of terrestrial locomotion (Whitehead 1993), convergent in kind with ungulate specialization. ‘Sunbathing’ at the sleep tree or sleep cliff in early morning is common (R. Palombit pers. obs.). Ambient temperature affects activity budgets (Dunbar 1994) and social behaviour, such as ventro-ventral contact and huddling of mothers with infants, which are negatively correlated with temperature (Brent *et al.* 2003).

Foraging and Food Omnivorous. Feeding occurs throughout daylight hours. Of the daily activity budget, feeding variably accounts for 20% (Ghana; Depew 1983), 26% (Tanzania; Ransom 1981), 31% (Ethiopia; Nagel 1973), 31% (Nigeria; Warren 2003), 40% (Kenya; Barton 1989), 41% (Côte d’Ivoire; Kunz & Linsenmair 2008b) and 51% (Kenya; Harding 1976). Diet shifts continually with season and even time of day, allowing exploitation of a range of items as they become available in space and time. Time spent feeding does not vary significantly across seasons, however (Bercovitch 1983). Diets do not differ qualitatively between the sexes, but ♀♀ spend significantly more time feeding than do ♂♂ (except when engaged in sexual consortships) (Bercovitch 1983).

Ecological adaptability of *P. anubis* is exemplified by a dietary diversity so pronounced that early researchers remarked it would be easier to list foods *not* eaten, than to attempt a complete inventory. Tallies of plant species eaten vary from 22+ (Rowell 1966), 45+ (Barton *et al.* 1993), 62+ (Ransom 1981), 84 (Kunz & Linsenmair 2008b), 94+ (DeVore & Hall 1965), to 111 (Warren 2003). Plants constitute the majority of diet, up to 98% in Kenya (DeVore & Hall 1965) and Côte d’Ivoire (Kunz & Linsenmair 2008b). Digging up rhizomes – as well as other forms of underground storage parts in plants (e.g. bulbs, tubers, corms) – represents a principal ecological adaptation made possible by baboons’ combination of prehensile hands and committed terrestriality. Underground storage parts account for up to 16% of the plant diet (Barton *et al.* 1993). Grass (e.g. *Paspalum conjugatum*) is a principal food for Olive Baboons in savanna/woodlands, but also for ‘forest dwelling’ Olive Baboons, which forage extensively in nearby grass plains (Rowell 1966). Diverse grass parts are utilized: young meristems growing in moist soil, seeds (filtered by pulling distal ends of intact stems through the mouth [R. Palombit pers. obs.]) and nutrient- and water-rich subterranean rhizomes.

Ripe and unripe fruits eaten, particularly in forests where preference is for fleshy fruits, such as figs *Ficus* spp. (DeVore & Hall 1965, Barton *et al.* 1993). In more arid regions they eat less pulpy fruits of trees and bushes/shrubs (e.g. *Carissa edulis*, *Scutia myrtina* [R. Palombit pers. obs.] and *Parkia biglobosa* [Kunz & Linsenmair 2007]). Olive Baboons are likely dispersal agents for numerous plants (e.g. *Securinega virosa*, *Azadirachta indica*, *Nauclea latifolia*, *Lannea acida*, *Diospyros mespiliformis*, *Tapura fischeri*, *Oxyanthus racemosus* [Lieberman *et al.* 1979, Kunz & Linsenmair 2008a]). Seeds are also eaten, particularly of drier fruits (e.g. *Acacia tortilis*, *Acacia drepanolobium* [R. Palombit pers. obs.]). Partially digested seeds are harvested from the fresh faeces of herbivores (e.g. Impala *Aepyceros melampus*, African Buffalo *Syncerus caffer*, Savanna Elephant *Loxodonta africana*). Flowers are eaten seasonally (e.g. *A. xanthophloea*, *A. drepanolobium*, *Cullumia squarrosa*

[DeVore & Hall 1965]). Along waterways Olive Baboons eat aquatic plants (e.g. *Trifolium* sp. and roots/storage parts of Nymphaeaceae [R. Palombit pers. obs.]). Numerous species among the herbaceous ground cover provide food in the form of fruits, seeds, flowers and, occasionally, young leaves. Fungal mycorrhiza and fruiting sporophores are exploited (R. Palombit pers. obs.); discovery of large mushrooms excites as much feeding competition as predatory capture of meat (see below). Gum is an important dietary supplement in drier habitats (e.g. *A. drepanolobium*-dominated woodland in C Kenya). Adult Olive Baboons access tree cambium by peeling bark off or, more often, by snapping saplings (requiring strength more often possessed by adult ♂♂). *Papio anubis* is a human commensal in some locales, feeding in garbage dumps near towns, small settlements and tourist lodges (Kemnitz *et al.* 2002). They also exploit foods introduced by humans (e.g. the base stem of prickly pear cactus *Opuntia vulgaris* [R. Palombit pers. obs.]) and plants domesticated for agriculture, see below).

Insects are eaten consistently but opportunistically, usually via random discovery of individuals (particularly orthopterans and lepidopterans) in grass or underbrush, or small numbers of ants and termites exposed as searching baboons systematically overturn rocks (DeVore & Hall 1965, Rowell 1966). Olive Baboons of Laikipia Plateau, C Kenya, regularly eat harvest ants (*Crematogaster* spp., *Camponotus* spp., *Tetraponera* spp.) residing symbiotically inside galls of *A. drepanolobium* (R. Palombit pers. obs.). Also eaten are temporarily superabundant insects, e.g. termite alates during nuptial flights and infestations of army worm caterpillars (DeVore & Hall 1965). Other invertebrates taken include scorpions and snails (terrestrial and aquatic) (DeVore & Hall 1965, Rowell 1966). Although the Olive Baboon’s catholic diet is unambiguously vegetarian, meat constitutes a potentially important protein supplement. In two populations occupying different habitats, a successful predation event was observed every 22 h (Harding 1973) and 30 h (Rowell 1966). As with plant foods, a great variety of vertebrate prey are eaten, including fish, frogs, lizards, crocodile eggs, terrapins, birds (caught on the ground or occasionally on the wing, e.g. guineafowl *Agelastes* spp., Yellow-necked Spurrow *Francolinus leucoscepus*, nightjars, quail, plover), birds’ eggs, various rodents (mice, ground squirrels, tree squirrels), bats, Cape Hares *Lepus capensis*, Vervet Monkeys *Chlorocebus pygerythrus*, small antelopes (e.g. Guenther’s Dik-dik *Madoqua guentheri*), Oribi *Ourebia ourebi*, Thomson’s Gazelle *Eudorcas thomsonii* and Grant’s Gazelles *Nanger (granti) granti*, and the young only of larger ungulates (Impala, Bushbuck *Tragelaphus scriptus*, Hartbeest *Alcephalus buselaphus*) (Rowell 1966, Kingdon 1971, Harding 1973, Brashares & Arcese 2002). Of these animals, hares, mice and small antelopes are the most common prey. The ecological relationship with prey such as Impalas, Bushbucks and Vervet Monkeys is curious, since Olive Baboons also associate with these animals without causing alarm (see below). Carrion is exceptional as a food.

Prey is located by (literally) stumbling upon it, and captured by seizing it and immediately commencing eating (usually while the prey is still alive). Behaviour reminiscent of more deliberate ‘hunting’ also occurs. Careful and apparently purposeful scanning of vegetation, flushing of prey, and pursuit precede some instances of successful captures, suggesting organized predatory behaviour (Harding 1973). Olive Baboons hunt individually, however, not cooperatively. Juveniles, as well as adults, are able to capture small prey (e.g. mice and small birds), which is eaten quickly in a gulp or two; larger prey (the size of an adult hare and above) requires a long processing time

and are most often captured by adult ♂♂ (Harding 1975). Capture of large prey arouses social tension as well as overt aggression, as the carcass makes its way 'up the hierarchy', being surrendered to progressively higher-ranking ♂♂ arriving at the scene of the kill (R. Palombit pers. obs.). Direct food sharing (cf. Robust Chimpanzees *Pan troglodytes*) has not been observed, although adult ♂♂ tolerate the proximity of certain individuals (particularly fertile ♀♀), which will snatch scraps of meat from the ground. An interesting, but as yet unsubstantiated, proposition is that variation in predatory behaviour reflects the action of cultural transmission, generating contrasting 'traditions' of meat-eating (Strum 1975).

Polyspecific associations are relatively rare, but Olive Baboons associate with Impalas, Bushbucks, Plains Zebras *Equus quagga* and Vervet Monkeys in apparent mutualism. Ungulates and Olive Baboons beneficially attend to each other's alarm calls (DeVore & Hall 1965), while young Vervets and Olive Baboons sometimes play with one another (Kingdon 1971).

Social and Reproductive Behaviour Social. Olive Baboon groups vary from 12 to as many as 130 individuals. Average group size is reported as 87.5 individuals (S.D. = 20.4, $n = 4$) in C Kenya (Berger 1972b), 65 individuals (S.D. = 34, $n = 7$) in Kenya (Harding 1976), 30 individuals (S.D. = 24.8, $n = 6$) in Ethiopia (Brett *et al.* 1982), 32 individuals (S.D. = 12.8, $n = 8$) in Tanzania (Ransom 1981), 30 individuals in Ghana (Depew 1983), 20.7 individuals (S.D. = 5.1, $n = 22$) in Nigeria (Higham *et al.* 2009), and 15 individuals ($n = 8$) in Côte d'Ivoire (Kunz & Linsenmair 2008b). Socioeconomic sex ratio of adult ♀♀ per adult ♂♂ varies from 1.65 (Tanzania; Ransom 1981), 2.02 (Kenya; Barton 1989), 2.22 (Ghana; Depew 1983), 2.5 (Kenya; DeVore & Hall 1965) to 3.83 (Kenya; Harding 1976). Greater preponderance of adult ♀♀ arises more through sex differences in maturation rates rather than differential mortality. Immature individuals typically outnumber adult ♀♀ 2 : 1.

Males typically disperse from natal groups at 6–9 years of age, although emigrations at ages as young as four years occur (Packer 1979a). Given the rarity of sightings of solitary individuals, they apparently soon enter another group rather than live alone for prolonged periods. Females are philopatric, remaining in their natal groups their entire lives (with rare exceptions). This sex difference generates the matrilineal structure of Olive Baboon groups: related ♀♀ affiliate with one another and compete with other sets of ♀♀ relatives. Male and ♀ relationships are organized into dominance hierarchies that are maintained by a rich repertoire of vocal, visual and tactile communicative displays (e.g. the subordinate 'grimace' facial expression), and by occasional aggression. Females usually acquire dominance status via 'youngest daughter ascendancy', in which a maturing ♀ assumes a rank position immediately below her mother and above her older sisters (as well as all of the ♀♀ ranking below her mother) regardless of body size (Hall & DeVore 1965, Ransom 1981, Strum 1987). Female hierarchies are typically linear and highly stable, changing little over lifetimes.

Male social relationships are also generally organized around dominance status, but in contrast to ♀♀ hierarchies are more variable, dynamic and even obscure at times (Packer 1979b, Harding 1980, Ransom 1981, Strum 1982, Sapolsky 1993). Male hierarchies are not always linear, e.g. when individual alliances generate 'clusters' of ♂♂ that collectively dominate one another (Hall & DeVore 1965). Males also experience substantial changes in rank during

their lives. This is partly because immigration of new male(s) may temporarily destabilize the hierarchy (Sapolsky 1993), and partly because coalitionary behaviour undermines the stability of dominance relationships. Thus, ♂ rank is apparently influenced by body and canine size, and physical stamina, but also by social skill in forming and maintaining coalitions. In addition to their unambiguous competitive basis, social relationships among ♂♂ also show conspicuous affiliative components, which are likely related to maintenance of these alliances (Harding 1980, Smuts & Watanabe 1990).

Olive Baboons are polygynous. Adult ♀♀ can copulate at any time, but proceptivity and receptivity generally track the monthly menstrual cycle (Hall & DeVore 1965, Ransom 1981, Bercovitch 1991). Adult ♂ sexual interest depends largely on the condition of the female's sexual skin, which is generally correlated to ovulatory status (Wildt *et al.* 1977, Higham 2008a, b, Daspre *et al.* 2009). Males closely follow and groom fertile ♀♀ while the sexual skin increases gradually in size, but cease this 'sexual consortship' after the rapid 'deflation' of the skin 2–3 days following ovulation (Bercovitch 1986). Females 'present' hindquarters to ♂♂ to solicit close examination of the sexual swelling and/or copulation. Copulation rarely involves conspicuous vocalizations (Bercovitch 1991). There is debated evidence that ♀♀ of greater reproductive quality (i.e. earlier menarche or greater offspring survival) have consistently longer swellings (Domb & Pagel 2001, Zinner *et al.* 2002a). This suggests an intriguing, but unsubstantiated, potential for ♂♂ to use visible variation in females' swellings to discriminate among potential mates and to mediate mating competition with rival ♂♂.

Male Olive Baboons compete intensely with one another to maintain sexual consortships – and thus copulatory access – with swollen fertile ♀♀, especially maximally swollen ♀♀. The strong sexual dimorphism of the species is a likely consequence of this competition.

Dominant ♂♂ are generally more successful than subordinate rivals in obtaining periovulatory matings, but coalitionary confrontations by multiple ♂♂ may override an individual's dominance advantage (Bercovitch 1988). Typically, two or more 'follower' ♂♂ tag along behind a consort pair for hours or even days (Danish & Palombit 2008), and then cooperatively displace a (sometimes higher-ranking) ♂ from his consortship through threats and/or aggression; one of the coalitionary challengers then becomes the new consort of the ♀ (Hall & DeVore 1965, Ransom 1981, Strum 1987, R. Palombit pers. obs.). This behaviour was originally interpreted as an example of reciprocal altruism, in which unrelated ♂ allies presumably take turns obtaining the mating opportunities achieved through successive coalitionary episodes (Packer 1977). Unambiguous symmetry of benefits has not been substantiated by subsequent research, however (Noë & Sluijter 1995). Middle-ranking ♂♂ are more likely than high- or low-ranking ♂♂ to develop the affiliative bonds that engender successful coalitionary cooperation. Newly immigrant ♂♂ are disproportionately the targets of such coalitions. Although most conspicuous in the reproductive context, ♂ coalitions also occur during disputes over meat, defence of infants, general aggression and for no obvious reason (Smuts 1985). Stable alliances between ♂♂ can obscure dominance relationships by altering the rank of a ♂ in the presence of his ally. Thus, a positive correlation between non-natal adult ♂ rank and mating success has been documented in some studies (Packer 1979a, b), but not in others (Bercovitch 1986). Variation in male–male aggressiveness and affiliation is also attributed to cultural transmission of contrasting social 'traditions' (Sapolsky & Share 2004, Sapolsky 2006).

Olive Baboons
Papio anubis.

Lactating ♀♀ (and sometimes pregnant ♀♀) associate conspicuously with a particular adult ♂ or two (Smuts 1985, R. Palombit pers. obs.). These cohesive 'friendships' may beneficially promote ♂ protection of ♀♀ and/or their dependent infants from harassment from other (higher-ranking) ♀♀ and especially ♂♂. This has been substantiated by playback experiments, which show that ♂♂ respond significantly more strongly to the distress vocalizations of their ♀♀ friends than control ♀♀ of similar rank and reproductive status (Lemasson *et al.* 2008). Furthermore, cortisol levels in lactating ♀♀ suggest that ♂ friends buffer ♀♀ from harassment-induced stress (Shur 2008). In particular, the hormonal data suggest that lactating ♀♀ are susceptible to stress from harassment by adult ♂♂ (rather than higher-ranking ♀♀), and that friendships with ♂♂ may ameliorate this stress. Mating patterns suggest that these ♂ associates are often, but not always, the fathers of the infants of their ♀ 'friends'. In cases where a ♂ is not the father of his ♀ friend's infant, Smuts (1985) hypothesized that he will be preferentially selected by the mother as sire of her next infant. Genetic data are currently unavailable to test these alternatives directly. Higher-ranking ♀♀ generally achieve greater lifetime reproductive success than lower-ranking rivals, due to earlier menarche, faster reproductive rate (e.g. inter-birth intervals up to six months shorter), or greater offspring survivorship (Smuts & Nicolson 1989, Packer *et al.* 1995, Garcia *et al.* 2006). Compared to subordinates, however, dominant ♀♀ experience higher rates of spontaneous abortion and miscarriage (Packer *et al.* 1995), though the explanation that this results from higher circulating levels of androgens is questioned (Altmann *et al.* 1995). In any event, any greater difficulties in completing pregnancies do not override other reproductive advantages of high rank, which derive primarily from priority of access to resources via supplanting of subordinate rivals from food sources. Thus, ♀♀ at the top of the hierarchy may obtain food at rates 30% higher than those at the bottom (Barton & Whiten 1993). In addition to these nutritional issues, rank-related reproductive rates may be influenced by psychosocial stress (Rowell 1970a, Bercovitch

& Strum 1993) and access to ♂♂ as protective associates (Smuts 1985). Agonistic interaction accounts for a larger proportion of the activity budget of ♀♀ than of ♂♂ (Bercovitch 1983). Coalitions among related ♀♀ do occur, but usually less frequently than among ♂♂ (Johnson 1987, Barton *et al.* 1996). Reconciliation behaviour following conflicts occurs among all age/sex classes, but is more common among ♀ kin (Castles & Whiten 1998).

The Olive Baboon has a rich and diverse vocal repertoire that has not been rigorously studied since Hall & DeVore's (1965) initial description (see also Ransom 1981). The loud bi-phasic 'wahoo' is arguably the most conspicuous call, audible up to 3.0 km, given primarily by adult ♂♂, and elicited by intense male-male aggression (intra- and inter-group), encounters with predators, or spontaneously (in sleep trees usually). This vocalization, however, occurs far less frequently than the more common barks, growls, grunts, screams and coughs that mediate intra-group social interactions in, currently, unclear ways.

There is great variation in mean home-range size; 4–5 km² in moist forest or semi-forest habitats (Rowell 1966, Ransom 1981); 0.4–1.7 km² (Kunz & Linsenmair 2008b), 1.5 km² (Warren 2003), 19.7 km² (Harding 1976), 31.0 km² (Smuts 1985) and 43.6 km² (Barton *et al.* 1992) in drier savanna/woodlands; 4.3 km² (Aldrich-Blake *et al.* 1971) and 0.9 km² (Dunbar & Dunbar 1974b) in arid thorn scrub. Mean daily distance travelled is 2.4–6.0 km in savannas (Harding 1976, Barton *et al.* 1992, Kunz & Linsenmair 2008b), 2.4 km in forests (Rowell 1966) and 1.2 km in arid Ethiopia (Dunbar & Dunbar 1974b). In savanna/woodland habitats day range increases as resources become seasonally scarcer, suggesting a time-minimizing (rather than energy-maximizing) foraging strategy (Barton *et al.* 1992). Access to waterholes particularly influences ranging in dry season. Groups are not territorial. Home-ranges overlap extensively. Inter-group interactions are frequently peaceful, after which one group (often the smaller) moves off (DeVore & Hall 1965). Chases may occur, but these are often adult ♂♂ herding ♀♀ of their own group away from the other group. Individuals from neighbouring

groups sometimes commingle completely, but tensions run high and intense fighting can suddenly break out, involving numerous individuals of both sexes; in one episode in Kenya multiple ♂♂ and ♀♀ mobbed a subadult ♂ from another group, fatally wounding him (R. Palombit pers. obs.).

Reproduction and Population Structure Onset of puberty in ♂♂ (i.e. testicular enlargement) occurs at 5–6 years of age (Packer 1979a) when ♂♂ are ca. 7–8 kg (Jolly & Phillips-Conroy 2003). Testes, body size and mane length attain maximal adult proportions at around the same time (Strum 1991, Jolly & Phillips-Conroy 2003), which has been reported at 6.5–7.5 years (Packer 1979a) and 9–10 years of age (Glassman *et al.* 1984, Strum 1991). Canine eruption occurs at about eight years (Strum 1991). Females reach sexual maturity (i.e. commence monthly menstrual cycling) at ca. 4.5–5 years, pass through a period of adolescent sterility and give birth for the first time at ca. 6–7 years (Packer 1979a, Scott 1984, Bercovitch & Strum 1993, Williams-Blangero & Blangero, 1995). Mean inter-birth interval (in months) ranges from 22.2 (Packer 1979b), 23.5 (Kenyatta 1995), 25.2 (S.E. = 1.2, n = 13; Smuts & Nicolson 1989), 29.9 (Higham *et al.* 2009), 30.3 (Depew 1983). Inter-birth intervals are much shorter for ♀♀ that obtain additional food through captive provisioning (mean = 15.0 months, S.D. = 0.70, n = 21; Garcia *et al.* 2006) or crop-raiding (16.5 months) (Higham *et al.* 2009). Breeding occurs throughout the year (Bercovitch & Harding 1993). In some (not all) populations a peak in births occurs at the onset of rains (e.g. in Oct–Dec in Kenya), just before food supplies also peak (DeVore & Hall 1965). Single young are born after a gestation of 180–185 days (154–185 days; Packer 1979a, Smuts & Nicolson 1989, Garcia *et al.* 2006). Weight at birth in captivity is 980 g for ♂♂ (670–1220 g, n = 77) and 920 g for ♀♀ (700–1400 g, n = 66; Coelho 1985). Twins not reported.

Direct care of infants (e.g. nursing, carrying) is predominantly by mothers, although mothers' ♀ kin and ♂ 'friends' (see above) may interact affiliatively with infants at high rates. Weaning is gradual and difficult to demarcate, but is generally complete by 300 days (Packer 1979a) to 420 days of age (Nicolson 1982). Adolescents of both sexes experience a growth spurt, which is delayed and more intense in ♂♂ (Glassman *et al.* 1984). Mean inter-birth intervals are 22–26 months for Tanzanian and Kenyan populations (Packer 1979a, Smuts & Nicolson 1989, Kenya 1995), and 30 months for a Ghanaian population (Depew 1983). If infants die, mothers resume cycling within 1–3 months and are shortly, thereafter, pregnant again (Collins *et al.* 1984, Smuts & Nicolson 1989). Infant mortality is 57% among primiparous mothers, 16% in multiparous ♀♀ (Nicolson & Smuts 1989), and is due primarily to disease, predation and nutritional/energetic stress. Infanticide by ♂♂ is widespread but uncommon (accounting for <5% of infant mortality), with the possible exception of the Gombe Stream N. P. population, Tanzania (where it apparently accounts for 10–25% of infant mortality; Palombit 2003). The patterning of infanticide suggests it is unlikely to constitute a ♂ reproductive strategy. Maximum longevity is 48 years in captivity (Kingdon 1971), though considerably less in the wild (ca. 20 years; Bronikowski *et al.* 2002).

Predators, Parasites and Diseases The primary non-human predator of the Olive Baboon is the Leopard *Panthera pardus*, which

usually (but not always) attack at night (preferentially targeting adult ♂♂). Hunting success of Leopards is significantly reduced by communal mobbing by multiple adult and subadult ♂♂ (and occasionally adult ♀♀) (Cowlshaw 1994). This aggressive and raucous defence may result in death to the Leopard, but ♂♂ sometimes immediately and hastily retreat from a Leopard, abandoning even adult ♀♀ and infants in their wake. The reasons for such contrasting ♂ responses to Leopard encounters are unknown. In one case, mobbing generated a foraging benefit, when a Leopard attacked by ♂♂ baboons fled, yielding a freshly killed Impala (Cavallo 1990). Other predators are Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta*, Nile Crocodiles *Crocodylus niloticus* and Pythons *Python* spp. Robust Chimpanzees communally prey on immature Olive Baboons (e.g. Gombe N. P.; Wrangham & Van Zinnicq Bergmann-Riss 1990). Medium-sized carnivores, such as Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus*, are unlikely predators, but potentially dangerous (given the defensive antagonism they occasionally elicit from Olive Baboons). Raptors are unlikely predators, but there is one report of Olive Baboon remains in the nest of an Africa Crowned Eagle *Stephanoaetus coronatus* (Mitani *et al.* 2001). Even the diets of known predators, including Leopards, typically emphasize other, less pugnacious prey (such as small ungulates) (Bailey 1993). A study in Côte d'Ivoire reported the relative frequency of Olive Baboon prey remains in Lion and Leopard scats as only 2% (Bodendorfer *et al.* 2006). Thus, although the Leopard, Lion and, locally, Robust Chimpanzee are serious predators, the Olive Baboon is not their primary prey. In terms of demographic impact, the most serious predator is humans, which probably kill tens of thousands of Olive Baboons each year through trapping, poisoning and hunting.

The Olive Baboon is vulnerable to infectious diseases such as tuberculosis (bovine and human), non-tuberculosis *Mycobacterium*, yaws *Treponema pertenu* and simian immunodeficiency virus (SIV) (Wallis & Lee 1999, J. Mwenda pers. comm.). Herpes B *Herpes simiae* has not been found in wild populations (Kingdon 1971). Olive Baboons living near settlements may be indirectly infected by humans (Wallis & Lee 1999), and humans by Olive Baboons (Legesse & Erko 2004). Olive Baboons are capable of hosting a wide variety of internal parasites (Toft 1986, Strum *et al.* 1989, Wallis & Lee 1999, Hope *et al.* 2004, Legesse & Erko 2004, Ocaido *et al.* 2004). Susceptible to protozoans, such as *Cryptosporidium*, *Endolimax nana*, *Entamoeba coli*, *Entamoeba histolytica*, *Enteromonas hominis*, *Giardia* as well as the malarial *Plasmodium gonderi* (although monkeys can theoretically act as vectors for malarial transmission to people in the presence of *Anopheles* mosquitoes, *P. gonderi* is not among the four *Plasmodium* species commonly responsible for malaria in human populations). Olive Baboons typically host a complement of metazoan endoparasites, particularly nematodes. *Trichuris*, *Strongyloides*, *Oesophagostomum* and *Ternidens* appear to be relatively common, though not necessarily in all populations. Also known is the nematode *Enterobius*, trematode fluke *Schistosoma mansoni*, tapeworms (*Diphylobothrium*, *Hymenolepis*, *Spirometra*, *Multiceps*), roundworms (*Ascaris*), hookworms (*Ancylostoma*, *Necator*), filarial worms (*Loa*) and cestode tapeworms (*Diphylobothrium*, *Spirometra*, *Anoplocephala*, *Dipylidium*). Cestodes (e.g. *Echinococcus*, *Mesocestoides*), whose primary hosts are other mammals (e.g. canids) or birds, may also occur in Olive Baboons. Ectoparasites include fleas (*Tunga*), lice (*Anoplura*), ticks (*Ixodidae*) and mites (*Proscorptidae*).

Natural infestation rates are poorly understood, partly because clinical symptoms are mild or absent in unstressed or otherwise healthy

individuals, but recent study of three populations reveals variation in gastrointestinal infection. Among Olive Baboons in C Kenya, *Strongyloides* and the pinworm *Enterobius* were found in 76% and 12% of samples, respectively ($n = 42$; Hahn *et al.* 2003). In a population in moist forest in Uganda 79% exhibited *Ascaris* infection, 37% *Strongyloides*, 16% *Trichuris* and 42% *Ternidens*. Protozoans in 140 samples were represented as follows: 32% *Cryptosporidium*, 58% *Giardia* and 99% *Eimeria* (Hope *et al.* 2004). In Ethiopia infection rates by the most common intestinal parasites were: 83% *E. coli*, 37% *Strongyloides*, 27% *Trichuris* and 20% *S. mansoni* ($n = 59$; Legesse & Erko 2004). Although infectious diseases and endoparasites are suggested to limit Olive Baboon demography (Rowell 1966) as well as geographic expansion of the species into equatorial rainforests (Kingdon 1971), direct empirical evidence is lacking. Nevertheless, the potential influence of parasites on demography is indicated by observed associations between: (1) age (and possibly dominance rank) of Olive Baboons and *Strongyloides* load, and (2) *Trichuris* egg output and ♀ reproductive status (Müller-Graf *et al.* 1996). Parasites also influence individual behaviour. Besides the servicing of intra-group social relationships, social grooming removes most ectoparasites from body areas inaccessible by self-grooming. Additionally, Olive Baboons' periodic change in sleeping sites may reduce potentially infectious contact with accumulations of faeces containing the eggs of endoparasites.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Considered an agricultural pest throughout its range – particularly to inadequately guarded farms near forest edges – and therefore officially classified as ‘vermin’ (African Convention) (Paterson 1999). Responsible for much of the animal-induced damage to African crops (up to 70% in some W Uganda localities), especially maize and cassava, as well as tuber crops ignored by other primates (Naughton-Treves *et al.* 1998, Hill 2000). Thus it rivals – and in some areas surpasses – the crop damage caused by Bushpigs *Potamochoerus larvatus* and Bush Elephants. Although recent studies suggest that patrolling and informed placement of farms reduce crop-raiding by Olive Baboons (Hill 2000), previous control measures have typically emphasized vigorous campaigns of extermination. The consequent killing of tens of thousands annually poses the most serious conservation threat, followed by habitat conversion (particularly near forests), and some continued trapping for biomedical research. Nevertheless, the Olive

Baboon remains abundant throughout much of its range. Long-term demographic trends remain unclear, however, in light of intensifying agricultural conflict with humans, habitat loss and local extinctions.

GENUS *Theropithecus*

Gelada

Theropithecus I. Geoffroy, 1843. Arch. Mus. Hist. Nat. Paris 2: 576.

The genus is monospecific in the extant fauna with the one species, Gelada *Theropithecus gelada*, restricted to the Central Ethiopian Plateau. Includes at least two extinct lineages, well documented by fossils of Pliocene and Pleistocene age (ca. 4 mya to ca. 125,000 years ago), in Africa (throughout), India, the Middle East and S Europe.

Theropithecus is closest phylogenetically to *Lophocebus* and *Papio*. Last common ancestor between *Theropithecus* and *Papio* at 4.5–3.2 mya (Perelman *et al.* 2011, Roos *et al.* 2011). Distinguished from *Lophocebus* by larger size and postcranial features associated with

terrestrial adaptation. Distinguished from *Papio* by relatively shorter hindlimbs, abbreviated index finger (giving a precise thumb–finger grip) and, especially, relatively large, high-crowned and complex molar teeth, all adaptations to feeding on small, tough, herbaceous vegetation while seated on the ground. Earliest representatives have *Papio*-like cranial shape; later ones show a progressively deepening face, with a high, vertical ascending ramus of the mandible.

Clifford J. Jolly

Theropithecus gelada **GELADA (GELADA BABOON)**

Fr. Gelada; Ger. Dschelada

Theropithecus gelada (Rüppell, 1835). Neue Wirbelt. Fauna Abyssin. Gehörig. Säugeth., p. 5. Semien (Simien), Ethiopia.Gelada *Theropithecus gelada* adult male.Lateral, palatal and dorsal views of skull of Gelada *Theropithecus gelada* adult male.

Taxonomy Polytypic species. Only extant member of genus *Theropithecus*. Two subspecies recognized: *T. g. gelada* and *T. g. obscurus* (de Beaux 1925, Yalden *et al.* 1977, Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003), although this distinction may not be warranted (Crook 1966, Mori & Belay 1990, Gippoliti 2010, C. Hunter pers. comm.). There appears to be no barrier between the Northern Gelada *T. g. gelada* and the Southern Gelada *T. g. obscurus* (both of which are found to the west of the Rift Valley). As such, there may be a phenotypic cline here (but see Gippoliti 2010). A third subspecies, *T. g. senex*, is described from a single specimen and not widely recognized (Gippoliti 2010). In 1990 a very isolated population of Geladas was discovered east of the Rift Valley (Wabi Shebeli Gorge, Arsi region). This population is comprised of individuals that are smaller and of lighter pelage than the more geographically proximate *T. g. obscurus*, resembling the more geographically distant *T. g. gelada* (Mori & Belay 1990, 1991). The taxonomic status of the Gelada's of the Arsi region remains to be determined but recent molecular evidence indicates that this population is distinct from Geladas west of the Rift Valley (having diverged 1.17 mya; range 0.7–1.2) leading to the suggestion that they represent a distinct subspecies (Belay & Mori 2006). Geographic variation within *T. gelada* remains poorly documented and the taxonomy is in need of validation. Gippoliti (2010) provides a detailed review of the history of the taxonomy of *T. gelada*, and points out errors and misunderstandings therein. Here we follow the taxonomy of de Beaux (1925). Synonyms: *obscurus*, *ruppelli*, *senex*. Chromosome number: $2n = 42$ (Chiarelli 1962b).

Description A large-bodied, terrestrial quadruped similar in size and appearance to *Papio* spp. Highly sexually dimorphic; weight of adult ♀♀ about 60% that of adult ♂♂. Muzzle prognathic (but

less so than *Papio*) and rounded with suborbital maxillary hollows. Nose upturned. Skin black except whitish or pale pink eyelids and red skin patch on chest and neck shaped like an hour-glass. Pelage of dorsum pale brown to near black with gold, red and grey tones; darker around hands and feet. Redness of chest patch highly variable depending on age (Bergman & Beehner 2008), reproductive stage, recent activity, or social position (Bergman *et al.* 2009). Black ischial callosities on buttocks with two black smooth pads below callosities produce a 'four-leaf clover' pattern. Tail medium-length (shorter than *Papio*) with tuft at tip.

Adult ♂: mane (= mantle = cape) of long, thick golden hair on shoulders, anterior torso and head. Fur around face and chest patch often greyish. Canines long (mean 43 mm, 39–49mm, $n = 13$; Washburn & Ciochon 1974). Adult ♀: more uniform in pelage colour, no mane. Chest/neck patch pale pink surrounded by vesicles that swell to indicate the periovulatory period (vesicles also present on inner thighs and paracallosal skin). Female chest patch brighter red when in oestrus or pregnant. Infants: skin light, pelage black for first five months.

Geographic Variation

T. g. gelada Northern Gelada. West side of Rift Valley north of the deep gorges of the Belagaz R. and upper Tacazze R. in Begemdir

and Tigre Provinces (Yalden *et al.* 1977, Gippoliti 2010). Mane pale brown to chocolate. Circumpectoral pelage iron grey, not extensive.

T. g. obscurus Southern Gelada. West side of Rift Valley south of the deep gorges of the Belagaz R. and upper Tacazze R. in Wolle Province and northern half of Shoa Province (Yalden *et al.* 1977, Gippoliti 2010). Mane dark chocolate to near black. Circumpectoral pelage pure white, extensive, going to inner side of upper arms. Note that Groves (2001) and Grubb *et al.* (2003) are incorrect in stating that *T. g. obscurus* occurs east of the Rift Valley.

T. g. ssp. nov. Eastern Gelada. East of the Rift Valley in the Wabi Shebeli Gorge, Arsi region (Mori & Belay 1990). Smaller. Mane pale brown.

Similar Species

Papio spp. more uniformly coloured, lack chest patches and pads below ischial callosities, ♂♂ having only one 'joined' callosity. Hamadryas Baboon *Papio hamadryas* and Olive Baboon *Papio anubis* both found in Ethiopia, but they are rare above 2000 m whereas Gelada are rare below 2400 m (Yalden *et al.* 1996).

Papio hamadryas. Sympatric. Altitudinal overlap from ca. 1700 to 3300 m. Males and ♀♀ have lighter pelage and red skin on face and rear. Male's mane more grey/white.

Papio anubis. Sympatric. Altitudinal overlap from ca. 1700 to 3850 m. Sympatric at Debre Libanos (ca. 2000 m; C. J. Jolly pers. comm.). Small or moderate mane. Pelage darker, agouti. Tail longer with sharp bend ('broken') at base and no tuft.

Distribution Endemic to the mountains of Ethiopia. Afro-montane–Afroalpine BZ. Main population confined to high, afroalpine, grassland escarpments near deep gorges in the Central Ethiopian Plateau. To the west of the Rift Valley, Geladas occur (or once occurred) as far to the north-east as Mt Azbi (near Adigrat; 13° 87' N, 39° 74' E (Gippoliti 2010). Today, known west of the Rift Valley from Begemdir and Tigre Provinces in the north (ca. 13° N) through Wolle Province and northern half of Shoa Province south to 09° 29' N in the Muger R. Valley (9–14° N, 37–40° E; Yalden *et al.* 1977, 1996, D. Yalden pers. comm.). Western limit at Ambo Mineral Springs, ca. 24 km west of L. Tana (12° 00' N, 36° 40' E; Gippoliti 2010). Not today known from west or north of Blue Nile Gorge, which transects the Plateau. An isolated population lives in the Arsi Region, east of the Rift Valley (7° 30' N, 40° E; Mori & Belay 1990, 1991).

Habitat Restricted to high montane grasslands of Ethiopian Plateau (Jolly 1967, Pickford 1993). Found along grassland steppes near steep escarpment edges that provide refuge from predators and sleeping sites. Nutritional content of grasses eaten is sensitive to ambient temperature (Dunbar 1998). Availability of grasses restricts Gelada habitat to a typical altitudinal range of 2400–4200 m, but known from 1700–4600 m (Yalden *et al.* 1977, 1996, Iwamoto 1993, Hunter 2001). Water resources, mainly streams and ponds, plentiful. Mean annual precipitation ranges 1300–1500 mm in north to ca. 1100 mm in south (Kebede 1964, Dunbar 1998). Mean daily temperature ranges 7–10 °C in the north to ca. 16 °C in the south (Iwamoto & Dunbar 1983). Daily temperature range is large (~25 °C), commonly below freezing at night, suggesting

Gelada *Theropithecus gelada* adult male showing lip-flip.

high energetic demands of thermoregulation (Dunbar 1984). Gelada found in association with afroalpine vegetation dominated by montane grasses (mainly *Festuca* spp.), herbs (e.g. *Thymus* spp., *Trifolium* spp. and *Geranium arabicum*), Giant Heath *Erica arborea*, St John's Wort *Hypericum revolutum* and patches of Giant Lobelia (*Lobelia rhynchopetalum*) (Dunbar 1978).

Abundance Densities west of the Rift Valley range from 15–73 ind/km². Patchily distributed corresponding to areas of grassland near sleeping cliffs. Within patches, estimated densities of 147/km²

Theropithecus gelada

of available grass cover (Iwamoto & Dunbar 1983). In the 1970s total population west of the Rift Valley estimated at ca. 500,000 (Dunbar 1993a). Thought to be much lower at present. Population estimate for the only protected population area in which Gelada occur (in and around Simien Mountains N. P.) is ca. 4300 individuals (Beehner *et al.* 2007). Size of the population east of the Rift Valley (i.e. the Arsi population) is not known but appears to be extremely small.

Adaptations Diurnal and terrestrial. Activity budgets comprise moving 10–20%, resting 1–20%, social 10–30% and feeding 50–70% (Kawai & Iwamoto 1979, Hunter 2001). Geladas spend more time foraging than other herbivorous primates. Must feed more because of energy requirements for thermoregulation and to counterbalance low nutrient content of grass (Dunbar 1984). Physiological stress for Geladas highest at colder temperatures (either during colder months or at higher altitudes; Beehner & McCann 2008). They have specializations for grass foraging including: (1) ‘scooting’ locomotion, hindquarters on ground and foraging with both hands; (2) extra pad below ischial callosity allowing hindquarters to slide on ground while foraging; (3) first finger and thumb shortened and highly opposable, for grasping blades of grass. Probably related to frequent ‘scooting’ posture that obscures the rear, red chest patch signals reproductive state just as do perineal sexual swellings in *Papio* ♀♀. Function of patch in ♂♂ is unknown but thought to vary with level of strenuous activity (e.g. aggression) and social status (Dunbar & Dunbar 1974b, Dunbar 1984, Bergman *et al.* 2009).

Foraging and Food Graminivorous. Only graminivorous primate. Geladas forage primarily in a seated position while gathering blades of grass simultaneously with both hands. They carry grass sheaves to the mouth, remain in a seated position, move (scoot) ca. 0.5 m and renew grass-picking in next feeding bout. For subterranean food items, Geladas dig up items using both hands as hoes to scrape out ground, also in a seated position (Crook & Aldrich-Blake 1968, Iwamoto 1979). Feeding composed of picking 86% and digging 14% (Iwamoto 1979). They feed primarily on high-protein, monocotyledon grasses (mainly *Danthonia subulata*, *Festuca* spp. and *Agrostis* spp.) at altitudes above 1700 m (Dunbar 1977, Iwamoto 1979). Diet consists of ca. 90% grass, with addition of underground corms during the dry season (Iwamoto 1979, Hunter 2001). Geladas are non-ruminants. They digest a high cellulose diet chiefly by bulk feeding and thorough mastication of food (Dunbar & Bose 1991) with larger molars than *Papio* spp. (Teaford 1993). Day range ca. 1.5 km (0.7–3.2, $n = 55$), home-range ca. 7.2 km² (6.1–8.2, $n = 2$). Geladas feed throughout the day, although morning hours are preferentially spent on social activity (Kawai & Iwamoto 1979).

Social and Reproductive Behaviour Highly social. Complex, multi-level social structure, superficially similar to Hamadryas Baboons (Snyder-Mackler *et al.* 2012). The basic component of a Gelada group is a one-male unit (OMU): one breeding ♂, 1–12 adult ♀♀, dependent offspring and sometimes a follower male(s) (Mori 1979b, Kawai *et al.* 1983, Dunbar 1986). Other adult ♂♂ form all-male groups of 2–15 ♂♂ (Dunbar 1993b). OMUs and all-

Gelada *Theropithecus gelada* adult female showing sexual swellings and pectoral vesicles.

male groups that share a common home-range are called a ‘band’. Bands range from 30–250 individuals (Kawai *et al.* 1983, C. Hunter pers. comm.). OMUs from two or more bands that forage together form a ‘herd’. Herds may comprise as many as 1200 individuals; these are among the largest wild-foraging primate groups. No territorial behaviour. Before puberty, juvenile ♂♂ leave natal unit and join all-male groups (Dunbar & Dunbar 1975b). They remain in all-male groups for 2–4 years, then try to acquire access to reproductive ♀♀. There are two strategies: (1) take over existing OMU by ousting incumbent leader ♂ or, less commonly, (2) join unit as subordinate follower ♂ to acquire peripheral and/or juvenile ♀♀ (Dunbar 1993b). Male dominance hierarchy in all-male groups. Chasing displays between ♂♂ common, actual fighting rare. Males in all-male groups frequently harass OMU ♂♂ in attempt to take control of unit (Mori 1979c). Copulations only between OMU ♀♀ and incumbent leader ♂ (Mori 1979b).

Adult ♀♀ constitute core of Gelada society. Females remain in natal OMU for life and are close relatives (le Roux *et al.* 2011). Female dominance hierarchy within units (Mori 1979a, le Roux *et al.* 2011). High-ranking ♀♀ reproduce at a faster rate (Dunbar & Dunbar 1977, Dunbar 1980a, but see le Roux *et al.* 2011). Cohesion of OMUs maintained through ♀ bonds (Dunbar & Dunbar 1975b, le Roux *et al.* 2011). OMU ♀ bonds persist beyond tenure of one leader ♂ (le Roux *et al.* 2011). Females can join together, attack leader ♂ and evict him from the unit (Dunbar & Dunbar 1975b).

Geladas have one of the largest vocal repertoires in the Papionini (Gustison *et al.* 2012) with 22–30 distinct vocalizations (Kawai 1979), including 11 contact calls and 11 aggressive-defensive calls (Aich *et al.* 1990). The large number of contact vocalizations is thought to be related to their large, complex social system (Kawai 1979). Some vocalizations are unique to animals of various social status (e.g. emitted only by highest-ranking OMU ♀) (Aich *et al.* 1990).

Geladas *Theropithecus gelada*.

Reproduction and Population Structure Female reproductive condition signalled by swelling of vesicles around chest patch. Menstrual cycle 30.7 days (28–34, $n = 10$; Dunbar & Dunbar 1974d, Harvey & Clutton-Brock 1985). Median age at menarche 56.4 months (41–78, $n = 40$). Median age at first birth 68.8 months (57.8–81.0, $n = 13$; J. Beehner pers. obs.). Pregnancy indicated by reddening of chest patch by mid-gestation (Dunbar & Dunbar 1974d). Gestation 183 days (175–195, $n = 16$; Roberts *et al.* 2012). Weaning 517 days (163–736, $n = 17$; J. Beehner pers. obs.). Approximately 1–3 cycles per conception (Dunbar & Dunbar 1974d). Single offspring born per ♀ every 29 months (14–50, $n = 51$; J. Beehner pers. obs.). One possible case of twinning observed (J. Beehner pers. obs.). Birth-weight 464 g (Harvey & Clutton-Brock 1985). Birth sex ratio equal ($n = 134$; Ohsawa 1979, Dunbar 1980a). Adult ♂ to ♀ sex ratio 1:2.3–1:3.0 ($n = 2308$; Dunbar 1980a, Beehner *et al.* 2007). Adult sex ratio favours ♀♀ because of faster maturation and lower mortality (Dunbar 1984). Reproduction occurs throughout year with moderate birth peaks in Jun–Jul and Nov–Dec. Survivorship estimated to be 91% to 18 months of age and 88% to four years of age. Life expectancy at birth is 12.3 years for ♂♂ and 13.8 years for ♀♀ (Dunbar 1984). Live to at least 20.8 years in captivity (Jones 1982). Occasional mortality from intra-specific fighting (J. Beehner pers. obs.). Several reports of infanticide by adult ♂♂ (Moos *et al.* 1985, Mori *et al.* 1997, 2003), usually in the months following unit takeovers. Infanticide in Geladas appears to be part of the ♂ reproductive strategy (Beehner & Bergman 2008). See also Roberts *et al.* (2012).

Predators, Parasites and Diseases Primary predators are Leopards *Panthera pardus* and Spotted Hyaenas *Crocuta crocuta* (Dunbar 1984). Juveniles jump and look nervously at any large bird, suggesting that large raptors are also predators. Geladas killed by humans and domestic dogs. Some mortality caused by parasitic tapeworm, *Multiceps* sp. (Ohsawa 1979). Main cause of mortality probably respiratory and other infections contracted during periods of rain and subzero temperatures (Dunbar 1984, Ohsawa & Dunbar 1984).

Conservation IUCN Category (2012): Least Concern. Vulnerable as *T. g. gelada* and Least Concern as *T. g. obscurus*. CITES (2012): Appendix II.

In a review of the taxonomy and geographic range of Gelada, Gippoliti (2010) concluded that the diversity within Gelada may be grossly underestimated and that, as such, more research on the variability within Gelada is urgently required. Gippoliti (2010)

identifies priority regions for taxonomic research and conservation action.

It should be noted that the latest IUCN assessment of degree of threat for the Gelada is based on rough estimates made during the 1970s. More recent surveys indicate that the estimates of the 1970s were much too high. For example, the population of the Simien Mountains was estimated at 10,000 during the 1970s whereas a recent survey yielded an estimate of 4300 (Beehner *et al.* 2007). Numbers probably in decline due to restricted range and loss of specialized habitat. Geladas face intense competition from expanding human populations and their livestock. Geladas are hunted for ceremonial use of skins, killed for crop-raiding, and sold locally as pets. The only 'protected area' in which Geladas occur is the Simien Mountains N. P. (and World Heritage Site) but the protection here is poor (Beehner *et al.* 2007). Priority actions for the long-term conservation of this genus/species should be to enhance protection of the Simien Mountains N. P. (*T. g. gelada*), the Menz Highlands (*T. g. obscurus*) and the Arsi region (*T. g. ssp. nov.*). It is uncertain, however, how enhanced protection for these three sites might be achieved. Strengthening traditional local protection for the Guassa might help restore the conservation values of the Menz Highlands, otherwise an effectively managed national park seems necessary. The Arsi population may need protection within a national park in order to improve long-term prospects for survival. The taxonomic status of the Arsi population needs to be assessed (Belay & Mori 2006). A survey to determine the size and distribution of the Arsi population is a priority, as is an assessment of its IUCN/SSC Red List degree of threat status (since this is likely to be assessed as a Critically Endangered subspecies).

Measurements

Theropithecus gelada

HB (♂♂): 720 (690–740) mm, $n = 2$

HB (♀♀): 580 (500–650) mm, $n = 2$

T (♂♂): 480 (460–500) mm, $n = 2$

T (♀♀): 460 (320–640) mm, $n = 5$

HF (♀♀): 156 (154–157) mm, $n = 3$

E (♀♀): 41 (37–50) mm, $n = 3$

WT (♂♂): 19.0 (16.5–20.5) kg, $n = 5$

WT (♀♀): 11.7 (8.3–13.8) kg, $n = 8$

Various localities. HB, T, HF, E (Napier & Napier 1967, Hill 1970). WT (Dechow 1983).

Tribe CERCOPITHECINI

Cercopithecins: Guenons (Allen's Swamp Monkey, Talapoin Monkeys, Patas Monkey, Savanna Monkeys, Mountain Monkeys, Arboreal Guenons)

Gray, 1821. London Medical Repository 15: 296–310.

ABOVE: Tentative phylogenetic tree for the guenons Cercopithecini (partly after Tosi *et al.* 2005 and Moulin *et al.* 2008)

RIGHT: L'Hoest's Monkey *Allochrocebus lhoesti* skeleton.

BOTTOM RIGHT: De Brazza's Monkey *Cercopithecus neglectus* myology.

The Cercopithecini are, for the most part, generalized, long-tailed, medium-sized monkeys. For the purposes of this work, this tribe comprises six genera: *Allenopithecus*, *Miopithecus*, *Erythrocebus*, *Chlorocebus*, *Allochrocebus* and *Cercopithecus*. All are generally described as 'guenons' and, in the past, have occasionally been lumped in the single genus *Cercopithecus* (Verheyen 1962). These six genera are currently considered to embrace 33 species, making this quite the most speciose of all African primate taxonomic groups. Their ecological success seems to be based on extremely fast and well-coordinated movement in the trees, optimized body sizes for each species-specific substrate and, probably, physiological resistances to a variety of equatorial pathogens and parasites. The divide between Cercopithecini and Papionini is not clear-cut, with two genera, *Miopithecus* and *Allenopithecus*, showing a mosaic of features that make them difficult to allocate with any certainty; but they have non-papionine chromosome counts and are generally regarded as being stem guenon lineages that retain many conservative features in spite of being quite specialized in other respects.

Although there is little doubt that *Allenopithecus* and *Miopithecus* belong to the Cercopithecini, there has been some discussion about this because both have a mix of cercopithecine and papionine features. Like many papionins, but unlike other cercopithecins, both exhibit periodic

sexual swellings in the ♀. *Allenopithecus* has molar flare (the buccal and lingual walls of the molars are convex, so that the cusp tips appear somewhat drawn together), which is characteristic of most Papionini; and in the ♂ the ischial callosities fuse across the midline as in all genera of Papionini except for *Macaca*. On the other hand, *Allenopithecus* and *Miopithecus* both lack the maxillary fossae and the M_3 hypoconulids seen in (most) Papionini, and in this they resemble the other Cercopithecini. They appear to have a similar range of facial gestures as the Papionini, whereas the other Cercopithecini make less use of facial signals and appear to have less mobile faces. In the past this difference was taken to imply less developed social systems in the latter, more developed in the former. In fact it seems more likely to have a connection with some fundamental differences in mechanisms for social cohesion that might, in turn, be mediated by opposite facial signals. Dominant animals among arboreal species are less able to coerce conspecifics than species living mainly on the ground because escapes are easier and close approaches depend more upon conciliation than upon coercion (Marler 1965, Kingdon 2007). If cohesion among arboreal monkey species has forced group members to *avoid* sending aggressive or ambiguous signals to one another there could have been active selection for the suppression of emphatic facial signals such as those typical of terrestrial monkey species. These differences in visual communication deserve further study. All Papionini have diploid chromosome numbers $2n = 42$, whereas the numbers are higher than this in all Cercopithecini.

Diana Monkey *Cercopithecus diana*. Bottom, left to right: Owl-faced Monkey *Cercopithecus hamlyni*. De Brazza's Monkey *Cercopithecus neglectus*. L'Hoest's Monkey *Allochrocebus lhoesti*. De Brazza's Monkey *Cercopithecus neglectus*.

Eye-contact (aggressive/centrifugal) and eye-eversion (submissive/centripetal) in a guenon.

LEFT: Potentially expressive movements of the head and features of a guenon.

BELOW LEFT: Schematic diagram of tonal distribution on the faces of six guenons illustrating how 'flag' or 'visual target' designs can be enlarged or diminished, sometimes masking or compromising facial expressions. *Cercopithecus lowei* has least differentiated pattern. Arrows on disks suggest intensification of tonal contrast or extension of tonal area. Top to bottom: Owl-faced Monkey *Cercopithecus hamlyni*; De Brazza's Monkey *Cercopithecus neglectus*; Lowe's Monkey *Cercopithecus lowei*; Campbell's Monkey *Cercopithecus campbelli*; Vervet Monkey *Chlorocebus pygerythrus*; Diana Monkey *Cercopithecus diana*.

The majority of guenons are restricted to the equatorial forest belt but a small number of species, belonging to three groups, range more widely; the Savanna Monkeys Group *Chlorocebus* (*aethiops*) range throughout the more wooded parts of sub-Saharan Africa, the Patas *Erythrocebus patas* is primarily a Sahelian species, and the Gentle Monkeys Subgroup *Cercopithecus* (*mitis/albogularis*) have an extensive coastal, riverine and montane range, mostly through the south-eastern quarter of Africa.

Cercopithecini can be diagnosed and distinguished from most other Old World monkeys by possession of only four cusps on their third lower molars; but see Groves (1978) and Napier (1981) for discussion of the difficulties of making a clear-cut diagnosis. Cercopithecini vary in their chromosome count more than any other group of primates, with numbers ranging from 48 to 72. According to Dutrillaux *et al.* (1988b) and Ruvolo (1988) this genetic diversity is due to unusually frequent translocations and inversions.

Behavioural differences between guenons and papionins are subtle, but Rowell (1988) has noted some distinguishing traits, notably greater reliance on species-specific visual and vocal signals in guenons, and more emphatic gestural signals in papionins. Male guenons are generally intolerant of other conspecific adult ♂♂ and both sexes tend to defend territories in which ♂ tenure is often more ephemeral than in the hierarchical multimale societies that preponderate among papionins.

The evolutionary history of this tribe of primates has confounded the expectations of many early scientists. For example, in conformity with the widespread assumption that arboreal primates were definitively more 'primitive', Schwarz (1928b) regarded most of the very varied assemblage of *Cercopithecus* as deriving from the most arboreal forms. Subsequent molecular and morphological studies have shown that this pattern is actually an inversion with the most arboreal species being the most recently evolved (Verheyen 1962, Thorington & Groves 1970, Dutrillaux *et al.* 1980, 1988b, Ruvolo 1988, Purvis 1995). Dutrillaux *et al.* (1980) showed that there was a basal split in the earliest Cercopithecini into one branch that retained semi-terrestrial ancestral traits and a second branch that became more arboreal, culminating in two separate lineages of small, wholly arboreal monkeys; Mona Monkeys Group *Cercopithecus* (*mona*) and Cephus Monkeys Group *Cercopithecus* (*cephus*) (Dutrillaux *et al.* 1988b, Tosi *et al.* 2005; figure p. 245). Some of the roots of this counter-intuitive progression lie in the peculiar climatic history of Africa, which has often tended to favour non-forest and semi-arboreal organisms, as outlined in earlier profiles.

GENUS *Allenopithecus*

Allen's Swamp Monkey

Allenopithecus Lang, 1923. Amer. Mus. Novit. 87: 1.

A monotypic genus embracing Allen's Swamp Monkey *Allenopithecus nigroviridis*. Shares some resemblances with cercopithecins and with *Miopithecus* in particular, but also shares several conditions with the Papionini, notably fused ischial callosities in adult ♂♂, flared molars and periodic sexual swellings in ♀♀ (Groves 2001). Heavy build, short limbs, very broad hands and feet, leaf-shaped ears and shortish tail are also somewhat macaque-like. These features imply the selective retention of some conservative features combined with some specialized adaptation to the deep seasonal flooding of the riverine and swamp forests in which this species lives.

T. Harrison (pers. comm.), like Groves (2001) and others, considers papionin-like features of *A. nigroviridis* to be symplesiomorphies of Cercopithecidae with no implication of a close phylogenetic relationship. There is no fossil record for this genus.

Allenopithecus has a lower chromosome count than most Cercopithecini ($2n = 48$; other guenons range from 54 to 72 while all Papionini have 42). Early treatments sometimes placed this species within *Cercopithecus* (Pocock 1906), often as a subgenus

(Verheyen 1962). Molecular research (Tosi *et al.* 2005, Perelman *et al.* 2011) indicates that *Miopithecus* represents the surviving lineage closest to *Allenopithecus* (none the less they diverged 9.3–8.2 mya [late Miocene]). The same authors estimated an 11.5 (10.2–12.8) mya (mid-Miocene) separation between ancestral *Allenopithecus* and ancestral *Macaca*, thus confirming earlier studies that allied *Allenopithecus* with the Cercopithecini. Ruvolo (1988) positioned *Allenopithecus* as the first branch to separate out at the base of the cercopithecine tree. Instead, Dutrillaux *et al.* (1980, 1988b), in early comparisons of chromosome banding patterns, placed *Allenopithecus* below a deep bifurcation, close to the more arboreal branch of cercopithecins that became the genus *Cercopithecus*. The phylogeny adopted in this work broadly follows the arrangement supported by Tosi *et al.* (2005) and Perelman *et al.* (2011). See figure p. 245.

For other characteristics of this genus, see the species profile.

Colin P. Groves & Jonathan Kingdon

Allenopithecus nigroviridis ALLEN'S SWAMP MONKEY

Fr. Singe des marais; Ger. Sumpfmeeerkatze

Allenopithecus nigroviridis (Pocock, 1907). Proc. Zool. Soc. Lond. 1907: 739. Upper Congo R., DR Congo.Allen's Swamp Monkey *Allenopithecus nigroviridis* adult male.

Taxonomy Monotypic species. Originally described by Pocock as *Cercopithecus nigroviridis*. Separated from *Cercopithecus* by Thorington & Groves (1970). *Allenopithecus* first described as a genus by Lang (1923). Some morphological features more similar to those of macaques *Macaca*, drill mangabeys *Cercocebus* and baboon mangabeys *Lophocebus* than to guenons: ear shape (pointed), tooth shape (flare molars) and skull shape (more prominent and oblique than in

Cercopithecus; Verheyen 1962). These characters, as well as results from blood proteins analysis (Ruvolo 1988), chromosomal analysis ($2n = 48$; Dutrillaux *et al.* 1988b), vocal repertoires (Gautier 1988) and molecular studies, converge in suggesting that the Swamp Monkey is near the root of the cercopithecine tribe (Verheyen 1962). Synonyms: none. Chromosome number: $2n = 48$ (Dutrillaux *et al.* 1988b).

Description Medium size, stocky, khaki-coloured monkey, sexes similar in colour. Pronounced sexual dimorphism in body size and weight. Muzzle dark grey. Facial disc grizzled with long, dense fur on cheeks. Black lines around cheeks. Cheek hair bushy, directed backwards. Supraciliary band with stiff black hairs. Throat light grey. Upperparts and outer sides of limbs and tail are khaki-coloured. Limbs short. Tail shortish, only a little longer than HB (90–107%). Underparts dirty-white to grey. Both sexes have sexual skin. Adult ♂ especially stocky. Scrotum large, pale blue. Orange-red perineal patch of bare skin between the root of the tail and the dorsal margin of the callosities. Adult ♀ has more extensive sexual skin, which undergoes cyclical turgescence (Hill 1966). Pelage of newborn resembles that of adult but coat paler, more yellowish-brown. Crown markedly paler, covered with long, fine, silky, almost white hairs. Natal coat replaced at around ten weeks (Pournelle 1962).

Geographic Variation None recorded.

Similar Species None.

*Allenopithecus nigroviridis*

Distribution Endemic to central Africa: DR Congo and Congo. Presence in SE Cameroon and NE Angola requires confirmation. Rainforest BZ. Mainly linked to the left bank tributaries of the Congo R., between Lomami R. and Kasai R. Malbrant & Mclatchy (1949) reported Swamp Monkey from the right bank of Congo R. between Likouala R. and near the mouth of Sangha R. On islands in the Sangha R. close to Bomassa (N Congo) at border with Cameroon. One group seen on Ndoki R., 25 km north-east from Bomassa. Thus Swamp Monkey occurs at least to 01° 13' N; 16° 31' E in NW Congo. Probably limited in the north by Ubangui R. and its tributary Uélé R. In south could be present to Kwango R. Known limits of distribution: 03° N–06° 30' S; 16° 31'–26–27° E (Gautier 1985, Maisels *et al.* 2006b).

Habitat Riparian forests along rivers, lakes or islands, especially where hydromorphic soils are present: periodically inundated forests, swamp forests, low vegetation types such as dense thickets of *Pandanus*, impenetrable thickets of herbaceous vegetation (Zingiberaceae, Marantaceae, Araceae) and stands of palms (*Calamus*, *Ancistrophyllum*, *Eremospatha*) that occur in swampy areas, especially along small rivers (Gautier 1985). Altitudinal range from about 100 m to at least 350 m. Annual rainfall 1700–2100 mm (Ergo & de Halleux 1979).

Abundance Abundant in the Salonga N. P. (DR Congo), reaching 100 monkeys/km² (deduced from the sizes of three groups and their home-ranges; A. Gautier-Hion pers. obs.). Not observed in dry upland areas of Lomako Forest. Fairly common in the swamp forest bordering the Lomako River System (W. S. McGraw pers. comm.). Considering that suitable hydromorphic biotopes probably cover more than a quarter of the surface area on the left bank of the Congo R., and that the human population density there is low, Swamp Monkey populations are probably numerous and not yet threatened.

Allen's Swamp Monkey *Allenopithecus nigroviridis* adult male.

Adaptations Diurnal and semi-terrestrial. Incipient sacculated stomach suggests some capacities to digest plant material (Hill 1966). Large vocal sacs used for production of loud-calls by adult ♂ (Gautier 1988). Cutaneous glandular area on chest of adult ♂ (Hill 1966) used for scent-marking trunks and branches (Loireau & Gautier-Hion 1988). Along river edges Swamp Monkeys travel through the thickest vegetation at low levels, using stilted roots of *Pandanus* trees and walking across suspended soil and debris retained by the web of roots; where necessary they wade into the water or swim. Where the substrate is clear or unflooded they either walk across the ground with a quadrupedal stance like baboons *Papio* or they gallop. Swamp Monkeys in trees <10% of time. When in trees, usually <5 m high. Climbing into tall trees primarily relates to feeding. At night groups prefer to sleep in trees that overhang rivers. Swamp Monkeys are good swimmers, spontaneously plunging into the water, especially when alarmed. During the day and on terra firma, they flee on the ground (Gautier 1985, Gautier-Hion *et al.* 1999).

Foraging and Food Omnivorous. Fruits, seeds, arils, stems, piths of herbaceous plants, cotyledons of young seedlings, stems of palm seedlings, young leaves, leaf petioles, flowers, nectar and mushrooms are eaten. Animal prey, including flying insects, spiders, caterpillars, small fishes, crustaceans and snails, account for about 20% of the diet. Earthworms are probably eaten. Swamp Monkeys

Lateral view of skull of Allen's Swamp Monkey *Allenopithecus nigroviridis* adult male.

forage in groups or subgroups. Plant food taken from trees, shrubs and herbs near the ground level. They forage mainly on the ground, picking up fallen mature and immature dry fruit and seeds that have fallen from tall trees. Succulent ripe fruits are, however, mainly harvested directly from trees. Among the most conspicuous of the foraging activities are the uprooting of numerous young palm saplings (20–30 cm high) and digging. In freshly drained areas Swamp Monkeys regularly sift the litter, scratching or digging holes to a few centimetres depth to expose animal prey, probably earthworms. Up to 35 monkeys seen digging simultaneously. Intensive seasonal feeding on nectar of *Daniellia pynaertii* (Caesalpinaceae) flowers (Gautier-Hion & Maisels 1994). In inundated areas covered by herbaceous plants or *Pandanus* shrubs they spend long periods diving and surfacing, presumably in search of aquatic prey. Also wade rivers and actively fish with one hand (Gautier-Hion *et al.* 1999).

Allen's Swamp Monkey *Allenopithecus nigroviridis* adult male.

Social and Reproductive Behaviour Social. At Salonga N. P. the size of groups ranged from 23 to 57 individuals (mean 35, $n = 26$). One group of at least 85 individuals was counted early in the morning close to their sleeping site, suggesting that subgroups may forage independently during the day. Groups are multimale but the ratio of adult ♂♂ to adult ♀♀ is low; only four adult ♂♂ in a group of 32 individuals. During progression, large adult ♂♂ may be grouped together at the front of the group. Solitary adult ♂♂ occasionally observed (Gautier-Hion *et al.* 1999, A. Gautier-Hion pers. obs.). At Lomako only groups of four individuals ($n = 3$) were seen (McGraw 1994).

The shape of home-ranges (50–70 ha; $n = 3$) is determined by river banks and their hydromorphic habitat. No overlaps among home-ranges yet detected, nor have any territorial interactions been observed (A. Gautier-Hion pers. obs.). There are no data on courtship, mating behaviour, or parent–young interactions. Swamp Monkeys found in polyspecific associations in about 30% of 56 cases. These associations included one to four species; Wolf's Monkey *Cercopithecus wolffi*, Red-tailed Monkey *Cercopithecus ascanius*, Black Mangabey *Lophocebus aterrimus*, Red Colobus *Procolobus badius tholloni* and Angola Colobus *Colobus angolensis*. Bi-specific groups were the commonest (38%), followed by tri-specific (27%) and quadri-specific (30%) groups. Wolf's Monkey was present in 75% of cases. The presence of Swamp

Monkeys in polyspecific associations is of short duration. No mixing between Swamp Monkeys and De Brazza's Monkey *Cercopithecus neglectus* observed (A. Gautier-Hion pers. obs.).

Vocal repertoire of the Swamp Monkey is consistent with its having branched off a common cercopithecine ancestral stock. Cohesion-contact 'grunts' and warning 'chirps' are very similar to those of Putty-nosed Monkeys *Cercopithecus nictitans*; loud-calls of adult ♂♂ recall the 'gobble' of mangabeys; the copulation 'quaver' given by ♀♀ recalls that of ♀♀ red colobus *Procolobus*. Finally, the metallic components of its chirps recall those of talapoin *Miopithecus* (Gautier 1988). When arriving at their sleeping sites, Swamp Monkeys, like talapoin, utter a chorus of calls that include most of their repertoire, including the isolation calls of young, alarms, 'screams' and cohesion calls, all punctuated by the gobbles of adult ♂♂. During and after copulation, adult ♀♀ give specific calls that are frequently heard but are easily mistaken for those of adult ♀♀ Tshuapa Red Colobus *Procolobus rufomitatus tholloni*.

In the field, only one olfactory marking episode observed; an adult ♂ embraced a trunk at 6 m above the ground while rubbing it up and down with his throat and chest (A. Gautier-Hion pers. obs.). In captivity marking is typically provoked in adult ♂♂ by the introduction of new supports into the enclosure; ♂♂ rub the new supports with their muzzle, throat and chest and occasionally stop to scratch the chest or lick the marked area. Females show no marking behaviour but they do sniff marked areas.

Allen's Swamp Monkey *Allenopithecus nigroviridis* adult male.

Reproduction and Population Structure Adult ♀♀ have regular sexual swellings. Gestation lasts about 5½ months. In the wild, ♀♀ with young infants observed in Feb–Apr while copulation calls heard mainly during Jul–Aug (A. Gautier-Hion pers. obs.). This suggests a seasonal pattern of reproduction similar to that found in guenons, where the mating period coincides with the main dry season and birth period with the short dry season (Butynski 1988). Females give birth to one young. Birth weight 221 g. Ratio of adult ♂♂ to adult ♀♀ in groups is about 1 : 8. Population structure, longevity, birth and mortality rates are unknown for wild populations. Live to at least 23 years in captivity (Jones 1982).

Predators, Parasites and Diseases No predation events observed. Close to villages (where Swamp Monkeys feed on nuts of Oil Palms *Elaeis guineensis*) they are sometimes captured in traps. Like other guenons, Swamp Monkeys utter loud alarm calls towards raptors. Carnivores and snakes are likely predators as well. As with *Miopithecus*, locating their sleeping sites close to river banks constitutes an effective anti-predator strategy. Nothing known concerning diseases and parasites.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The Swamp Monkey's preference for hydromorphic habitats provides some protection against predators (including hunters) and habitat destruction (including loggers). However, Swamp Monkeys are prone to hunting and trapping. Since 1981 extensive logging concessions have been granted in the Congo Basin.

Measurements

Annie Gautier-Hion

GENUS *Miopithecus* Talapoin Monkeys

Miopithecus I. Geoffroy, 1842. C. R. Acad. Sci. Paris 15: 720.

This genus includes two species, the Southern Talapoin *Miopithecus talapoin* and Northern Talapoin *Miopithecus ogouensis*. *Miopithecus talapoin* occurs in lowland forest south of the Congo R. from the Angolan coast and Kwango R. Valley east to the Kasai R. (Thompson 2001). *Miopithecus ogouensis* occurs in lowland forest north of the Congo R. throughout much of the Ogooué R. Basin as far north as the Sanaga R. There are no fossils closely related to this genus.

The chromosome count for *Miopithecus* is $2n = 54$, which is the same as for Patas *Erythrocebus patas* (it is striking how infant Patas resemble enlarged, longer-limbed versions of young *M. talapoin*). The phylogenetic position of this lineage of highly distinctive and diminutive monkeys has recently been revised. There is strong statistical support for the view that *Miopithecus* evolved after the common ancestor of the terrestrial cercopithecins (Xing *et al.* 2007). This conclusion, based upon SINE insertions, is surprising because *Miopithecus* shares many features with *Allenopithecus*, while the other three genera of semi-terrestrial guenons (*Erythrocebus*, *Chlorocebus*, *Allochrocebus*) share more of their external characteristics with the arboreal guenons (*Cercopithecus*) than they do with either *Miopithecus* or *Allenopithecus*. However, it should be noted that putatively the most primitive member of the arboreal *Cercopithecus* radiation, Dryad Monkey *Cercopithecus dryas*, is also a diminutive monkey, supporting the concept that the *Cercopithecus* lineage started as small-bodied animals.

Another recent molecular study (which retains *Miopithecus* closer to *Allenopithecus*) estimates that *Miopithecus* diverged from *Erythrocebus* >8 mya (late Miocene) and from *Allenopithecus* 9.3 mya (Tosi *et al.* 2004). See also Perelman *et al.* 2011. In several respects (body-size, large social groups and preference for riverine understorey vegetation, not to mention its greenish pelage and strictly seasonal breeding), *Miopithecus* shows convergent characteristics with the South American squirrel monkeys *Saimiri* spp.

Lateral view of skull of Northern Talapoin Monkey *Miopithecus ogouensis* adult male compared with that of Patas Monkey *Erythrocebus patas* juvenile.

Miopithecus can be diagnosed by small size and associated paedomorphic features (especially the small facial skeleton compared to the large braincase), the reduced hypoconulid on the third lower molar, the female's periodic sexual swellings, and the highly developed facial gestures, in which it resembles the Papionini (in most Cercopithecini facial gestures have been replaced by whole-head movements that emphasize species-specific colour patterns). Body proportions appear to differ between the two species of *Miopithecus* but detailed comparative studies have yet to be made. For all specific characters, see species profiles.

Jonathan Kingdon & Colin P. Groves

Miopithecus talapoin SOUTHERN TALAPOIN MONKEY (ANGOLAN TALAPOIN MONKEY)

Fr. Talapoin du sud; Ger. Südliche Zwergmeerkatze

Miopithecus talapoin (Schreber, 1774). Die Säugethiere 1: 101, 186, pl. 17. Angola.Southern Talapoin Monkey *Miopithecus talapoin* adult male.Southern Talapoin Monkey *Miopithecus talapoin* adult male.

Taxonomy Monotypic species. Disputed taxonomy. Originally named *Simia talapoin* Schreber, 1774, then included in the genus *Cercopithecus* (Erxleben 1777), then raised to the genus *Miopithecus* (I. Geoffroy, 1842). On the basis of craniological studies, considered a subgenus of *Cercopithecus* (Verheyen 1962). Type specimen of unknown origin but (wrongly) thought by Pocock (1907) to be from Gabon or Cameroon. He then described a new subspecies from Angola, *M. t. ansorgei* (Pocock, 1907). Machado (1969), examining 15 live or dead specimens from Angola, showed that the type specimen corresponded to monkeys found on the left bank of the Congo R. and not from Gabon or Cameroon. *Miopithecus t. ansorgei* was then subsumed in *M. talapoin*. The northern form is now named *Miopithecus ogouensis* Kingdon, 1997. The subspecies *pilettei* Lönnberg, 1919 from Mt Rwenzori, E DR Congo, is likely due to a deception or false provenance (Gautier-Hion *et al.* 1999). Synonyms: *ansorgei*, *capillatus*, *melarhinus*, *niger*, *pileatus*, *pilettei*, *vlesschouwersi*. Chromosome number: unknown.

Description Small, grizzled, yellowish-olive monkey. Africa's second smallest monkey. Sexes similar in colour. Adult ♂ larger than adult ♀. Lips and subocular areas ochre-pink. Cheeks and chin white. Facial mask bare, black. Ears large, bare, black. Head and back grizzled yellowish-olive. Outer limbs pallid chrome-yellow. Tail grizzled brown above and yellowish-grey below. Underparts and inner surfaces of limbs white. Females: pink sexual swellings. Scrotum pale blue (Machado 1969, Kingdon 1997).

Geographic Variation None recorded.

Similar Species

Miopithecus ogouensis Northern Talapoin. North of Congo R. Allopatric. Slightly smaller; pelage shorter; ears relatively small; bare skin of face and ears pinkish; outer limbs golden-yellow; underside yellowish to greyish-white not contrasting sharply with sides.

Distribution Endemic to N Angola and SW DR Congo south (left bank) of lower Congo R. Rainforest BZ. Present in SW DR Congo (from 04°S) and coastal regions of N Angola (up to 12°30'S; Machado 1969), extending to the eastern limit of the floodplain especially along tributaries of the Kwango R. in the Kasai R. watershed (about 18°E; Gautier-Hion *et al.* 1999). Recently discovered on right bank of Kasai R. at Mimia (02°29'S, 20°E, Thompson 2001). This discovery brings the range of *M. talapoin* close to that of Allen's Swamp Monkey *Allenopithecus nigroviridis*.

*Miopithecus talapoin*

Lateral view of skull of Southern Talapoin Monkey *Miopithecus talapoin* adult male.

Habitat Not well known. Likely a riverine species (as *M. ogouensis*) living in dense vegetation and colonizing old plantations (Machado 1969).

Remarks One of Africa's least known monkeys. Ecology and behaviour not studied but likely similar to *M. ogouensis*. Kingdon (1997) suggests that *M. talapoin* could have more terrestrial habits than *M. ogouensis*, as a result of longer dry seasons and less extensive flooding due to cooler and drier climate.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Miopithecus ogouensis NORTHERN TALAPOIN MONKEY (GABON TALAPOIN MONKEY)

Fr. Talapoin du nord; Ger. Nördliche Zwergmeerkatze

Miopithecus ogouensis Kingdon, 1997. The Kingdon Field Guide to African Mammals, p. 55. West Gabon.

Northern Talapoin Monkey *Miopithecus ogouensis* adult female.

Northern Talapoin Monkey *Miopithecus ogouensis* adult female.

Taxonomy Monotypic species. There has been much confusion concerning the taxonomy of the northern and southern forms of talapoin monkeys. Machado (1969) found that the description for the type form *Miopithecus talapoin*, commonly called 'Gabon Talapoin', was based on a specimen from south of the Congo R. not from north of the Congo R. He convincingly argued that there were two species of talapoins but provided no formal description or name for the northern species. His claim that there were two species was subsequently supported by research on cellular and endogenous viral sequences that also suggested the existence of subspecies (Van der Kuyl *et al.* 2000). The brief description and name for the Northern Talapoin, *Miopithecus ogouensis*, put forth by Kingdon (1997, p. 55) as 'A *nomen nudum* ... in anticipation of a formal description' was accepted (Groves 2001, Grubb *et al.* 2003). It is important to note that, as a result of these recent taxonomic changes, most of the published data on talapoin monkeys are based upon observations of *M. ogouensis*, not on *M. talapoin* as stated. Synonyms: none. Chromosome number: 2n = 54 (Dutrillaux *et al.* 1988b).

Description Smallest Old World monkey. Sexes similar in colour. Adult ♀ weighs about 82% as much as adult ♂. Head large. Lips and eyelids yellowish-pink. Nose and 'sideburns' slightly darker than face. Cheek-stripes black. Face and ears naked and flesh-coloured. Crown and dorsal pelage speckled, varying from yellowish-olive to olive-brown. Ears and preauricular tufts small. Pelage short. Limbs thin. Outer surface of limbs, hands and feet yellowish to golden-yellow. Inner surfaces of limbs and ventral surface vary from yellowish to greyish-white, not contrasting sharply with sides. Sides of tail greyish, ventral and dorsal surfaces yellowish, darker at tip. Underside of tail base yellowish. Adult ♀ ♀ with pink sexual swellings. Scrotum large, pale blue. Young similar in colour to adults.

Geographic Variation None recorded.

Similar Species

Miopithecus talapoin Southern Talapoin. South of Congo R. Allopatric. Slightly larger; pelage longer; ears relatively large; bare skin of the

Lateral, palatal and dorsal views of skull of Northern Talapoin Monkey
Miopithecus ogouensis adult male.

face and ears black; outer limbs pallid chrome-yellow; underside white or whitish contrasting sharply with sides (Kingdon 1997, Groves 2001).

Distribution Endemic to central Africa. Rainforest BZ. Coastal watersheds of S Cameroon, W Congo, Equatorial Guinea (Rio Muni), Gabon and Angola (Cabinda). From the Atlantic coast eastward to the upper reaches of the north-west tributaries of the Congo R. (e.g. Alima R., Likouala R., Sangha R., Dja R.). Northern limit is at ca. 06° N in Mbam et Djerem N. P., C Cameroon (Maisels *et al.* 2006a). Southern limit is in Cabinda at ca. 05° 40' S. Not found in the region south of the loop of the Ogooué R. (Lopé Reserve, Forêt des Abeilles, Mt Doudou area) (Gautier-Hion *et al.* 1999). Reported, but not confirmed, in gallery forest in Central African Republic at ca. 08° N (Blancou 1958, J. L. Tello pers. comm.). Known limits of distribution: 06° N–05° 40' S; 08° 36'–16° E (Maisels *et al.* 2006a).

Habitat Riverine forest, flooded forest, swamp, secondary forest and old plantations. Favours dense undergrowth of lianas and small shrubs; avoids primary forest with open undergrowth. Not known to occur farther than 500 m from a water-course with suitable night sleeping sites. Such water-courses must be at least 10 m wide and deep enough to allow the monkeys to dive and swim (Gautier-Hion 1971a). Altitudinal range is from sea level to at least 400 m. Annual rainfall 1600 mm to >2800 mm.

Abundance Night censuses by boat along banks of Ivindo R., NE Gabon, yielded a minimum of 0.16 groups/km (n = 50 km), and a density of ca. 30–40 ind/km². Mean density based on home-ranges of three commensal groups was 90 ind/km² (Gautier-Hion 1971a).

Miopithecus ogouensis

Adaptations Diurnal and arboreal. Vertical thin-stems specialist able to leap vertically between thin supports. Spends most of the day in low vegetation, sometimes near the ground. Individuals (mainly juveniles) may gallop on the ground over short distances when obliged to cross open areas. Sometime stands up on hindlegs and tail tip in a 'tripod' posture (Gautier-Hion 1971a, b). Good swimmer with head submerged. Dives into water when disturbed at the sleeping site. Immatures play together in water. A 3–4-month-old hand-reared baby spontaneously plunged into a water bucket (Gautier-Hion & Gautier 1971). In NE Gabon one group swam every evening and morning to and from its sleeping site on a small island 20 m from the mainland (J.-P. Gautier pers. comm.). Each group regularly uses the same sleeping site (80% of time for nine groups, n = 343 nights). Sleeping sites always located near a river. Subgroups of up to four individuals sleep huddled together in trees, palms or lianas overhanging rivers (Gautier-Hion 1971a).

Foraging and Food Frugivorous-insectivorous. Northern Talapoins forage in a group. They are agile and lively monkeys; daily movements average 2300 m (1500–2950, n = 120 days, three groups) with two peaks, one in early morning (mean 400 m/h) and one at 16:00–17:00h (350 m/h). Home-range size averages 120 ha (110–140, n = 3 groups), of which at least 50% is seasonally flooded forest. They forage for fruit mostly during early morning and late afternoon, and for insects at all times of day. Arthropods comprise up to 80% of stomach contents (mean 35% of diet). Favoured mobile prey are Orthoptera (ca. 50% of prey), and moths and butterflies. Also eat caterpillars, spider cocoons and ants. Fruit and seeds account for ca. 58% of overall diet, and ca. 90% of the plant portion of the diet. Leaves and buds make up ca.

6% of the diet. About 70% of the food is taken from flooded forest, and at least 13% taken from lianas. Groups close to human settlements feed heavily on cassava tubers taken from cassava soaking sites, especially when fruit is in short supply (i.e. when fruit accounts for <45% of the diet). Also raids crops of maize and cucumbers (Gautier-Hion 1971a).

Social and Reproductive Behaviour Social. Multimale groups of 34–115 individuals (NE Gabon). Largest groups are those living close to human settlements (mean 66 animals, $n = 4$ vs. mean 37 animals, $n = 6$ for 'wild' groups). No clear evidence of territorial behaviour (Gautier-Hion 1971a). One group of 70 animals observed in Cameroon (Rowell 1973). During daily travels adult ♂♂ are grouped at the front of the group with a few moving at the back; pregnant and lactating ♀♀ with their infants tend to be grouped on their own; juveniles follow in subgroups of up to ten individuals mixed with some adults and subadults. During day resting (11:00–14:00h) adult ♀♀ with infants and juveniles stay at the centre of the group. Adult ♂♂ and oldest subadults stay at the periphery. In the evening, juveniles go back to their mothers (Gautier-Hion 1970). During one breeding period, Rowell (1973) observed an almost complete segregation of the adults by sex. She also recorded 'baby sitting' of juveniles by adult ♂♂. During one month in the mating season, Rowell & Dixon (1975) found that adult ♂♂ travel more with adult ♀♀, and that ♀♀ leave their infants (about six months old at this period) with juveniles. Only ♀♀ observed to carry young. Mothers push away attempts from other ♀♀ to carry their babies (Gautier-Hion 1971b).

During the night three main types of subgroups are formed: female-offspring subgroups, either pregnant ♀♀ with 1–2 juveniles (1–2 years of age) or lactating ♀♀ with infants plus 1–2 juveniles; immature subgroups (juveniles and/or subadults 2–4 years of age); lone adult ♂♂ or sometimes pairs of adult ♂♂. Immature subgroups and lone adult ♂♂ tend to sleep in higher strata than female-offspring subgroups (Gautier-Hion 1970, 1971a). Northern Talapoin are occasionally found in polyspecific associations with other arboreal cercopithecines, most often Moustached Monkeys *Cercopithecus cephus*. There is, however, no consistent tendency to form such associations (Gautier & Gautier-Hion 1969).

Highly graded vocal repertoire that includes 11 basic call types within which there are 31 different sounds. Some calls are very high pitched. A specific call is given during copulation by one or both partners. Harassing calls also given by immatures towards mounting or copulating animals (Gautier 1974). Low pitched 'cohesion calls' by adult ♀♀ and immatures precede and accompany oriented group movements (Gautier 1974). The frequency of the cohesion call increases as the likelihood of loss of contact among individuals in the group increases. Adult ♂♂ give a deeper cohesion call than adult ♀♀. The cohesion call is given in long series by a single adult ♂ during oriented group movements or during a change of route. Adult ♀♀ and immatures also give the cohesion call after any strong disturbance (Gautier 1974).

Reproduction and Population Structure Males reach full adult size at about six years. Females give birth for the first time at about four years ($n = 4$; Gautier-Hion & Gautier 1976). Northern Talapoin are highly seasonal breeders. Mating takes place during the

long dry season (Jun–Aug); births during the short dry season (Jan–Feb; Gautier-Hion 1968, 1971a; Rowell 1973). In a given group all ♀♀ (up to 27) may give birth in less than a two-month period (Dec–Jan; Gautier-Hion 1970). Most ♀♀ breed every year. At the peak of sexual activity sexual skin surrounds the callosities and the anus (Gautier-Hion 1968). Copulation is preceded by a display during which the ♂ and the ♀ follow each other in a *chassé-croisé*: partners look at one another, the ♀ presents to ♂, ♂ sniffs the female's genitalia; partners wait for each other, groom and make mutual hand contact. These displays observed both in wild and in captivity and may last >30 minutes. Captive ♀♀ copulate up to nine times per day with the same ♂ (Gautier-Hion 1971b). Adult ♂ sexual behaviour is dependent upon rank (Scruton & Herbert 1970, Gautier-Hion 1971b). Mode cycle duration in captive ♀♀ is 31 days ($n = 43$; Rowell 1977) and mean cycle duration is 33 days (Scruton & Herbert 1970). Gestation is 158–166 days ($n = 6$; Rowell 1977). At birth the infant weighs ca. 180 g ($n = 2$), which is about a fifth of the female's weight. Head of the newborn infant almost as large as its body. Twins not observed (Gautier-Hion 1971b). A captive ♀ died when 25 years old and a captive ♂ at 19 years (A. Gautier-Hion pers. obs.).

In one group of 115 individuals in NE Gabon, the adult sex-ratio was 13 ♂♂ to 27 ♀♀ (1 : 2). Adults constitute about 35% of group members. At the end of the birth season the group included 27 newborns, 16 juveniles one year old, 21 juveniles two years old and 11 subadults (Gautier-Hion 1971a).

Predators, Parasites and Diseases Since Northern Talapoin are small (1–2 kg), they are potential prey for numerous carnivores, raptors and snakes. African Golden Cats *Profelis aurata* observed several times at dusk close to a group arriving at its sleeping site, inducing alarm calls by monkeys. In the dense low strata typically used by Northern Talapoin, their small size and homochromatic colour make them difficult to see. In addition, the consistent location of their sleeping sites over rivers constitutes an effective anti-predator strategy. Female-offspring subgroups sleep closer to the water than other subgroups, sometimes less than 3–4 m above the water (Gautier-Hion 1971a). No data available on parasites or disease.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The Northern Talapoin remains widespread and abundant. In the 1960s cassava eating by Northern Talapoin was widespread. In NE Gabon every village had 'its' Northern Talapoin group, which regularly slept in trees and lianas overhanging the place where villagers washed themselves each evening. In so doing, Northern Talapoin probably gained protection from predators deterred by human presence, and stayed close to cassava soaking sites located close to settlements. Northern Talapoin in NE Gabon were not fearful of people in the 1960s because hunters did not waste a cartridge for such a small prey. Trapping campaigns were undertaken only when crop-raiding became excessive. They were not at all afraid of women and just hid in the close-by foliage when they arrived to collect the cassava (Gautier-Hion 1971b). The situation has since changed; with increasing scarcity of game from over-hunting Northern Talapoin are now hunted. In 1982 the main commensal groups studied between 1965 and 1968 were no longer present close to the villages (J.-P. Gautier pers. comm.).

Key References Gautier-Hion 1970, 1971a; Oates 2011; Rowell 1973; Rowell & Dixon 1975.**Annie Gautier-Hion****GENUS *Erythrocebus*****Patas Monkey***Erythrocebus* Trouessart, 1897. Catalogus Mammalium tam Viventium quam Fossilium 1: 19.Patas Monkey *Erythrocebus patas* adult male.

Erythrocebus is a monotypic genus. The single species, the Patas Monkey *E. patas*, is so distinctive, both in its appearance (lanky, greyhound-like proportions; overall red colour with white underside;

small moustache) and in its habitat (open grasslands and woodlands), that it has almost invariably been awarded generic status separate from *Cercopithecus*. None the less, both morphological (Groves 1989, Sargis *et al.* 2008) and molecular evidence now indicate its close affiliation with savanna monkeys *Chlorocebus* and mountain monkeys *Allochocebus* (Dutrillaux *et al.* 1988a, b, Tosi *et al.* 2004, Tosi 2008). There is no evidence for *Erythrocebus* ever occurring south of its present limits in N Tanzania (De Jong *et al.* 2009). Chromosome number $2n = 54$ (Romagno 2001).

Erythrocebus shares with *Chlorocebus* a number of derived cranial features: the orbits in lateral view do not slope forward inferiorly; the tympanic tube has a V-shaped lower margin (seen only in juveniles in *Cercopithecus*); and the orbits are angular instead of oval. At the same time, the two genera lack derived conditions of *Cercopithecus* (shape of the nasal aperture and nasal bones, and conditions of the upper incisors). As shown by Gebo & Sargis (1994), *Erythrocebus* shares the extreme adaptations to terrestriality of *Allochocebus* (as listed under that genus).

Like other members of the Cercopithecini, *Erythrocebus* lacks molar flare and a hypoconulid on the third lower molar, and the ♀ does not develop prominent sexual swellings. Ischial callosities small and well separated in both sexes. Skull of the ♂ distinctive, with a long, narrow but protuberant muzzle. Hands and feet show more resemblances with *Chlorocebus* than with any other guenons (Kingdon 1988a).

Current molecular evidence suggests that *Erythrocebus* diverged from the cercopithecine tree during the Messinian (5.3–4.5 mya), an exceptionally dry period that probably led to the early evolution of Saharan endemics (Purvis 1995, Perelman *et al.* 2011). Such an origin is consistent with restriction of *Erythrocebus* to the southern margins of the Sahara/Sahelian belt, although it seems unlikely that the ancestral *Erythrocebus* was as extremely adapted to drought and open landscapes as is the extant *E. patas*. Kingdon (1971) suggests that the later emergence of *Chlorocebus* might have served to displace *Erythrocebus* from more mesic habitats (e.g. woodlands) out into the drier margins of its range, with concomitant adaptations.

Colin P. Groves & Jonathan Kingdon

Erythrocebus patas PATAS MONKEY (HUSSAR MONKEY, NISNAS)

Fr. Patas; Ger. Husarenaffe

Erythrocebus patas (Schreber, 1775). Die Säugethiere 1: 98. Senegal.Patas Monkey *Erythrocebus patas* adult male.

Taxonomy Polytypic species. Three subspecies recognized here, in contrast to Kingdon (1997), who recognized four (*E. p. patas*, *E. p. pyrrhonotus*, *E. p. baumstarki* and *E. p. villiersi*), Dorst & Dandelot (1969), who recognized two (*E. p. patas* and *E. p. pyrrhonotus*) and Groves (2001, 2005c, Grubb *et al.* 2003), who recognized none. The decisions to recognize no subspecies were assisted by documented changes in females' facial colouration with changes in reproductive condition (Loy 1974, Palmer *et al.* 1981). Loy (1974) reported that the animals in his captive colony originated from Ethiopia. Following Napier (1981), Groves (2001, 2005c) suggested that these changes could account for some of the variation that had been previously attributed to subspecific variation. Loy later found, however, that the animals originated from Nigeria (Goldman & Loy 1997, J. Loy pers. comm.). In a ten-year study of Patas in Kenya, Isbell *et al.* (2009) found that although pelage colour of individual ♀♀ may vary from light orange to orange-red over time, facial colouration does not change with reproductive status and nose colouration remains white once ♀♀ reach adulthood. These differences in facial colouration suggest that Patas in West Africa (*E. p. patas*) and Patas in most of East Africa (*E. p. pyrrhonotus*) are distinct subspecies. The Tanzanian population (*E. p. baumstarki*) is apparently isolated (De Jong *et al.* 2009), a condition that would facilitate the evolution of subspecific differences. The facial colouration of adult ♂♂ is different from all other populations, noticeably lacking a white moustache and white nose. This population is thus also considered a subspecies. The Aïr Massif, C Niger, population, has been assigned to the subspecies *villiersi*. This isolated population is said to differ from *E. p. patas* only in body size, a characteristic that is also heavily influenced by environmental conditions. In the absence of other differences, particularly facial colouration, we do not here recognize *villiersi* as a subspecies of *E. patas*.

The year that Schreber described and named Patas is variously given as '1774' (Dandelot 1974, Napier 1981, Groves 2001, Grubb *et al.* 2003) or '1775' (Hall 1966, Groves 2005c). Examination of this publication indicates that the correct year is '1775'.

Synonyms: *albigenus*, *albo-fasciatus*, *albosignatus*, *baumstarki*, *circumcinctus*, *formosus*, *kerstingi*, *langheldi*, *nigro-fasciatus*, *poliomystax*, *poliophaeus*, *pyrrhonotus*, *rubra*, *rufa*, *sannio*, *villiersi*, *whitei*, *zechi*. Chromosome number: $2n = 54$ (Baylet & Grattepanche 1964).

Description Medium-sized, long-legged, terrestrial monkey with reddish-brown crown, back and flanks, and cream or white below. Deep-chested but torso slender and limbs longer than those of other primates of similar size. Adult ♂: chest and front of neck cream or white. Scrotum turquoise or aquamarine blue. Anus red. Proximal one-third of tail carried arched behind the body while walking. Adult ♀: weighs about half as much as adult ♂ and with less contrast in colour. Tail less arched. Infant: face pink, pelage dark brown or black when born, changing to adult ♀ colouration by three months. Scrotum changes from grey to blue at ca. three years of age. Photographs of *E. patas* from several countries available at: www.wildsolutions.nl

Geographic Variation Three subspecies recognized:

E. p. patas Western Patas Monkey. Senegal to Chad. Adult ♂: chin white; muzzle pinkish, grey or black; nose black; cheeks grey or white, ruffed with long hairs; 'moustache' white; ear tips white. Neck, back and flanks fawn with long hairs. Chest and ventrum beige. Shoulders with cape-like pelage, red hair mixed with grey and black. Lower legs and feet white. Adult ♀: similar to adult ♂ but legs and feet cream to orange-red. During pregnancy facial

*Erythrocebus patas*

skin becomes lighter, facial hair, especially on nose, turns white, and black temporal and superciliary lines disappear (Loy 1974).

E. p. pyrrhonotus Eastern Patas Monkey. Sudan to W Ethiopia, N DR Congo, N Uganda and localized areas of W and C Kenya (De Jong *et al.* 2008). Adult ♂: muzzle black; nose white; black 'mask' around eyes continuing as black superciliary line above the eyes onto forehead and crown; cheeks white, separated from dark reddish-brown forehead and crown by black temporal lines to black ears; 'moustache' white; ear tips white. Back and flanks reddish-brown. Shoulders mixed red, brown and black. Legs white. Pelage longer than *E. p. patas*. Adult ♀: similar to adult ♂ but muzzle lighter and legs creamy. No facial colouration changes during pregnancy. Shoulders, back and flanks orange or orange-red to red but individuals variable over time. Shoulder pelage ca. 5 cm long but not cape-like.

E. p. baumstarki Southern Patas Monkey. NC Tanzania (De Jong *et al.* 2009). Adult ♂: face black; 'moustache' and nose black; black temporal lines contrast with white pelage below and above; ear tips black. Legs greyish. Adult ♀: similar to adult ♂ but lighter coloured.

Similar Species None.

Distribution Endemic to tropical Africa. Sahel Savanna, Sudan Savanna, Guinea Savanna and Somalia–Masai Bushland BZs. Widespread in grassland and woodland savanna below the Sahara Desert and above the tropical forest belt. Western limit is Dakar-Yoff, NW Senegal (17° 29' W; A. Galat-Luong & G. Galat pers. comm.). From NW Senegal through Sudan to W Ethiopia to N DR Congo, N Uganda, W, C and S Kenya and NC Tanzania. Distribution discontinuous in the east. In Kenya, Patas occur in Turkana, West-Pokot, Busia, Baringo, Laikipia, Nyeri, Makueni and Taita Taveta Districts. Historic geographic range in Kenya ca. 88,800 km². Current geographic range in Kenya ca. 48,200 km² (04° 00' N–03° 00' S;

34° 06'–38° 27' E; De Jong *et al.* 2008). In Tanzania, on west and south-west sides of Mt Kilimanjaro, with an isolated population in western Serengeti, near the Grumeti R. Historic geographic range in Tanzania ca. 30,800 km² (01° 28'–04° 02' S; 33° 36'–37° 37' E). Current geographic range in Tanzania ca. 20,700 km² (01° 28'–04° 02' S; 33° 36'–37° 25' E; De Jong *et al.* 2009). Another isolated population on Air Massif, Niger (Wolfheim 1983, Kingdon 1997, Groves 2001). Reaching 17° N, Patas (on the Air Massif, Niger), together with the Green Monkey *Chlorocebus sabaeus* in Senegal and Tantalus *Chlorocebus tantalus* in Mali, probably has the northern-most range of any species of guenon in West Africa at this time.

Habitat Grasslands, savannas and savanna-woodlands. In West Africa, Patas occur in Guinean and Sahelian savanna-woodlands. Patas enter bamboo *Oxytenanthera abyssinica* in SE Senegal (A. Galat-Luong & G. Galat pers. comm.). In Kala Maloue N. P., Cameroon, they occur in habitats dominated by *Acacia seyal*, *Acacia nilotica* and *Balanites aegyptiaca*, and in grasslands dominated by *Zornia glochidata* and *Panicum* spp. where mean annual rainfall is ca. 500 mm and there is one wet season (May–Sep). Mean monthly temperature ranges from 23 °C in Jan to 34 °C in May (Nakagawa 1999). In Murchison Falls N. P., NW Uganda, Patas are present in *Acacia sieberiana*, *Tamarindus indica* and *Combretum aculeatum* woodland where the mean annual rainfall is ca. 1000 mm (Hall 1965). In Kenya and NC Tanzania Patas may be limited now to areas with poorly drained and seasonally waterlogged vertisolic ('black cotton') soils. In such areas Whistling Thorn *Acacia drepanolobium* is the dominant tree, and *Pennisetum mezianum*, *Pennisetum stramineum* spp. and *Themeda triandra* are the predominant grasses (Taiti 1992, Young *et al.* 1997). In Tanzania, mean annual rainfall over the range of Patas is 250–1050 mm (De Jong *et al.* 2009), and in Kenya this is 270–1435 mm (De Jong *et al.* 2008). On the Laikipia Plateau, C Kenya, Patas occur where the mean annual rainfall is ca. 500–800 mm (Young *et al.* 1998; De Jong *et al.* 2008; Isbell *et al.* 2009). Here rainfall is trimodal, with two distinct wet seasons (Apr–Jun and Oct–Nov) and a transitional wet/dry season (Jun–Aug; Isbell *et al.* 2009). Annual mean monthly minimum and maximum temperatures in Laikipia, during 1993–2002, were 9° and 32 °C, respectively, with the widest mean monthly differential (20 °C) occurring in the dry season months of Feb–Mar (L. A. Isbell pers. obs.). Altitudinal limits are from sea level at Saloum Delta N. P., Senegal (where Patas enter mangrove; Labouze *et al.* 1996), to 300 m in SE Senegal (A. Galat-Luong & G. Galat pers. comm.) to 2000 m at Kekohey (north of L. Naivasha, Kenya), to 2030 m at Ol Pejeta Conservancy on the Laikipia Plateau, to 2050 m in West Pokot, W Kenya (De Jong *et al.* 2008). Patas drink daily when possible, and they appear to be restricted within drier habitats to those having a year-round supply of water (De Jong *et al.* 2008, 2009).

Abundance Little is known about the current abundance of Patas. They are apparently more abundant in the west of their geographic range than in the east (S. Gartlan pers. comm.). In SE Senegal, Patas are the most frequently sighted mammal outside national parks (J. Pruetz pers. comm.). As of 2000, there were ca. 300 Patas on the Laikipia Plateau, the region in Kenya where they are most abundant (Isbell & Chism 2007). The density is 0.2–1.5 ind/km² where groups are found (Chism & Rowell 1988, Isbell & Chism

Patas Monkey *Erythrocebus patas* running (analysis from film and dissection).

2007). In Murchison Falls N. P. density was 0.03 ind/km² in the 1960s (Hall 1965).

Adaptations Diurnal and largely terrestrial. Although similar to *Cercopithecus* spp. in many ways, Patas differ by having longer forearms and legs (Hurov 1987, Strasser 1992), longer tarsal bones (Strasser 1992), shorter metatarsal bones (Gartlan 1974, Matsubayashi *et al.* 1978), and hindfoot digitigrady (Meldrum 1991), all of which increase stride length (Hildebrand 1982). Their unique morphology is viewed as an adaptation for high-speed terrestrial locomotion primarily for escaping predators and/or for efficient travel, either for long-distance daily travel while foraging for small and scattered foods, or for exploiting waterholes or high densities of foods that are widely separated (Hall 1965, Chism & Rowell 1988, Isbell 1998, Isbell *et al.* 1998a, b, 1999b, Nakagawa 1999). At Segera, on the Laikipia Plateau, Patas spend 25% of their time moving, more than half of which (14%) is spent feeding and foraging while walking. The time that Patas spend acquiring food while walking is nearly four times greater than in the sympatric Vervet *Chlorocebus pygerythrus*. Feeding while not moving accounts for an additional 22% of their time (Isbell *et al.* 1998a).

In East Africa, where Patas sleep in small *A. drepanolobium* (mean height 2.6 m, 0.5–6.0 m; Enstam & Isbell 2002), groups seldom sleep in the same area on successive nights (Hall 1965, Chism & Rowell 1988), and group members typically sleep individually in separate trees except for mothers and their dependent offspring (Chism & Rowell 1988). In West Africa, where Patas have access to larger sleeping trees (mean height 7.8 m, 4–12 m; Nakagawa 1999), co-sleeping is more common (Nakagawa 1992).

Foraging and Food Omnivorous. In East Africa, Patas are strongly associated with *A. drepanolobium* from which they obtain gum (37% of their diet at Segera) and arthropods (30–40%) – dietary staples available year-round (Isbell 1998, Isbell & Young 2007). The majority of their arthropod diet comes from ants (adults, larvae and eggs) of the genus *Crematogaster*, which live in the swollen thorns of *A. drepanolobium*. Adult ants aggressively defend their colonies, swarming rapidly and biting when they detect disturbances.

Largely because of the ants' defensive behaviour, Patas typically bite open and feed on the contents of only one or two swollen thorns per tree before moving on. Patas have been described as feeding at a steady walk (Hall 1965), scanning for arthropods in the grass, and for gum and arthropods on trees as they walk. At Segera they also feed on flowers (7%), fruits and seeds (10%), leaves (2%) and vertebrates such as geckos and birds' eggs and nestlings (1%) (Isbell 1998). In addition to *A. drepanolobium*, they feed on *Acacia xanthophloea*, *A. seyal*, *Lycium europeum*, *Sarcostema viminale*, *Lippia javanica*, *Cucumis aculeata*, *Commelina* spp., *Hibiscus* sp., *Plectranthus* sp. and *Termitomyces* sp. (Chism & Rowell 1988, Isbell 1998). In areas where *Opuntia* cactus has been introduced, Patas readily eat the succulent leaves (Chism & Rowell 1988). The wet season diet of Patas in Kala Maloue N. P. includes flowers (65%), arthropods (12%), gums (7%), leaves (6%), stems (5%) and fruits (5%) taken mainly from *A. sieberiana*, *A. seyal*, *B. aegyptiaca*, *Cassia* sp., *Abelmoschus* sp., *Commelina* sp. and *Ipomoea* sp. (Nakagawa 1989).

Only minor differences exist in the diet of individuals of different age/sex classes. At Segera the diet of infants is more similar to that of the resident ♂ whereas the diet of juveniles is more similar to that of adult ♀♀. The resident adult ♂ and infants ate gum most often (44% and 38%, respectively), followed by swollen thorns (36% and 31%, respectively). Adult ♀♀ and juveniles ate swollen thorns most often (41% and 39%, respectively), followed by gum (34% and 36%, respectively). Flowers were the third most numerous food type for all age/sex classes (7–16%). Seeds were the fourth most numerous food type for the resident adult ♂ and infants (4% and 8%, respectively), whereas free-living arthropods were the fourth most numerous food type for adult ♀♀ and juveniles (5% for each) (Isbell 1998).

Patas are affected by the distribution and abundance of water (Nakagawa *et al.* 2003, De Jong *et al.* 2008, 2009). In Laikipia they benefit from cattle ranches that have established water troughs and tanks from which they drink daily, especially during the dry season (Chism & Rowell 1988, Isbell & Chism 2007). During the dry season, these monkeys are relatively easily found because they are often near such water sources, but when there are puddles of rainwater on the ground during the wet season, they become much more difficult to find in their large home-ranges. In West Africa aggression observed between groups at waterholes (Struhsaker & Gartlan 1970). In Kala Maloue N. P., Patas drink daily from waterholes during the dry season, and preferentially use areas where such waterholes occur (Nakagawa 1999). A large decline in population size there was attributed to a three-year drought (Nakagawa *et al.* 2003). In Niokolo-Koba N. P., Senegal (J. Pruetz pers. comm.) and in NC Tanzania (De Jong *et al.* 2009) they drink at streams in riverine forests.

Patas begin moving out of their sleeping trees around 07:30h (Chism & Rowell 1988, Nakagawa 1989). They feed and forage while moving at a rate of ca. 320 m/h until around 11:30h (Chism *et al.* 1983, Nakagawa 1989) or around 13:30h (Hall 1965), when there is usually a rest period of about two hours. Following the rest period they resume feeding, foraging and moving. At Segera inactivity (resting, sleeping, standing still) accounts for about 40% of adult time, while self-grooming and social grooming account for about 14% of adult time (Isbell *et al.* 1998a). Patas travel fastest in the late afternoon (435 m/h), just before settling into their sleeping trees (Chism *et al.* 1983).

Daily travel distance for a group with a mean of 45 members was extrapolated to 3188 m based on straight-line distances of the group during 30-minute periods ($n = 133$ days; Isbell *et al.* 1999b, Enstam & Isbell 2007). At Mutara, also on the Laikipia Plateau, mean daily travel distance for a group of 16–23 was 3830 m (1380–5880 m, $n = 61$ days) and, for a group of 47–54, 4420 m (2380–7500 m, $n = 55$ days; Chism & Rowell 1988). In Kala Maloue N. P. the mean daily travel distance for a group of 8–14 ranged from 4350 m in the early dry season ($n = 10$ days) to 6200 m in the mid-dry season ($n = 10$ days; Nakagawa 1999). Patas travel extraordinarily long distances for their body size, but daily travel distance does not increase significantly with group size, suggesting that these monkeys move more in rank formation than in file formation (Altmann 1974).

Home-range size does increase with group size, however. In Laikipia, home-ranges, systematically mapped over 1.0–1.5 years, were 23.4 km² for a group of 16–23 individuals, 28.5 km² for a group of 20–51, and 32 km² for a group of 47–54 (Chism & Rowell 1988, Enstam & Isbell 2004). Actual home-ranges may be larger. The home-range of the group of 20–51 was ca. 40 km² based on sightings of the group in several places >2 km from areas that had been mapped (Enstam & Isbell 2004). In Murchison Falls N. P. one group of 31 had a home-range of ca. 52 km² (Hall 1965). Though Kingdon (1971) mentioned that home-ranges may be as large as 80 km², this has not been confirmed. None the less, Patas have the largest home-ranges for their body size of any primate (Clutton-Brock & Harvey 1977, Chism & Rowell 1988, Isbell *et al.* 1998a).

Social and Reproductive Behaviour Social. Patas live in single-male, multifemale groups for most of the year. Group sizes in West Africa and East Africa are similar. In Waza N. P., Cameroon, groups had 7–34 members. Group compositions ranged from 1–2 adult ♂♂, 3–17 adult ♀♀, 0–7 juveniles and 0–7 infants ($n = > 5$; Struhsaker & Gartlan 1970). In Murchison Falls N. P. groups had 5–31 members. Group compositions ranged from 0–1 adult ♂, 2–18 adult ♀♀, 2–14 juveniles and 0–10 infants ($n = 8$; Hall 1965). In Laikipia groups had 13–56 members. Group compositions ranged from 0–1 adult ♂, 1–19 adult ♀♀, 5–22 juveniles and 0–16 infants ($n = 10$; Chism & Rowell 1988).

The size of a group can fluctuate widely over time. At Segera a group observed for ten years increased from 28 to 51 individuals in the first six years, then declined to seven over the next four years (Isbell *et al.* 2009). In Kala Maloue N. P. a group fluctuated between 26 and 45 over 13.5 years, decreasing from 45 to 16 over the first 2.5 years, increasing to 37 during the following 7.5 years, and decreasing again to 26 in the final 3.5 years (Nakagawa *et al.* 2003). Group composition can also change dramatically over the short term as a result of seasonal births. Birth sex ratios are unknown because immature Patas are difficult to sex visually unless observed as newborns at close proximity. The next opportunity to sex immatures occurs at ca. two years of age when ♀♀ develop a pink vulva.

Females typically remain in their natal groups throughout life. Groups are not territorial but are intolerant of other groups. Interactions between groups are aggressive, with adult ♀♀ and immatures of one group often running at high speed for prolonged distances (up to 3 km) as they chase the other group away (Chism *et al.* 1984, Chism 1999b). Resident ♂♂ are seldom involved in inter-

group encounters except during the breeding season (Struhsaker & Gartlan 1970, Chism & Rowell 1988, Chism 1999b). Physical contact is rare during inter-group encounters. The frequency of inter-group encounters varies depending on the extent of home-range overlap. At Mutara groups shared 44–58% of their home-range with other groups (Chism & Rowell 1988) and 72 inter-group encounters were observed in two years. At Segera, ca. 20 km from Mutara, only 5–10% of the home-range of one group was used by other groups and only 11 inter-group encounters were observed in ten years (L. A. Isbell pers. obs.). Segera differed from Mutara by (1) having fewer artificial water sources, (2) a greater tolerance by ranch management for Olive Baboons *Papio anubis* (and thus a higher density of this potential competitor for water) and (3) a near absence of *Opuntia* (an introduced cactus that was abundant, highly clumped and a main food resource for Patas at Mutara [Chism & Rowell 1988, J. Chism pers. comm., L. A. Isbell pers. obs.]). In Murchison Falls N. P. home-range overlap is minimal (Hall 1965). In Kala Maloue N. P. home-range overlap is extensive, with 80% of the home-range of one group being used by at least one of three other groups (Nakagawa 1999).

Within groups, adult ♀♀ often have poorly defined dominance hierarchies, particularly over short periods. This is because many dyads interact agonistically so rarely that relative positions in the dominance hierarchy are unclear (Isbell & Pruettz 1998). At Segera adult ♀♀ were, on average, 13.5 m from their three nearest neighbours, perhaps too far apart for agonistic interactions to be frequent. Large inter-individual distances have been suggested as a strategy by Patas to minimize detection by predators (Hall 1965), but they also correspond closely to the spatial distribution of food (Isbell & Enstam 2002). Dominance hierarchies are more obvious in captivity and in other situations, e.g. where foods are larger and thus more usurpable, or perhaps when there is demographic instability (Isbell & Pruettz 1998, Isbell 2008, N. Nakagawa pers. comm.). Dominance hierarchies may also be unstable over time, partly resulting from challenges to older ♀♀ from younger, maturing ♀♀ (Isbell & Pruettz 1998, Chism 1999a). Adult ♀♀ and immatures display by bouncing off vertical surfaces such as trunks of trees and fenceposts. Affinitive interactions among group members are mainly expressed as allogrooming, but coalitions are sometimes formed against others, including the resident ♂ (Nakagawa 1992, Muroyama 1994, L. A. Isbell pers. obs.). Females rarely groom the resident ♂ (Chism & Rowell 1988, Nakagawa 1992).

Males disperse from their natal groups as juveniles before their testes descend (by ca. three years of age) (Hall 1965, Chism *et al.* 1984, Nakagawa *et al.* 2003, Rogers & Chism 2009, L. A. Isbell pers. obs.). Males do not face increased aggression from the resident ♂ and are not evicted, but may leave to forestall more intense aggression in the future (Rogers & Chism 2009). At Segera, of two ♂♂ that left and later returned to their natal group, one was killed by the resident ♂ and the other returned only after the resident male's disappearance (L. A. Isbell pers. obs.). This suggests that maturing ♂♂ may prefer their natal group (particularly at low group densities) but stay away because of the high potential cost of intra-sexual aggression (L. A. Isbell pers. obs.). Extragroup ♂♂ range solitarily or in small associations with other ♂♂ and may converge upon groups of ♀♀ and the sole resident adult ♂ during the breeding season (Chism *et al.* 1984, Chism & Rowell 1986, Harding & Olson 1986, Ohsawa *et al.* 1993, Chism & Rogers 1997, Carlson & Isbell 2001). At Segera, over a seven-year period, 14 ♂♂ joined the group for at least ten

Patas Monkey *Erythrocebus patas* adult male.

days; all but two joined the group during the breeding season. Mean tenure length was 5.9 months (0.7–12.4; Enstam *et al.* 2002). One of the 14 ♂♂ later achieved tenure of 2.6 years (L. A. Isbell pers. obs.). At Mutara, where the population density was higher, 16 ♂♂ became resident in two groups during a two-year period; the longest tenure length was nine months (Chism & Rowell 1986). Multimale influxes and high rates of ♂ replacement occur more often with higher densities of Patas ♂♂ (Chism & Rogers 1997, Carlson & Isbell 2001).

Adult ♂♂ are intolerant of each other in the presence of adult ♀♀ and their offspring (Hall 1965). The resident adult ♂ frequently sits at the top of the taller trees and scans into the distance (Hall 1965, Harding & Olson 1986). When he detects another adult ♂, he yawns, exposing his canine teeth, and ‘barks’ or ‘bark-grunts’ before chasing the intruder (Hall 1965, L. A. Isbell pers. obs.). Yawning is also done in other tense situations, such as during habituation to human presence and the close approach by a human after habituation. Other displays include branch-shaking and vertical bouncing. Resident ♂♂ are socially peripheral, interacting with other group members only when grooming, mating, excluding others from preferred resources (♀♀, food, water and space), or being threatened by coalitions of ♀♀.

At 2.5 years of age ♀♀ begin to solicit adult ♂♂, particularly during the breeding season. They have no sexual swellings; signs of oestrus are limited to behavioural changes. Females solicit the ♂ by running past him with the tail curled up and stopping abruptly in a crouched position in front of him. Sometimes they accompany this by puffing out their cheeks and drooling (Chism *et al.* 1984). Matings are often aborted as a result of harassment by immatures and sometimes by adults of either sex (Loy & Loy 1977, Zucker & Kaplan 1981, Carlson & Isbell 2001). Males are single-mount ejaculators (Loy 1975).

Although there is a distinct breeding season, ♀♀ also solicit matings from ♂♂ outside the breeding season and even during

pregnancy (Rowell & Hartwell 1978, Enstam *et al.* 2002). Such out-of-season solicitations increase in frequency during a change in the social environment, e.g. when a new ♂ becomes resident with the ♀♀ or after a ♀ has lost her infant as a result of infanticide (Rowell & Hartwell 1978, Enstam *et al.* 2002). Infanticide has been inferred only once in Patas (at Seger, out of 85 births); its rarity appears to be a function of the willingness of ♀♀ to solicit matings from multiple ♂♂, and of the replacement of resident ♂♂ during the breeding season (Enstam *et al.* 2002, Isbell *et al.* 2009). A ♂ that becomes resident with the group of ♀♀ during the breeding season may be a sire of the next cohort of infants (Ohsawa *et al.* 1993, Enstam *et al.* 2002).

Patas do not interact with most other animals in their environments, the exceptions being potential predators, their own prey, and Olive Baboons and Temminck’s Red Colobus *Procolobus badius temminckii*. Patas groups sometimes travel and play with Temminck’s Red Colobus groups in Saloum Delta N. P. (Galat-Luong & Galat 2005). Their main responses to potential predators involve vocalizations (alarm calls), active pursuit and avoidance. Adult ♀♀ and immatures give at least three different alarm calls to mammalian predators: (1) a ‘chirp’ or ‘nyow’, a high-pitched, staccato call, in response to the presence of Olive Baboons, Domestic Dogs *Canis familiaris* and Lions *Panthera leo*; (2) a loud ‘chutter’, which is softer than the chirp, given to Black-backed Jackals *Canis mesomelas* and Domestic Dogs; and (3) a ‘cough’ call, which is softer than the loud chutter and given when a Black-backed Jackal or African Wild Cat *Felis sylvestris* is close to, or within, the group (Enstam & Isbell 2002). The adult ♂ Patas’ equivalent to the females’ chirp is a two-note ‘bark-grunt’ (probably the ‘whoo-wherr’ vocalization of Hall [1965]) and is acoustically similar to the bark-grunt given when the resident ♂ detects another adult ♂ Patas. If Patas are in trees when they detect mammalian predators, they leave the trees. If they are already on the ground, they remain on the ground. Depending

Patas Monkey *Erythrocebus patas* adult female.

on the type of predator and the circumstances, they may run away quickly (Olive Baboons, African Wild Dogs *Lycaon pictus* and domestic dogs), chase the predator (Black-backed Jackals and African Wild Cats), or collectively mob it (Leopards *Panthera pardus*) (Hall 1965, Chism & Rowell 1988, Enstam & Isbell 2002). Patas also give 'soft chutters' to snakes. While chattering, they gather around the snake, stand bipedally and stare at it. Adult ♀♀ give 'gecker' vocalizations to raptors and sometimes chase them (Olson & Chism 1981, Enstam & Isbell 2002). Patas raid birds' nests and eat nestlings and eggs, largely ignoring mobbing attacks by the victims' parents. Patas seem perturbed enough as they feed on biting ants and their brood that they do not deplete trees of their ants but move to other trees to feed on ants that have not yet been disturbed (Isbell 1998).

Vocalizations given toward mammalian and avian potential predators are audible to humans outside the group. In contrast, vocalizations directed toward other group members are typically difficult to hear unless the observer is nearby. 'Moo' calls are the most frequent vocalizations, and are given in a variety of situations. 'Moos' are given by infants that are separated from their mothers, by ♀♀ as they approach and interact with mothers and their neonates, by ♀♀ that encounter another group, and by all age/sex classes when the rest period is over and the group begins to move again (Chism 1986, Nakagawa 1992, 1998, L. A. Isbell pers. obs.). Immatures squeal when they are at risk of physical attack by another group member. Immatures and adult ♀♀ frequently chatter, or gecker, and less frequently scream during agonistic interactions (Loy *et al.* 1993, L. A. Isbell pers. obs.).

Reproduction and Population Structure Beginning at three years of age, ♀♀ give birth to one infant every ca. 11.8 months at

Mutara ($n = 31$ inter-birth intervals; Chism *et al.* 1984, Chism & Rowell 1986), every 12.9 months at Segera ($n = 29$; Isbell *et al.* 2009) and every 14.4 months in Kala Maloue N. P. ($n = 33$; Nakagawa *et al.* 2003). At Segera an average of 79% of all adult ♀♀ in one group reproduced each year ($n = 9$ years). In the first five years, during a period of population increase, the mean reproductive rate was 92% per year (Isbell *et al.* 2009). Mean gestation length in captivity is 23.8 weeks ($n = 142$; Sly *et al.* 1983). Birth-weight is ca. 504 g (Harvey *et al.* 1987). Births are seasonal but variable across study sites. At Mutara births occur primarily in Dec–Feb (Chism *et al.* 1983). At Segera the birth season starts one month later (Enstam *et al.* 2002). In Kala Maloue N. P. births usually occur in Jan–Feb (Muroyama 1994, Nakagawa 1999, Nakagawa *et al.* 2003). In Waza N. P. births occur in Nov–Jan (Struhsaker & Gartlan 1970). In Niokolo-Kobu N. P. births occur in Jan–Mar (J. Pruett pers. comm.). Regardless of the locality or the months in which births occur, the birth season of Patas is invariably within the dry season (Butynski 1988). Females usually give birth during the day (Chism *et al.* 1983).

When infants are born, other ♀♀ are attracted to them and attempt to take them from their mothers. Though 'allomothering' does not obviously harm infants most of the time, infants protest at being taken and mothers attempt to retrieve them (Chism 1986, 2000), suggesting that allomothering is selfish rather than mutualistic, and might be better called 'kidnapping'. Of 85 infants born over nine years at Segera, allomothering/kidnapping resulted in the deaths of four infants, all of which were born the year following the worst year of reproduction during the study, when only 27% of adult ♀♀ reproduced. In all other years 67–100% of adult ♀♀ reproduced (Isbell *et al.* 2009). Infants from other groups are sometimes kidnapped during inter-group encounters (Nakagawa 1995, Chism

Patas Monkey *Erythrocebus patas* adult male.

1999b). When infants are two months old they spend ca. 25% of their time out of physical contact with their mothers. By the time they are three months old, weaning begins, and infants spend 45% of their time out of contact with their mothers. By four months, infants rarely sleep with their mothers during the day. By seven months, mothers no longer carry infants except in emergencies (Chism 1978, 1986). Infants orphaned at six months can survive (Isbell *et al.* 2009).

In captivity, Patas can live to about 24 years of age (Nowak 1999). Life-span in the wild appears to be considerably shorter. At Segera mean infant mortality during the first year was 30% over nine years. During a five-year period of population increase, mean infant mortality was 15%. In the following four years, as the population declined, infant mortality increased to 48% per year. Of 85 infants born during the study, 22 (26%) died in their first year (Isbell *et al.* 2009). The oldest ♀♀ were estimated to have lived at least nine years. Of the 11 adult ♀♀ that were parous when the study began, the minimum average age at death was 6.2 years. Of the 24 adult ♀♀ born during the 10-year study and surviving long enough to reproduce, 22 died. The mean age at death for those ♀♀ was 4.7 years. Mean annual mortality for adult ♀♀ was 33%. During the five years of population increase, mean annual adult ♀ mortality was 28%, and during the four years of population decline, it increased to 47% (Isbell *et al.* 2009). At Kala Maloue N. P. mean annual adult ♀ mortality was 22% ($n = 32$), and the oldest ♀ lived to about 17 years (Nakagawa *et al.* 2003). With rapid maturity, short inter-birth intervals and early age at death, Patas have the life-history traits of r-selected species.

Predators, Parasites and Diseases Little is known about the impact of predators on Patas. Black-backed Jackals and Domestic Dogs *Canis familiaris* are their only confirmed predators (Chism & Rowell 1988, L. A. Isbell pers. obs.). Puff Adders *Bitis arietans* observed to kill but not eat infant Patas (Chism *et al.* 1984). Overnight disappearances of monkeys coupled with Leopard tracks in their sleeping areas strongly implicate Leopards (Chism & Rowell 1988,

L. A. Isbell pers. obs.). Other potential predators include Lions, Spotted Hyenas *Crocuta crocuta*, African Wild Dogs, Olive Baboons, Robust Chimpanzees *Pan troglodytes* (in West Africa only) and Martial Eagles *Polemaetus bellicosus* (Chism *et al.* 1983, Enstam & Isbell 2002, J. Pruetz pers. comm.). Servals *Felis serval*, Caracals *Felis caracal* and African Wild Cats are potential predators of infant Patas. Immatures give alarm calls to Tawny Eagle *Aquila rapax*, African White-backed Vulture *Gyps africanus* and Eastern Chanting Goshawk *Melierax poliopterus*, which are probably not potential predators of Patas (L. A. Isbell pers. obs.). At Segera, while in tall trees, Patas spend up to 50% of their time scanning the environment (compared to 36% in short trees, $n = 12$ individuals). Their more frequent alarm-calling in tall trees suggests that they are scanning for predators (Enstam & Isbell 2004). Patas also disperse widely at their sleeping sites and rarely sleep in the same area on consecutive nights. These behaviours probably minimize detection by Leopards (Hall 1965, Chism *et al.* 1983, Chism & Rowell 1988, Nakagawa 1989).

Little is known about diseases in Patas. McGrew *et al.* (1989b) found five genera of intestinal nematode (*Stongyloides*, *Necator*, *Physaloptera*, *Streptopharagus*, *Trichuris*) and two genera of protozoa (*Entamoeba*, *Iodamoeba*) in a Senegalese population. Patas also harbour simian immunodeficiency virus (SIV) (Galat-Luong *et al.* 1994a). After particularly heavy El Niño-caused rains in Kenya in 1997, five of 14 adult ♀♀ in one group became ill, which was manifested by weakened and stiffened hindlimbs, weight loss, lethargy, apparent confusion and, in some individuals, cataracts and bleeding in the eyes (Isbell *et al.* 2009). Despite being hindered in their movements, none was immediately taken by a predator and all were able to keep up with the group until just before they disappeared and were presumed dead. Although most died within four months, one survived for >1 year with the symptoms. All failed to reproduce after they developed the symptoms.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Erythrocebus p. patas of West Africa is widespread and relatively common, although surveys have not been conducted for >25 years. Their range may even be expanding as Sahelian habitats spread southwards. Increased interaction with humans may, however, be reducing their numbers (S. Gartlan pers. comm.). In Kenya, the geographic range of Patas has declined from ca. 88,800 km² (prior to 1995), to roughly 48,200 km² in 2008 (ca. 54% of the known historic range). In addition, the populations of Patas in Kenya have become increasingly fragmented and isolated (De Jong *et al.* 2008). Patas are declining in Kenya partly as a result of conversion and fragmentation of habitat into small-scale agricultural use and the removal of trees, particularly *A. drepanolobium*, for charcoal manufacture (Chism & Rowell 1988, Isbell & Chism 2007). A survey of Trans-Nzoia, Uasin Gishu, Baringo and Laikipia Districts in 2001 located Patas only in the latter two districts (K. Ngece & L. A. Isbell pers. obs.). Their presence in Machakos, Busia, West Pokot and Nyeri Districts was confirmed during a survey in 2003–04 (De Jong *et al.* 2008). The status of Patas in Uganda is unknown but populations are presumed to be declining as expanding human populations move into habitats once considered marginal for agriculture. In Tanzania they appear to be in rapid decline with a population in 2008 estimated at 150–900 individuals living over an area of ca. 20,700 km². The range of the

Patas in Tanzania is estimated to have declined by ca. 33% between 1995 and 2008. All three of the populations of Patas in Tanzania have become smaller and increasingly isolated (De Jong *et al.* 2009).

Measurements

Lynne A. Isbell

GENUS *Chlorocebus*

Savanna Monkeys

Chlorocebus Gray, 1870. Catalogue of Monkeys, Lemurs and Fruit-eating Bats in the Collections of the British Museum, p. 26.

With the exception of Gray (1870) and Groves (1989, 2001), the six major populations of the Savanna Monkeys Group *Chlorocebus* (*aethiops*) have previously been treated as *Cercopithecus* and the various forms have often been lumped under a single species, *Cercopithecus aethiops*. The six forms that are provisionally recognized in this work are Grivet *Chlorocebus aethiops*, Tantalus *Chlorocebus tantalus*, Green Monkey (Callithrix) *Chlorocebus sabaeus*, Vervet *Chlorocebus pygerythrus*, Malbrouck *Chlorocebus cynosuros* and Djam-Djam (or Bale Monkey) *Chlorocebus djamdjamensis*. The need for a comprehensive genetic study of the *Chlorocebus* radiation and the provisional nature of all previous taxonomic arrangements, including ours, can be illustrated by the difficulties surrounding *C. cynosuros*. This taxon was based upon a type specimen collected from north of the mouth of the Congo R. Because this gigantic river is one of the major natural barriers in Africa and the savanna monkeys south the Congo R. are broadly similar to the small population north of the Congo R., it is reasonable to suppose that the northern population derives from an early introduction by humans. Implicit in this situation is the likelihood that *cynosuros* from north of the Congo R., like any other isolated population deriving from a very small number of ancestors, will show genetic founder-effects.

Although many individuals from Angola share characteristics of the *cynosuros* type there is considerable variation among animals from south of the Congo R. and this variability increases to the east. E. E. Sarmiento (pers. comm. and *C. cynosuros* profile) was unable to find consistent differences between supposed *pygerythrus* and *cynosuros* from either side of L. Malawi. Only a thorough molecular study is likely to resolve the many questions raised and this

Green Monkey *Chlorocebus sabaeus* adult male.

qualification extends to most areas where regional populations of savanna monkeys meet.

Savanna monkeys are semi-terrestrial, grey, greenish or brownish monkeys with black faces surrounded by white facial ruffs. They range throughout sub-Saharan Africa outside true forest and desert and are particularly successful in acacia woodlands and riverine galleries.

Lateral view of skull of Tantalus Monkey *Chlorocebus tantalus* adult male.

Four savanna monkey *Chlorocebus* species (adult males).

Top left: Green Monkey *Chlorocebus sebaeus*.

Top right: Tantalus Monkey *Chlorocebus tantalus*.

Bottom left: Malbrouck Monkey *Chlorocebus cynosuros*.

Bottom right: Vervet Monkey *Chlorocebus pygerythrus*.

Chlorocebus has no known fossil record but is a well-established group with closest affinities with two very different monkey genera, the Patas *Erythrocebus* and the mountain monkeys *Allochrocebus* (*preussi*) Group. These three genera represent the less arboreal bifurcation of the Cercopithecini (see figure, p. 245).

Chlorocebus is treated here as a full genus partly as a move towards less subjective taxonomies. While we have not yet adopted the criteria proposed by Goodman *et al.* (1998) in their entirety we have consciously

taken into account the 'age of divergence' criteria that were put forward in their paper. With the refinement of molecular clocks and calibration against fossils, contemporary scientists are, at last, providing some convincing phylogenetic trees and with them some basis for more objective ranking. This has been particularly relevant to the taxonomy of the Cercopithecini, which has always been an exceptionally large, diverse and opaque group in terms of understanding inter-relationships. The molecular phylogenetic trees assembled by Tosi *et al.* (2005) and Tosi (2008) show that the savanna monkeys, the Patas and the mountain monkeys cluster closely, a conclusion that is in accord with all genetic studies since Dutrillaux's pioneering work in the 1970s and 1980s, as well as with studies based on the postcranial skeleton (Gebo & Sargis 1994, Sargis *et al.* 2008). As a result of these findings it is illogical to call Patas '*Erythrocebus*' while retaining *Cercopithecus* for its two sibling groups. Divergence of the common ancestor of *Erythrocebus*, *Chlorocebus* and *Allochrocebus* from *Cercopithecus* (*sensu nova*) is estimated at 8 mya (late Miocene) (Tosi *et al.* 2005, Perelman *et al.* 2011), a divergence that is possibly older than that of *Miopithecus* (which is no longer disputed to be a full genus). According to Tosi *et al.* (2005) and Roos *et al.* (2011), *Erythrocebus*, *Chlorocebus* and *Allochrocebus* diverged from one another 5–6 mya (late Miocene), an age that justifies generic status for all three groups (Goodman *et al.* 1998).

Not surprisingly, the excision of savanna monkeys from *Cercopithecus* has not met with universal acceptance and we are grateful to L. Isbell & K. Jaffe (pers. comm.) for expressing some arguments contrary to our current views. They write: 'Groves (1989, 2001) places the Vervet in a separate genus, referring to it as *Chlorocebus pygerythrus*, with five subspecies. Although Patas *Erythrocebus patas* share these same morphological characteristics with Vervets, he dismisses the alternative of including both Vervets and Patas in the same genus because they share relatively few derived traits and it would mean that Patas would become *Chlorocebus*, which has priority over *Erythrocebus* by 27 years. However, based on molecular data that separate the more terrestrial from the more arboreal species within the Cercopithecini, Tosi *et al.* (2002) recommend that Vervets and Patas be placed together in the genus *Chlorocebus* to recognize their shared terrestriality. Also using molecular data, Tosi *et al.* (2003, 2004) agree with Groves (1989, 2001), placing Vervets in their own genus. We do not concur with these authors. We recommend that both Vervets and Patas be included in the genus *Cercopithecus* for the following reasons: (1) molecular data do not eliminate that alternative; (2) shared morphological characteristics do not always reveal true phylogenetic relationships and unique morphological characteristics do not always reveal the absence of phylogenetic relationships; (3) it is no more difficult to change the generic name for Patas than to change the generic name for Vervets

Tantalus Monkey *Chlorocebus tantalus* adult male.

since each alternative requires one traditional name to be changed; (4) terrestriality is a matter of degree rather than a discrete category among the Cercopithecini (McGraw 2002, see also below); (5) in addition to Vervets and Patas, the “terrestrial” clade includes one and possibly two species still in the genus *Cercopithecus* (L’Hoest’s Monkey *C. lhoesti* and the Sun-tailed Monkey *C. solatus*) (Tosi *et al.* 2004, 2005, Xing *et al.* 2007); (6) differences in diets and in foraging, ranging and social behaviour are slight between Vervets and Patas and *Cercopithecus* spp. and the differences are no greater than those within the genus *Cercopithecus* (Enstam & Isbell 2007); and (7) Vervets have hybridized with both Patas and Zanzibar Sykes’s Monkeys *Cercopithecus mitis albobularis* in captivity (Matsubayashi *et al.* 1978, Erhart *et al.* 2005).’

Some of the arguments put forward above articulate views that before the genetic revolution were not far from our own!

Djam-Djam, as a highly localized Ethiopian highland bamboo forest endemic, is the only member of the *C. (aethiops)* Group that does not range widely through savanna and woodland. We think this form might represent the relict of an early *Chlorocebus* stock

that, having adapted to the cool, dry conditions of a botanically impoverished montane Ethiopia, has resisted, so far, being replaced by later savanna monkey populations because of its adaptations to the special demands posed by bamboo forests. It seems possible that intermediate types from other parts of the Ethiopian massif represent the product of past genetic mixture outside Djam-Djam’s current refuge in the bamboo forests of S Ethiopia.

Chlorocebus shares with *Erythrocebus* a number of derived cranial features: the orbits in lateral view do not slope forward inferiorly; the tympanic tube has a V-shaped lower margin (seen only in juveniles in *Cercopithecus*); and the orbits are angular instead of oval. At the same time, the two genera lack derived conditions of *Cercopithecus* (shape of the nasal aperture and nasal bones, and conditions of the upper incisors). As shown by Gebo & Sargis (1994), *Chlorocebus* lacks the extreme terrestrial adaptations of the postcranial skeleton shared by *Erythrocebus* and *Allochrocebus*.

Colin P. Groves & Jonathan Kingdon

Chlorocebus aethiops GRIVET MONKEY

Fr. Grivet; Ger. Äthiopische Grünmeerkatze

Chlorocebus aethiops (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 28. Sennaar, Blue Nile, Sudan.Grivet Monkey *Chlorocebus aethiops* adult male.

Taxonomy Polytypic species. The savanna monkey of NE Africa, the Grivet, has frequently been treated as a subspecies of the polytypic species or superspecies *Cercopithecus (aethiops)* (Schwarz 1926, Kingdon 1971, Thorington & Groves 1971, Napier 1981, Groves 1989, 1993, Grubb *et al.* 2003). Following Dandelot (1959, 1974), however, most of the recent taxonomies treat the Grivet as a full species (Hill 1966, Yalden *et al.* 1977, 1996, Lernould 1988, Kingdon 1997, Groves 2001, 2005c). Groves (1989, 1993, 2001, 2005c) returned the savanna monkeys to the genus *Chlorocebus* and treated some of the subspecies as full species, including the Grivet *Chlorocebus aethiops*. This taxonomy is supported by Tosi *et al.* (2003) and is the one followed here. The allocation of regional populations to full species has faced widespread criticism. For example, relatively modest differences in blood proteins between *C. aethiops* and Green Monkey *Chlorocebus sabaeus* suggest that subspecific ranking could be appropriately retained in this instance (Lucotte *et al.* 1982). This would ally all *Chlorocebus* (or at least the three boreal populations, *aethiops*, *tantalus* and *sabaeus*) under a common specific name. Such issues can only be resolved by further study, particularly at the molecular level.

Although regional types such as *C. aethiops* are well differentiated over much of their ranges, the existence of morphs or subpopulations that show mixed or intermediate characteristics on the edges of geographic ranges has reinforced objections to elevation of the types within *Chlorocebus* to species status. *Chlorocebus aethiops* is no exception (Yalden *et al.* 1977, Napier 1981, Lernould 1988). For example, the animals from the Omo R. region of extreme SW Ethiopia ('*zavattarii*' types) suggest admixture with Vervet *Chlorocebus pygerythrus*, as do those ca. 60 km south of Bale Mountains N. P. (T. Butynski pers. obs.). On the other hand, *Chlorocebus* living around the shores of the low-lying Rift Valley Lakes Abaya and Ch'amo of C Ethiopia are unequivocally *C. p. arenarius* and show no admixture with *C. aethiops*. In the western highlands of Ethiopia darker variants (*C. a. matschiei*) possibly represent adaptation to higher, wetter habitats or, alternatively, admixture with Djam-Djam *Chlorocebus djamdjamensis* (Kingdon 1997). Apparent hybrids between *C.*

aethiops and *C. djamdjamensis* reported but no sites of sympatry are known (Mekonnen *et al.* 2012, J.-M. Lernould pers. comm.). Here we follow the taxonomy of Kingdon (1997) in recognizing two subspecies; *C. a. aethiops* and *C. a. matschiei*.

Synonyms: *cailliaudi*, *cano-viridis*, *?cinereo-viridis*, *engytithia*, *griseo-viridis*, *griseus*, *matschiei*, *subviridis*, *toldti*, *weidholzi*, *zavattarii*. Dandelot & Prévost (1972), Dandelot (1974), Hill (1966) and Grubb *et al.* (2003) consider *ellenbecki* and *hilgerti* to be synonyms of *C. aethiops* but here and elsewhere (Groves 2001, 2005c) they are treated as synonyms of *C. pygerythrus*. Chromosome number: $2n = 60$ (Dutrillaux *et al.* 1988b).

Description Long-tailed, medium-sized, semi-terrestrial, savanna monkey with white hairs on upper lip and white tail tip. Sexes similar in colour but adult ♀ smaller than adult ♂. Adult ♀ weighs about 67% as much as adult ♂. Lips and chin with white hairs (i.e. white moustache). Face black. Cheek whiskers pure white, long, prominent, contrasting sharply with crown, concealing the ears. Brow band narrow, white, confluent with whiskers. Crown and back grizzled and variable in colour; pale olive-fawn, greyish-green, dark fawn or russet. Crown darker than back. Limbs mouse-grey. Hands and feet pale grey with brownish tinge. Underside and inner limbs white to pale grey. Tail base with white tuft below and to either side. Tail greyish above, white below. Distal 15–20% of tail pure white to creamy white. Scrotum sky blue (Hill 1966, Dandelot 1974, Napier 1981). Infant born with dark, brownish-grey fur and pink face and ears, but acquires similar colouring to the adult at an early age.

Geographic Variation

C. a. aethiops Common Grivet Monkey. East of White Nile R., Sudan, through C and N Ethiopia, S and C Eritrea into Djibouti. Back grizzled olive-fawn or greyish-green, sometimes with reddish tint (e.g. at Awash N. P., C Ethiopia; C. J. Jolly & J. E. Phillips-Conroy pers. comm.).

C. a. matschiei Matschie's Grivet Monkey. Endemic to SW Ethiopia within and west of Rift Valley (Kaffa and Djimma Districts; Dandelot 1974). Back colour variable, grizzled dark fawn to russet. Toes dark brown. Longer fur around face.

Similar Species

Chlorocebus tantalus. Probably allopatric along eastern edge of range, separated from *C. aethiops* by the White Nile R. Ghana east of the White Volta R. to Ubangi R. then C and S Sudan, N Uganda and NW Kenya. Lips and chin without white hairs. Brow band more sinuous, constricted in centre, separated from whiskers by line of black hairs at outer corner of eye. Whiskers long, stiff, yellowish, sometimes speckled, tips curled upwards, contrasting sharply with crown and concealing the ears. Hands and feet pale grey. Tail base with white tuft below and to either side. Tail tip creamy white. Scrotum sky blue sometimes surrounded by orange-hued hairs (Dandelot 1974, Napier 1981).

*Chlorocebus aethiops*

Chlorocebus djamdjamensis. Parapatric on the Bali Massif, SC Ethiopia.

Only in bamboo forest above 2400 m. Temples black. Brow-band absent or narrow. Tail short. No white tufts at base of tail.

Chlorocebus pygerythrus. Probably narrowly sympatric along northern edge of range where *C. pygerythrus* x *C. aethiops* hybrids occur. S Somalia, S Ethiopia, E and SW Uganda, through Kenya south through South Africa. Lips and chin without white hairs. Brow band broad, confluent with whiskers. Whiskers short, pure white, not concealing the ears. Hands and feet dark grey to black. Tail base lacks white tufts. Patch of red hairs beneath base of tail (i.e. red subcaudal patch) and around anus in adult ♂. Tail tip dark grey to black. Scrotum turquoise blue.

Distribution Endemic to NE Africa. Sudan Savanna, Somalia-Masai Bushland, and Afromontane–Afroalpine BZs. Historically as far north as NE Sudan, east of Nile R. to at least 19° 30' N; 33° E along the Nile R. Whether *C. aethiops* occurs this far north along the Nile R. today is doubtful as there has been much loss of forest along the Nile R. At this time the northern limit along the Nile R. is probably south of 15° N (i.e. Khartoum; Kock 1969). None the less, this is probably the northern-most point for any guenon in Africa. Apparently no records for Egypt. South in Sudan to at least 05° 10' N; 31° 46' E at Mongalla, SE Sudan (Dandelot 1974). From the Nile R. of E Sudan eastward through SW, C and N Ethiopia, and S, C and N Eritrea (Yalden *et al.* 1977, 1996, Zinner *et al.* 2001c, 2002b, D. Zinner pers. comm., T. Butynski pers. obs.) to the Goda Mts and Mabla Mts, N of the Gulf of Tadjoura, C Djibouti (11° 46' N; 42° 40' E; Künzel *et al.* 2000). This is apparently also the southern limit along the Red Sea coast. Northern limit in Eritrea (based on records from the mid-1800s) is on the NW border with Sudan at the confluence of the Barka R. and Anseba R. (ca. 17° N; 37° 24' E; Yalden *et al.* 1977, Zinner *et al.* 2001c, D. Zinner pers. comm.). In 2003, observed by D. Zinner (pers. comm.) at Dawit Berhane (west of Nakfa near the confluence of the Zara R. and Anseba R.; 16° 38' N;

37° 50' E). This is the northern-most (recently documented) point for any guenon in eastern or central Africa. Among guenons, only the Patas *Erythrocebus patas*, Tantalus *Chlorocebus tantalus* and Green Monkey *Chlorocebus sabaeus* might range as far north (ca. 17°) as *C. aethiops*. North-eastern limit in Eritrea appears to be in the region of Semanawi Bahiri in EC Eritrea (15° 46' N; 38° 28'; Butynski 1995a). Hall (1966) gives northern limit along the Red Sea coast as Tokar (18° 25' N; 37° 45' E (but this needs validation). Southern limit in Ethiopia is unclear as there is confusion with the northern limit for *C. p. hilgerti* that is at least partly caused by apparent *C. p. hilgerti* x *C. a. aethiops* hybrids (Dandelot 1959, Dandelot & Prévost 1972, Yalden *et al.* 1977, Lernould 1988, T. Butynski pers. obs.). South-western limit in Ethiopia (on the border with Sudan) appears to be near Kantiere (06° 31' N; 35° 01' E), possible to the Omo R. (Groves 2001). In C Ethiopia *C. aethiops* and *C. pygerythrus* meet in the Rift Valley between L. Shala and L. Zwai (Groves 2001) as well as at L. Abaya (Dandelot & Prévost 1972, Lernould 1988). *Chlorocebus aethiops* present ca. 50 km west of L. Shala, near Hosa'ina (07° 33' N; 37° 51' E; Q. Luke pers. comm.). About 20 km south of Mena (ca. 06° 05' N; 39° 40' E, 1400 m), which is on the east side of the Rift Valley about 60 km south of Bale Mountains N. P., 'hybrids' are present. These monkeys have the black hands, feet and tail tip of *C. pygerythrus* and the white caudal tuft of *C. aethiops*. About 30 km to the south-west of here, on the Genalé R. (06° 00' N; 39° 42' E, 1100 m), 'good' *C. pygerythrus* are present (T. Butynski pers. obs.). South-eastern limit for *C. aethiops* in Ethiopia appears to be in the vicinity of Härer (09° 14' N; 42° 15' E; Yalden *et al.* 1977). No records found for *C. aethiops* in Somalia. T. Butynski (pers. obs.) now strongly suspects that further research will find that there is a broad '*C. aethiops*–*C. pygerythrus* clinal zone' across S Ethiopia from about Kantiere in the west then south-eastwards through L. Shala, L. Zwai and L. Abaya to Härer with monkeys gradually appearing more *C. pygerythrus*-like (and less *C. aethiops*-like) north to south through this clinal zone.

Habitat Savannas, woodlands, riverine forests, deciduous forest, montane forest and cultivation mosaics, always close to permanent sources of drinking water and to large trees for sleeping (Yalden *et al.* 1977, Zinner *et al.* 2001c, 2002b). Prefer woodland/riverine forest/grassland margins but often feeds in open areas. Lives in forest where other species of guenon are absent, such as 5 km into the Semanawi Bahiri Forest of EC Eritrea (Butynski 1995a). Also use pure stands of eucalyptus *Eucalyptus* spp. and Prickly Pear Cactus *Opuntia* sp. (Zinner *et al.* 2001c, 2002b). Present from <200–>3000 m in Ethiopia (Yalden *et al.* 1977, 1996), but records >2500 m are few (Mekonnen *et al.* 2012). From ca. 750–2600 m in Eritrea (Zinner *et al.* 2001c, 2002b). Mean annual rainfall over the range of *C. aethiops* in Eritrea is 350–1000 mm (Zinner *et al.* 2001c) but the lower limit is probably close to 300 mm for those *C. aethiops* living in riverine forest along the Setit/Tacazze R. (Eritrea's only permanent river) and the larger seasonal rivers. In Ethiopia, *C. aethiops* present where mean annual rainfall is >2000 mm (Dunbar & Dunbar 1974b). Mean annual rainfall near Awash N. P. (08° 30' N, 39° 40' E) is 551 mm (313–839, n = 34 years). Here most rain falls during Jul–Aug (C. J. Jolly & J. E. Phillips-Conroy pers. comm.).

Most of what we know about the ecology and behaviour of *C. aethiops* comes from 58 h of observations during five months of

field work in the Bole Valley, WC Ethiopia (09° 25' N; 38° 00' E), during 1971 and 1972 (Dunbar & Dunbar 1974b). The Bole Valley is 1700 m at the river bed. There is one wet season (May–Oct) and one dry season (Nov–Apr). Mean annual rainfall ca. 2000 mm. Daytime temperatures are generally around 35 °C. Dominant trees are *Ficus* spp., *Syzygium guineense*, *Bridelia micrantha*, *Podocarpus gracilior* and *Albizia* spp.

Chlorocebus aethiops must drink at least every other day, depending on the amount of moisture in the diet. Drinking water in Eritrea is mostly found in valleys where water collects in rocky crevices after rains and where underground springs feed waterholes that are either naturally occurring or dug by Savanna Elephant *Loxodonta africana*, Common Warthog *Phacochoerus africanus*, Olive Baboon *Papio anubis*, Hamadryas Baboon *Papio hamadryas* or people. For *C. aethiops* in Eritrea, the median distance between sleeping sites and the nearest site with a high potential for permanent surface water was 459 m (14–3348, $n = 46$); 64% of *C. aethiops* were <1500 m from permanent surface water and only 2% were >3000 m from permanent surface water (Zinner *et al.* 2001c, 2002b).

Abundance Density of *C. aethiops* in the Bole Valley estimated at 73 ind/km² and biomass estimated at 207 kg/km² (Dunbar & Dunbar 1974b). *C. aethiops* is the most widespread and most commonly encountered monkey in Ethiopia (Dunbar & Dunbar 1974b, Yalden *et al.* 1977). Overall, densities of *C. aethiops* seem to resemble those of many *C. pygerythrus* populations in East Africa (i.e. <1–9 ind/km² with localized densities much higher at 10–>100 ind/km² (Wolfheim 1983, Cheney 1987).

Adaptations Semi-terrestrial, diurnal, and opportunistic. Follow riverine vegetation strips always keeping close to trees or shrubs, foraging both on the ground and in trees and shrubs. Commensal with humans at many sites, sometime living next to settlements and within agricultural sites (T. Butynski pers. obs.). In Eritrea, the median distance from *C. aethiops* sleeping sites to the nearest human settlement was 2858 m (58–24,609, $n = 46$), and to the nearest agricultural area this was 297 m (0–8402, $n = 46$); 32% of records <1000 m from the nearest village and 37% of records <500 m from the nearest agriculture (Zinner *et al.* 2001c, 2002b).

Chlorocebus aethiops rests in shade during the heat of the day, probably thereby avoiding heat-stress, water-stress and predators. Depends on concealment in dense vegetation when threatened by large eagles. Colouring well suited to concealment when motionless but when moving the black face in a white setting, and the tip of the tail and the white tuft at the base of the tail, are conspicuous, perhaps especially to conspecifics. When walking directly away from an observer, the laterally extended pure white whiskers and the pure white tuft at the base of the tail are roughly in line with one another and ‘flash’ as the animal moves (T. Butynski pers. obs.).

Unlike Tantalus *Chlorocebus tantalus* to the west and *C. pygerythrus* to the south, *C. aethiops* in Ethiopia and Eritrea makes use of closed forest. It seems highly likely that this is a case of ‘competitive release’ from the more forest-adapted *Cercopithecus* spp., perhaps particularly the widespread Gentle Monkey *Cercopithecus mitis*. At most sites where *C. tantalus* or *C. pygerythrus* occur in the vicinity of closed forest there is at least one species of *Cercopithecus* present (usually *C. mitis*). At none of these sites does *Chlorocebus* enter the

closed forest (indeed, *Chlorocebus* appears to avoid even the forest edge). While *Chlorocebus* and *Cercopithecus* live side-by-side at many sites over the range of *Chlorocebus*, they seldom, if ever, share the same sites or form polyspecific associations (Enstam & Isbell 2007, De Jong & Butynski 2009). It is, therefore, significant that over that part of the range of *Chlorocebus* where (1) there is access to closed forest, and (2) *Cercopithecus* is absent, *Chlorocebus* (i.e. *C. aethiops*) is found living deep within (at least some) closed forests (e.g. 5 km within Semanawi Bahiri Forest, E. Eritrea; T. Butynski pers. obs.). Not all closed forests, however, harbour *C. aethiops*. For example, *C. aethiops* appears to be absent from the Herenna Forest on the southern slope of Bale Mountains N. P., down-slope from, and well south of, *C. djamdjamensis* (T. Butynski pers. obs.). It may be that altitude and/or levels of rainfall determine whether *C. aethiops* will occupy a particular closed forest with, perhaps, the wetter forests at the higher altitudes being unsuitable.

Foraging and Food Omnivorous. In the Bole Valley, mean home-range size was 24.5 ha (19.5–29.4, $n = 2$) and mean day range was 700 m (600–800, $n = 4$ days). During the daylight hours, *C. aethiops* spent ca. 27% of the time feeding. Amount of time spent feeding tended to increase gradually through the day with most feeding taking place in the afternoon. Peaks in movement occurred in the early morning and early afternoon. They slept in trees and spent 57% of the daylight time in trees ($n = 1545$ scans; Dunbar & Dunbar 1974b).

In Bole Valley, food ($n = 352$ items) obtained from creepers (0.9%), shrubs (2.8%), grasses (3.7%), bushes (4.1%), herbs (33.5%) and trees (56.0%). Items eaten were bark (5.7%), insects (7.4%), flowers (17.6%), leaves (18.7%) and fruits/seeds (50.6%). Most frequently eaten items were fruits of *Maytenus undata* (18.7% of diet), fruits of *Ficus* spp. (17.3%), leaves and flowers of *Trifolium ruepellianum* (14.8%) and fruits of *S. guineense* (5.7%). *Chlorocebus aethiops* took 28.2% of 326 food items from the ground and 63.9% from trees (Dunbar & Dunbar 1974b). In Awash N. P., *C. aethiops* eat winged termites, fruits of *Celtis* sp., *Ficus sycamorus*, *Acacia tortilis*, *Acacia brevispica* and *Zizyphus* sp., and flowers of *Acacia tortilis* (C. J. Jolly & J. E. Phillips-Conroy pers. comm.). In Eritrea, fruits of figs *Ficus* spp. and the fruits and young shoots of *Opuntia* sp. (an exotic species that is both common and widespread) are frequent foods of *C. aethiops*. *Opuntia* has water content of ca. 96%, making it an important source of water during the long dry season. *Chlorocebus aethiops* is a crop pest at many sites, eating bananas, citrus and other crops (Zinner *et al.* 2001c, 2002b).

The above, and anecdotal information, suggests that the foraging behaviour and diet of *C. aethiops* resembles that of other *Chlorocebus* spp., but whereas gum is a major component of the diet of *C. pygerythrus* at some sites (up to 37%; Enstam & Isbell 2007), the eating of gum has not been reported for *C. aethiops*. Groups forage together, with ♂♂ and ♀♀ mixed with young of various ages. Foraging is restricted to a limited range. Judging from studies of other savanna monkeys the extent of home-ranges is likely to vary between ca. 10 ha. to ca. 100 ha. Solitary foragers are exceptional. Although *Chlorocebus* spp. are generally viewed as semi-terrestrial, *C. aethiops* might be considered an arboreal species when in closed forest. For example, R. I. M. Dunbar (pers. comm.) seldom observed *C. aethiops* on the ground in the dense gallery forest of the Bole Valley.

Social and Reproductive Behaviour Social. Live in multi-male/multifemale groups (L. Fairbanks, L. Swedell, R. I. M. Dunbar pers. comm.). Mean size of four groups in the Bole Valley estimated to be 19 individuals ($n = 4$ groups), with the largest group comprised of 29 individuals (Dunbar & Dunbar 1974b). In Awash N. P., estimated group size ranges from 10 to 35 individuals and most groups are multimale. Solitary adult ♂♂ are present (C. J. Jolly & J. E. Phillips-Conroy pers. comm.). In Eritrea, Zinner *et al.* (2002b) assessed the size of *C. aethiops* groups at 22 sites and obtained a mean of 9.1 ind/group (S.D. = 4.5, 3–22, $n = 22$). They also observed a solitary adult ♂, and an adult ♂ with a subadult ♂ that were 5–10 km from the nearest group (Zinner *et al.* 2002b). At Awash N. P. there are adult and subadult ♂♂ that are spatially peripheral to, but associated with, social groups (L. Fairbanks pers. comm.).

Not reported to be sympatric with other species of guenons. In the Bole Valley, *C. aethiops* are sympatric with Guereza *Colobus guereza*, Gelada Baboon *Theropithecus gelada* and *P. anubis*. *Chlorocebus aethiops* not observed in polyspecific association with *T. gelada*, and in association with *P. anubis* only 7% of the time ($n = 340$ observations; Dunbar & Dunbar 1974b). It should be noted, however, that the ‘Vervets generally reacted nervously when in association with Anubis Baboons, and would often withdraw if the *anubis* moved into the trees they were in.’ (Dunbar & Dunbar 1974b, p. 53). Sympatric with *C. guereza* and *P. anubis* in Awash N. P. but appear to avoid *P. anubis* even though they exploit the same arboreal resources (C. J. Jolly & J. E. Phillips-Conroy pers. comm.).

There are few data on the social and reproductive behaviour of *C. aethiops*. L. Fairbanks (pers. comm.), who studied *C. aethiops* in Awash N. P., *C. pygerythrus* in Amboseli N. P., Kenya, and an introduced population of *C. sabaes* on St Kitts I., West Indies, found that these three species are behaviourally indistinguishable. She observed infant care-taking by non-mothers, adult ♀ coalitions against adult ♂♂, and male–male competition among *C. aethiops* in Awash N. P.

Size of *C. aethiops* groups in Eritrea may average smaller than *C. pygerythrus* groups in Kenya (which average roughly 20 ind/group). As such, *C. aethiops* groups probably comprise at least twice as many adult ♀♀ as adult ♂♂, and young animals and infants outnumber adults. Males habitually forsake their natal groups while ♀♀ are much more sedentary. Cheney (1983) emphasized how the sexes in *C. pygerythrus* tend to have separate hierarchies enforced by ♂ aggression and a close association between dominant ♂♂ and equally high-ranking ♀♀ whose hierarchy depends upon matrilineal histories. There is no information for *C. aethiops* on the extent to which home-ranges of neighbouring groups overlap. Behaviour indicating inter-group hostility, led by the group’s adult ♀♀, has frequently been observed (C. J. Jolly pers. com.) and strongly suggests that *C. aethiops*, like the other *Chlorocebus* (Cheney 1987), is territorial.

The vocal repertoire of *C. aethiops* has not been studied, but the warning ‘chirps’ of immatures and adult ♀♀ and the loud ‘aarr’ call of the adult ♂♂ in SW and E Eritrea, and in S and C Ethiopia, sound like those of *C. pygerythrus* (T. Butynski, C. J. Jolly & J. E. Phillips-Conroy pers. obs.).

Reproduction and Population Structure Reproduction not studied. However, based on what we know concerning the relationship between birth seasons, breeding seasons and the timing of annual rainfall at other sites where *Chlorocebus* spp. occur (Butynski 1988),

some predictions can be made. For *C. aethiops* in the Bole Valley, where there is one wet season (May–Oct), one dry season (Nov–April) and a mean annual rainfall of 2000 mm, it is expected that there is an annual peak in births during Jan–Apr, that most mating occurs during Sep–Dec, and that food is most abundant during Aug–Nov. If reproductive parameters from other *Chlorocebus* spp. (Butynski 1988, Cheney *et al.* 1988, Enstam & Isbell 2007) are applied to *C. aethiops*, mean inter-birth interval is 1.2–1.7 years, gestation is ca 5.4 months, and age at weaning is 9–18 months. Else *et al.* (1986) found that *C. pygerythrus* in captivity has a 32.5 day ovulatory cycle. Extrapolating from other *Chlorocebus* spp., ♀ and ♂ *C. aethiops* reach sexual maturity at ca. 4 years and 5 years, respectively, and ♀♀ first give birth at ca. 5 years.

The only information on birth seasonality in *C. aethiops* comes from Awash N. P., which is ca. 250 km east of Bole Valley. Here many adult ♀♀ carry infants less than two months old during the main wet season (Jun–Aug), but only semi-independent infants observed during the dry season (Jan–Feb) (C. J. Jolly pers. comm.). Live to at least 24 years in captivity (Flower 1931).

Predators, Parasites and Diseases *Chlorocebus aethiops* has been captured and exported for thousands of years, as is attested by Cretan, Minoan and Egyptian murals. Humans, and their Domestic Dogs *Canis familiaris* (which, in the highlands of Eritrea, sometimes run in packs; D. Zinner pers. comm.), are therefore likely to have been the major predators for a long time. The African Crowned Eagle *Stephanoaetus coronatus* and Leopard *Panthera pardus* are probably the most frequent non-human predators of *C. aethiops* as they are important predators for most species of guenons (Enstam & Isbell 2007). Some of the other likely predators are Verreaux’s Eagle *Aquila verreauxii*, Martial Eagle *Polemaetus bellicosus*, Lion *Panthera leo*, Cheetah *Acinonyx jubatus*, Striped Hyaena *Hyaena hyaena*, Spotted Hyaena *Crocuta crocuta*, jackals *Canis* spp., Hamadryas Baboon, Olive Baboon, Central African Rock Python *Python sebae* and Nile Crocodile *Crocodylus niloticus*. The populations of most of these predators have, however, declined greatly over the range of *C. aethiops* during the past century (Yalden *et al.* 1996, Department of Environment 1999, Zinner *et al.* 2001c, 2002b).

The disease profile for *C. aethiops* is likely to prove to be as extensive and significant as for other *Chlorocebus*. Natural populations in Ethiopia harbour endemic simian immunodeficiency virus (SIV), without obvious ill effects (Phillips-Conroy *et al.* 1994). Juveniles and infants are rarely SIV-positive, so maternal transmission is evidently rare, but almost all animals become positive with the initiation of sexual contact. All sexually mature ♀♀ and most mature ♂♂ are therefore SIV positive, for an overall rate of about 50% (Jolly *et al.* 1996).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Persecuted as a crop pest (Dunbar & Dunbar 1974b, Yalden *et al.* 1977, Zinner *et al.* 2001c). Captured and exported in the past for medical research. Even as long ago as 1969, *C. aethiops* was being extirpated from many sites due to loss of habitat (Kock 1969). In Eritrea, forest cover declined from 30% of the land area in 1900 to <3% in 1990 (EAE 1995). There can be no doubt this loss of food trees and of sleeping trees has resulted in a concomitant decline of Eritrea’s population of *C. aethiops* and of other forest-

and woodland-dependent species. Already, almost 50% of the larger species of mammal historically present in Eritrea have been extirpated (DoE 1999). As noted by Zinner *et al.* (2002b, p. 157) for Eritrea, 'The ongoing reduction of riverine woodland, the expansion of agricultural activities through irrigation projects and an increasing human population, particularly by resettlement programmes for refugees from Ethiopia and Sudan, intensify the conflict between Grivets and humans.' None the less, *C. aethiops* remains Eritrea and Ethiopia's (and probably north-east Africa's) most widespread and common monkey (Dunbar & Dunbar 1974b, Yalden *et al.* 1977, Zinner *et al.* 2001c, 2002b). *Chlorocebus aethiops* is present in five of Ethiopia's nine national parks (Yalden *et al.* 1996) and Eritrea is planning a protected areas system that will support populations of *C. aethiops* (EAE 1995).

Measurements

Chlorocebus aethiops

HB (♂): 480 mm, n = 1

T (♂): 645 mm, n = 1

HF (♂): 135 mm, n = 1

Chlorocebus tantalus TANTALUS MONKEY

Fr. Tantale; Ger. Tantalus-Grünmeerkatze

Chlorocebus tantalus (Ogilby, 1841). Proc. Zool. Soc. Lond. 1841: 33. Locality not known.

Tantalus Monkey *Chlorocebus tantalus* young male.

Taxonomy Polytypic species. Schwarz (1926) and Grubb *et al.* (2003) considered Tantalus to be a subspecies of *Cercopithecus aethiops*. Dandelot (1959) raised Tantalus to species status and this is supported by Kingdon (1997) and Groves (2001, 2005c). Groves (1989) resurrected the generic name *Chlorocebus* for the Savanna Monkeys Group *C. (aethiops)*. Here we follow Kingdon (1997) and Groves (2001) in recognizing three subspecies for *C. tantalus*. Synonyms: *alexandri*, *beniana*, *graueri*, *griseistictus*, *itimbiensis*, *passargei*, *pousarguei*, *viridis*. Chromosome number $2n = 60$ (Chu & Giles 1957).

Description Medium-sized, long-tailed, black-faced, semi-terrestrial monkey. Adult ♂ like adult ♀ in colour but larger. Brow-

band wide, sinuous, of white or yellowish hairs above intensely black face. Brow hairs sometimes speckled at the tips. Black tuft between eyes. Brow-band sometimes separated from the whiskers by a black line at the outer corner of the eyes. Long white hairs on temple sweep upwards in older individuals. Cheek-hair sweeps backwards, separating above the ear, which is covered in mature animals. Crown and back grizzled gold to greenish. Ventrums white. Limbs and tail grey. Tuft of long whitish hairs to either side of base of tail. Tip of tail whitish. Perineal skin pink, sometimes with light covering of orange hairs. Penis red. Scrotum sky-blue surrounded by tuft of orange hairs. Tantalus is the largest of the *Chlorocebus* spp. (Kingdon 1997).

Geographic Variation

C. t. tantalus Common Tantalus Monkey. Ghana east of White Volta R. east to S Chad and Ubangi R. Back olive-green.

C. t. budgetti Budgett's Tantalus Monkey. S Chad and Ubangi R. through S Sudan east to Nile R. NE DR Congo, N Uganda and Kenya west of L. Turkana. Back more olive-brown, whiskers more yellowish with more extensive speckling. Feet and tail tip darker.

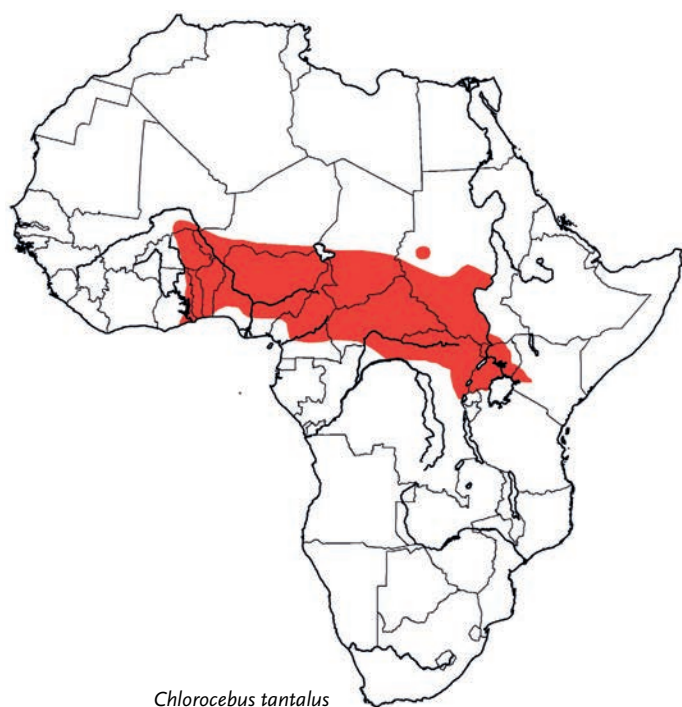

C. t. marrensis Jebel Marra Tantalus Monkey. On Jebel Marra Plateau, CW Sudan. Isolated by desert. Like *C. t. tantalus*, but colour tends to be lighter olive-fawn (Kingdon 1997, Groves 2001).

Similar Species

Chlorocebus sabaeus. Gambia to west of Volta R., Ghana. No white brow-band. Tail tip golden yellow. No tuft of whitish hairs at base of tail. Scrotum pale blue.

Chlorocebus aethiops. East of Nile R. and south of Khartoum, S Sudan through S Eritrea, C and N Ethiopia into Djibouti. Brow-band narrow, white, confluent with whiskers. Moustache white.

Chlorocebus pygerythrus. S Somalia, S Ethiopia, E Uganda and Kenya south through South Africa. Brow-band broad, white, confluent

*Chlorocebus tantalus*

with short whiskers. Hands and feet dark grey to black. Underside of base of tail of adult ♂ with patch of red hairs. No tuft of whitish hairs at base of tail. Tail tip dark brown to black. Scrotum turquoise blue, surrounded by white hairs.

Distribution Endemic to Africa, mostly north of the Equator. Sahel Savanna, Sudan Savanna and Guinea Savanna BZs. Mali, Burkina Faso and Ghana east of the White Volta R. eastward to north of Ubangi R. through S Sudan to Nile R., NE DR Congo, N Uganda into NW Kenya west of L. Turkana. Northern limit poorly known, but probably to ca. 17°N in Mali, making this one of the guenons with the northern-most distribution (T. Butynski pers. comm.). Around the boundaries of its distribution, zones of hybridization with other *Chlorocebus* spp. occur, often over a wide band. *Chlorocebus t. tantalus* interbreeds with the Green Monkey *Chlorocebus sabaeus* in Ghana west of the White Volta R. (Bole); *C. t. budgetti* with the Vervet *Chlorocebus pygerythrus hilgerti* in Kenya west of L. Turkana and with *C. p. rufoviridis* in SW Uganda east of L. Edward and L. Kivu, and north and west of L. Victoria (Kingdon 1971, 1997).

Habitat *Tantalus* occupies a variety of habitats, including savanna woodland, gallery forest, swamp forest and forest edge. Prefers riverine vegetation for access to water and sleeping trees. Mean annual rainfall of three habitats used by *C. tantalus* in Cameroon are: 3580 mm in forest edge at Bakossi (04°53'N); 1450 mm in Guinea savanna at Benoue N. P. (08°06'N); 650 mm in Sahel savanna at Kala Maloue N. P. (12°09'N) (Kavanagh 1981). Occurs from sea level in West Africa (Grubb *et al.* 1998) to at least 1600 m in Nigeria (Agmen *et al.* 2009) and to at least 1500 m in Uganda (T. Butynski pers. comm.).

Abundance Group density in Kainji Lake N. P., Nigeria, was 0.22 ind/km² in the Oli R. Valley and 0.05 ind/km² away from the

Valley in 1971–72. Given that the average group size is ten animals, the total population in Kainji Lake N. P. (3675 km²) was estimated to be ca. 2600 animals (Child 1974 in Wolfheim 1983). Despite its overall abundance, populations have been decreasing in some areas. In Sudan, for example, the northern boundary of distribution has retreated from 19°N to 15°N in the last 100 years because of tree-cutting along the Nile R. for firewood (Butler 1966). In Cameroon, on the other hand, populations are probably increasing because felling of rainforest provides *Tantalus* with suitable habitats such as secondary savanna and fallow land (S. Gartlan pers. comm. in Wolfheim 1983).

Adaptations Diurnal and semi-terrestrial. Generalized omnivorous diet and semi-terrestriality enable *Tantalus* to live in arid and/or open habitats. *Tantalus* invade recently cultivated fields in rainforest at Bakossi, Cameroon, while the indigenous Mona Monkey *Cercopithecus mona* seems less adept at exploiting changed habitats (Kavanagh 1980). *Tantalus* take long rests in large shaded trees at mid-day to avoid heat stress and terrestrial predators. As soon as they notice canids, such as Common Jackals *Canis aureus* and Domestic Dogs *Canis familiaris*, *Tantalus* climb to safety in nearby trees and emit loud alarm calls. It is believed that *Tantalus* at Bakossi keep silent in response to the presence of dogs accompanied by human hunters. *Tantalus* emit a 'quiet call' for intra-specific contact or to serve as a low-intensity alarm call. This call is hardly ever uttered by *Tantalus* in habitats where hunting pressure by humans is rare or absent (Kavanagh 1980).

Foraging and Food Omnivorous. *Tantalus* descend from sleeping trees in dense woodland or gallery forest early in the morning and begin feeding. They range extensively into savanna grassland when moving between wooded areas, but never feed there for long periods of time. After resting for 2–3 of the hottest hours of the day in large shade trees, they resume feeding and then go back to a wooded area to sleep. Mean home-range size was 55 ha (n = 5 groups), ranging from 12 ha at Bokossi to 103 ha at Benoue. Daily distance moved by groups varied with habitat and/or season: 0.7–3.7 km at Benoue (n = 1 group, 20 days) and 0.5–2.5 km at Kala Maloue (n = 2 groups, 20 days) (Kavanagh 1981, Nakagawa 1999). At both sites, about 30% of foraging was on the ground and 90% of foraging was <10 m above the ground (n = 1 group, 475 h for Benoue; n = 1 group, 512 h for Kala Maloue; Kavanagh 1978).

Generalist omnivores, feeding on plant parts and animals (mostly invertebrates but also, infrequently, reptiles and birds). *Tantalus* feed on a larger number of food items of lower quality (poorer in protein and energy, richer in fibre) than do sympatric Patas *Erythrocebus patas* in Kala Maloue (Nakagawa 2003). Sources of protein include flowers (9% of diet), leaves (9%) and invertebrates (6%), while sources of energy are fruits (56%) and lipid-rich seeds (17%) (n = 37 different kinds of foods). Among the more frequent items eaten are the flowers of *Kigelia africana* and *Tamarindus indica*, leaves of *Panicum* sp. and *Indigofera* sp., fruits of *Celtis integrifolia*, *Diospyros mespiliformis* and *Morela senegalensis*, and seeds of *K. africana* (Nakagawa 2000b). Adult ♀♀ choose protein-rich foods (i.e. invertebrates, leaves and flowers) while adult ♂♂ select foods that contain less protein but more energy (e.g. fruits; Nakagawa 2000b). Disperses seeds of forest edge species into grasslands (Agmen *et al.* 2009).

Tantalus Monkey *Chlorocebus tantalus* subadult male.

Social and Reproductive Behaviour Social. Tantalus form stable multimale heterosexual groups. Solitary adult ♂♂ also occur. Group size and composition reported from three sites in Cameroon (Kavanagh 1981, Nakagawa 1999). Mean group size is 29 animals (11–76, $n = 5$), including 1–10 adult ♂♂ and 3–18 adult ♀♀. There are 0.5–1.0 ♂♂ per ♀. In two populations, group adult ♂♂ observed in territorial defence, emitting loud vocalizations at high vantage points and rushing towards the intruding group. In another population agonistic interactions were rarely observed during group encounters, and consequently 18% of the home-range was shared with neighbouring groups (Kavanagh 1981).

Both ♂♂ and ♀♀ in a group form a lineal dominance hierarchy (Nakagawa 2008). Young ♀♀ and adult ♀♀, regardless of kin-relatedness to the infants, frequently display allomothering behaviours such as touching, holding, nuzzling, grooming and sometimes carrying young.

Reproduction and Population Structure A single infant is born. Twins not reported. Kavanagh (1983) found inter-population differences in birth seasons in Cameroon. Births take place during Oct–Nov at the end of wet season in Bakossi; during Jan–Feb during the mid-dry season in Buffle Noir, and during Jul–Aug in the wet season in Kala Maloue. No consistent relationship between rainfall seasonality and birth frequency has been found. However, in Kala Maloue, with the least amount of annual rainfall (650 mm), the birth season corresponds not only to a period of high rainfall but to a period of a high percentage of fruit in the diet, although the relationship between overall food availability and birth frequency is unknown. In Kala Maloue sympatric Patas have their mating season in the wet season and their birth season during Jan–Feb at the middle of the dry season. The latter corresponds with the mating season of Tantalus. To evaluate the optimality of species-specific birth seasons, Nakagawa (2000a) estimated the daily intake of available energy and gross protein, and the energy expenditure of both Tantalus and Patas

between their respective birth and mating seasons. The monkeys obtained a larger amount of available energy and gross protein in the birth season than in the mating season. No significant seasonal differences were found in their energy expenditure. Thus, births appear to be timed to the season in which the monkeys can obtain the most surplus energy and protein. Tantalus ♀♀ experience first birth at 4–5 years of age ($n = 3$) in Kala Maloue. Four out of six inter-birth intervals were one year and the remaining two were two years (mean 16 months) (N. Nakagawa pers. obs.).

Predators, Parasites and Diseases There is little information on predation of Tantalus. A one-year-old juvenile caught by a Common Jackal in Kala Maloue (N. Nakagawa pers. obs.). Side-striped Jackal *Canis adustus*, African Wild Dog *Lycaon pictus*, Spotted Hyaena *Crocuta crocuta*, Leopard *Panthera pardus* and Serval *Felis serval* are potential predators in Cameroon (Kavanagh 1980, 1983). Almost nothing is known concerning disease in Tantalus. Species-specific simian immunodeficiency virus (SIV) and simian T-cell leukaemia virus present in feral Tantalus, although infected monkeys demonstrate no external evidence of these diseases (Hirsch *et al.* 1993b, Saksena *et al.* 1993).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

While unsustainable firewood-collection in savanna regions eventually diminishes Tantalus populations, felling of rainforest is likely to favour increases in population. Further surveys needed to determine the conservation status of Tantalus living in various habitats across the species' extensive range.

Measurements

Chlorocebus tantalus

HB (♂♂): 515 (380–830) mm, $n = 10$

HB (♀♀): 415 (385–440) mm, $n = 6$

T (♂♂): 697 (575–1140) mm, $n = 10$

T (♀♀): 571 (555–600) mm, $n = 6$

HF (♂♂): 138 (90–152) mm, $n = 10$

HF (♀♀): 129 (125–135) mm, $n = 6$

E (♂♂): 38 (32–42) mm, $n = 6$

E (♀♀): 40 (40–40) mm, $n = 6$

WT (♂): 2.9 kg, $n = 1$

WT (♀): 2.7 kg, $n = 1$

Various localities. Linear measurements: ♂♂ compiled from three subspecies (Elliot 1913c, Hill 1966); ♀♀ *C. t. budgetti* (Hill 1966) WT: ♂ *C. t. tantalus* (Hill 1966); ♀ *C. t. tantalus* (H. Ohsawa, M. Inoue-Murayama & O. Takenaka pers. comm.)

Chlorocebus sabaeus GREEN MONKEY (*CALLITHRIX*)

Fr. Singe vert; Ger. Westliche Grünmeerkatze

Chlorocebus sabaeus (Linnaeus, 1766). Systema Naturae, 12th edn, 1: 38. Cape Verde Is.Green Monkey *Chlorocebus sabaeus* adult male.*Chlorocebus sabaeus*

Taxonomy Monotypic species. Member of the Savanna Monkeys Group *Chlorocebus* (*aethiops*). Although the differentiation of blood proteins and electrophoretic distances between *Chlorocebus sabaeus* and the related Grivet *Chlorocebus aethiops* are moderate and could support arguments for subspecies or intermediate ranking (Lucotte *et al.* 1982), full species status is now accepted by most authorities (Lernould 1988, Kingdon 1997, Groves 2001, 2005c). Hybridization with *Erythrocebus patas* in the wild (Galat 1998) and with *Macaca mulatta* in captivity (Zuckerman in Hill 1966). Synonyms: *callitrichus*, *chrysurus*, *wernerii*. Chromosome number: $2n = 60$ (Sineo *et al.* 1986, Dutrillaux *et al.* 1988b).

Description Medium-sized, long-legged, long-tailed, semi-terrestrial, olive-green monkey. Chest deep, waist slim. Adult ♀ like adult ♂ but smaller, weighing about 70% as much. Face black. Whiskers whitish to yellowish. Temporal 'cowlick' that is directed upwards in front of ears. Brow-band greyish (not white) indistinct or absent. Dorsum and upper limbs and base of tail grizzled olive-green (hairs speckled green, yellow and black). Hands and feet pale grey. Underparts whitish. Tail shortish, tip fawn to golden yellow in adults and grey in immatures. Anus red in adult ♂. Scrotum yellow to green except blue for dominant ♂♂. Newborn with face pale pink. Dorsal pelage black.

Geographic Variation There is a slight north to south gradient with regard to sexual dimorphism (♂♂ larger in north) and colour of dorsum, which is yellower in the north (Galat *et al.* 2011). Some local populations/groups have distinctive characteristics. Namely, nasal ridge may be more or less white-haired and face exhibits variable patterns of depigmented spots; conspicuousness of the brow-band varies; throat and front of chest ranges from whitish to orange (A. Galat-Luong pers. obs.).

Similar Species

Chlorocebus tantalus. Eastward of Nakambe/Volta R. in Burkina Faso and Ghana. Smaller. Cheek-hair long and yellowish with short black tips. White 'facial ring' broken by black line from eyes to temples. Brow-band distinct, white. Dorsum gold to greenish. Base of tail with white tuft of hairs to either side. Tail tip whitish. Perineum sometimes with orange hairs.

Distribution Endemic to W Africa. Sahel Savanna, Guinea Savanna and Northern Rainforest–Savanna Mosaic BZs.

Current Distribution Atlantic coast of Senegal, Gambia, Guinea-Bissau, Guinea and Sierra Leone eastwards to the Nakambe/Volta R. in Burkina Faso and Ghana. Western limit is Dakar, Senegal (17° 28' W; A. Galat-Luong & G. Galat pers. obs.). Northern limit is at ca. 17° N in Mauritania and Mali. Area of occurrence is ca. 1,000,000 km². Most northern populations are now relics. Reaching 17° N, the Green Monkey, together with the Tantalus *Chlorocebus tantalus* in Mali, the Patas *Erythrocebus patas* on the Air Massif, Niger, and the Grivet in Eritrea, probably has the northern-most range of any species of guenon at this time. Southern limit of the primary range is at ca. 05° 50' N both in Côte d'Ivoire (A. Galat-Luong & G. Galat pers. obs.) and Ghana. There are, however, isolated outliers in mangrove and associated secondary forest in Côte d'Ivoire at Ebrié Laguna near Jacqueline (05° 10' ; 04° 30' W; Galat 1983) and on Elouamin I., Iles Ehotilé N. P. (05° 09' N; 03° 18' W; Gonedélé Bi *et al.* 2009). Introduced to Cape Verde Is. and the West Indies (Barbados, Nevis and St Kitts).

Historical Distribution Geographic range not greatly reduced, but some populations living near or in cities have disappeared (e.g. a population lived in Dakar until 1998; G. Galat & A. Galat-Luong pers. obs.). One of the last monkeys to disappear as a result of human-caused habitat modifications.

Habitat Prefers Sudanian–sub-Guinean woodlands, gallery forests and wooded savannas. Mean annual rainfall over geographic range varies from 200–1200 mm. Green Monkeys stay in sight of trees. They prefer to sleep in trees at the fringe of wooded areas (or near water) with a good look-out over open land (A. Galat-Luong pers. obs.). They spend about half of the time in forest or arboreal savanna, one-third in shrubby savanna and little time in grasslands (G. Galat & A. Galat-Luong pers. obs.). Water generally available within 5–10 km. Groups use unique sleeping sites (i.e. preferentially chosen groves of trees) in the north. Sometimes two groups sleep at the same site (Galat 1983). In the south of their range a group can use several sleeping sites (Galat & Galat-Luong 1976). Do not use the same site twice in areas where hunted (Galat 1983).

Marginal habitats include Sahelian acacia forests (*Acacia nilotica*, *Acacia radiana*, *Acacia seyal*, *Acacia senegal*, *Acacia albidia*). Plant diversity may be low: no more than 43 plant species (including small herbs) recorded from one group's home-range (Galat 1983). May spend 80% of time (and three days consecutively) in mangrove swamps (*Rhizophora* sp., *Avicennia nitida*; Galat & Galat-Luong 1976). The time spent in trees depends on habitat structure, ranging from 28% (Senegal R. Valley, Senegal) to 72% (Saloum, Senegal) (Galat & Galat-Luong 1976). In the Senegal R. Valley, adults significantly more often recorded on the ground than young ($n = 5398$), and adult ♂♂ more often on the ground than adult ♀♀ ($n = 2732$). Spent 15% of time on vertical trunks, 50% on horizontal boughs, 17% on branches and 18% on twigs ($n = 3773$) (Galat 1983). Adults significantly more often recorded on larger branches than young ($n = 2733$), and adult ♂♂ more often than adult ♀♀ ($n = 994$). Altitude ranges from 0 to ca. 1000 m. Maximum temperature ranges from ca. 20 to 57°C. Minimum 1°C.

Abundance Densities are 1.6–1.7 ind/km² in Niokolo Koba N. P., Senegal (Galat *et al.* 1998) and 1.4 ind/km² maximum density in Comoé N. P., Côte d'Ivoire (Geerling & Bokdam 1973). Highest densities for Green Monkeys occur in refuges close to areas where raiding crops is habitual (maximum density of 7 ind/km² at Fathala, Senegal). Density inside home-ranges 10–112 ind/km²: 18–28 ind. in 1.78 km² at Assirick, Senegal (Harrison 1983a), 15 ind. in 15 ha at Bandia, Senegal (Galat 1983), and 174 ind. in 1.56 km² at Ndioum Wallo, Senegal (Galat 1983).

Adaptations Diurnal and semi-terrestrial. Opportunistic. Green Monkeys adapt to uncommon environments (e.g. mangrove swamps; Galat & Galat-Luong 1976, Gippoliti & Dell'Omo 1996) and foods. They swim (up to 100 m with an infant under the belly; Galat 1989), and play and dive in the sea at high tide (A. Galat-Luong pers. obs.). Use unique techniques to hunt Nile Grass Rats *Arvicantis niloticus* (Galat 1983), Laughing Doves *Streptopelia senegalensis* (Galat 1989) and Fiddler Crabs *Uca tangeri* (Galat & Galat-Luong 1976). Can live without water for six months, but not in arid areas. During the hotter hours and when food is scarce they take long rests in the shade for up to six hours per day (Galat 1983).

Foraging and Food Opportunistic omnivores. Green Monkeys feed in the morning and late in the afternoon. Subgroup foraging occurs (Galat 1983). Home-range size in Senegal 15–178 ha (Galat & Galat-Luong 1976, Galat 1983, Harrison 1983b) depending on habitat quality. Day range 0.5–2 km (Harrison 1983a, G. Galat pers. obs.) to 4–8 km (G. Galat pers. obs.). They can travel up to 2 km in 45 minutes (Galat 1983). Green Monkeys are generalists, feeding on fruits (24–50%, annual means), leaves (28–50%), seeds (13%), flowers (3–13%), buds, young twigs, stems, thorns, bark, gum (11–15%), fungi, and also bird faeces, termitarium earth, invertebrates (5–50%) and vertebrates, including eggs, young birds, sparrows, lizards and small mammals (Galat & Galat-Luong 1977, 1978b, McGrew *et al.* 1978, Galat 1983, Harrison 1983a). Important food plant species in Senegal are *Parinari* spp., *Ficus* spp., *Ziziphus mauritiana*, *Ziziphus mucronata*, *Icacina senegalensis*, *Acacia siberiana*, *Acacia nilotica*, *Adansonia digitata*, *Aphania senegalensis*, *Rhizophora* sp., *Nymphaea* sp. (Galat & Galat-Luong 1976, 1977, Galat 1983), *Pterocarpus erinaceus*, *Pseudospondias microcarpa* and *Nauclea latifolia* (Harrison 1982). In poor environments a single plant group or species can make up most of the diet (leaves of grasses up to 63% in wet season, all parts of *A. nilotica* up to 44%; Galat & Galat-Luong 1978a). During periods of scarcity, rodents can constitute, by time spent feeding, 47% (one 125 g Nile Grass Rat for three monkeys) and Laughing Doves 28% of the animal prey (Galat *et al.* 2011). Green Monkeys prey occasionally on adult Red-billed Hornbills *Tockus erythrorhynchus* (attacks on African Grey Hornbills *Tockus nasutus* fail; A. Galat-Luong pers. obs.) and young Scrub Hares *Lepus saxatilis* (Galat & Galat-Luong 1977, 1978a). Mobbing from Abyssinian Rollers *Coracias abyssinicus* and gulls *Larus* sp. is frequent at Senegal R. Valley (Galat 1983). In mangrove swamps, Fiddler Crabs can represent >50 g of fresh meat per animal per day (G. Galat pers. obs.). Crop raiding and food stealing occur (Galat 1983). Feeding takes 8–32% of time, locomotion 17–48% and resting 23–64% (Dunbar 1974, Galat & Galat-Luong 1976, Harrison 1983a). There are significant seasonal differences in how time is spent (Galat 1983, Harrison 1984, 1985).

Social and Reproductive Behaviour Social. Green Monkey groups are multimale/multifemale. Adult ♂♂ emigrate, sometimes into adjacent groups (Galat 1983). Mean sizes of groups in Senegal are: north, 52 ind. (15–174, $n = 11$ groups; Galat & Galat-Luong 1977, Galat 1983), 19 (5–35, $n = 5$; A. Galat-Luong pers. obs.); north-east, 16 ($n = 1$; Galat 1983); west (Dakar), 12 (8–18, $n = 3$; Galat 1983, A. Galat-Luong pers. obs.); west (Saloum), 34 (24–45, $n = 13$; A. Galat-Luong pers. obs.); south-west, 10 ($n = 1$; Galat 1983); south-east, 12 (8–16, $n = 5$; Dunbar 1974), 19 ($n = 12$; Harrison 1983b), 27 (10–40, $n = 7$, A. Galat-Luong pers. obs.). In Guinea, group size was: 1 ind. (31%), 2–10 (43.3%), 11–20 (20.9%), >21 (4.5%) ($n = 454$ individuals; Touré *et al.* 1997), and in Côte d'Ivoire mean group size was 6 ind. (4–9, $n = 3$; Galat & Galat-Luong 1980). There are two levels of organization in the larger groups, which can fragment into subgroups of up to 15 individuals (Galat 1983).

Social behaviour occupies 7–13% of time (Dunbar 1974, Galat & Galat-Luong 1976). In rich environments (annual rainfall >500 mm), home-ranges (and groups) are small, just large enough to include most of the plant diversity of the area (Galat 1989). Territorial behaviour is common if food is available (Galat & Galat-Luong 1976, 1977, 1978b, Harrison 1982, 1983b). Dominant ♂♂ give

territorial displays from high vantage points every morning at dawn and sometimes in the evening at twilight. Display includes powerful jumps, exhaled/inhaled barking and exhibition of the white belly, red penis and blue scrotum (Galat & Galat-Luong 1976). Territorial boundaries may remain unchanged for 25 years (G. Galat pers. obs.). Territorial behaviour is absent if resources are scarce, patchy and unpredictable (Galat & Galat-Luong 1978b). For example, in the Senegal R. valley, four groups, totalling >200 individuals, observed feeding together on *Z. mauritiana* without exhibiting agonistic behaviour, and several groups observed queuing for access to a single *Ptilostigma thonningii* (Galat 1989). However, artificial provisioning can induce territorial behaviour (Galat 1983). One group may dominate another (Galat 1983). 'Nurseries' can comprise infants from several groups (Galat 1983). In large (northern) groups, at the beginning of the wet season, adult ♂♂ may herd several pregnant ♀♀ and control subgroups made up of 12–15 individuals (Galat 1983). Herding is rare in the southern populations (Harrison 1983b).

Copulation is most often seen at dawn in the cool season (Galat 1983). Young are carried under the belly and are taken care of by their mother, sisters, aunts and sometimes adult ♂♂. More than 60 gestures and 30 vocalizations given, including chest-to-chest rubbing (Galat 1975, 1983). Alarm vocalizations distinguish predator categories (aerial or terrestrial) and degree of threat. Comparison of these behaviours with those described by McGuire (1974) on St Kitts indicates that they are almost identical, and that there was no genetic drift on St Kitts in these behaviours in spite of three centuries of isolation. Differences in some behaviours described for Vervet *Chlorocebus pygerythrus* (Struhsaker 1967a, b) are considerable (Galat 1975). Only 4% of adult ♂♂ Green Monkeys have a blue scrotum (Galat 1983), and they lack the strongly contrasted anal characters of the Vervet; Green Monkeys have a pale pink perianal ring (instead of intense red) and lack the white 'moustache' beneath the anus. As such, the 'red-white-and-blue' dominance display (Struhsaker 1967a, b) of the adult ♂♂ Vervet is replaced in the adult ♂♂ Green Monkey by a 'lateral display' whereby the ♂ presents his lateral profile and 'enlarges' himself by raising the tail over the back. Experiments with young ♂ Green Monkeys (Lucotte *et al.* 1982) demonstrated that they are able to display like *C. pygerythrus*, but that, for lack of reinforcement by effective visual stimuli, they do not give this display when adult. Vocalization structures are similar to *C. pygerythrus* but context (meaning) slightly differs (G. Galat & A. Galat-Luong pers. obs.).

In Saloum, Green Monkeys in association with Patas on 27% of encounters, with Temminck's Red Colobus *Procolobus badius temminckii* on 18%, and with both Patas and Temminck's Red Colobus on 3% (n = 78 encounters; Pourrut *et al.* 1996). In Gambia (at Pirang), Green Monkeys in association with Temminck's Red Colobus on eight of ten encounters (Galat-Luong 1988). Such associations appear to enable Temminck's Red Colobus to follow Green Monkeys into mangrove swamps (Galat-Luong & Galat 2005), and enable Green Monkeys to exploit the margins of the high forest. In Burkina Faso, seen sharing sleeping trees with White-naped Mangabeys *Cercocebus lunulatus* (Galat & Galat-Luong 2006b) and the same (secure) swamp area with Olive Baboons *Papio anubis* (A. Galat-Luong pers. obs.). Bushbuck *Tragelaphus scriptus* (Galat-Luong, 2006) and Lord Derby's Eland *Taurotragus derbianus derbianus* (A. Galat-Luong & G. Galat pers. obs.) also associate with Green Monkeys. Play is varied and may be inter-specific, including with Northern Lesser Galagos *Galago*

senegalensis, Patas, Temminck's Red Colobus, grass snakes and birds (Galat 1983, 1989, A. Galat-Luong pers. obs.).

Reproduction and Population Structure Birth seasons vary geographically: Feb–Mar (Saloum; A. Galat-Luong pers. obs.), Mar–Apr (Niokolo Koba; Dunbar 1974, Harrison 1983a), Dec–Jan and Jun–Jul (Senegal R. Valley; Bourlière *et al.* 1976). In the Senegal R. Valley ♀♀ can give birth twice a year, at seven-month intervals (Bourlière *et al.* 1976, Galat & Galat-Luong 1977). In Niokolo Koba one adult ♀ was observed to suckle two infants simultaneously (A. Galat-Luong pers. obs.). Male : female sex ratio varies from 1 : 1 to 1 : 3.5. Adult : immature ratio varies from 1 : 0.4 to 1 : 1.2 (Galat & Galat-Luong 1976, 1977). Galat-Luong (1994) estimated longevity in the wild at 27 years, a value close to the 30-year record for captives (Jones 1962, Baulu 1988). If climatic conditions and subsequent food availability change drastically, reproductive success may be 100% in one year and then near zero the following year (n = 3 groups; Galat & Galat-Luong 1977).

Predators, Parasites and Diseases Humans, Leopards *Panthera pardus*, Central African Rock Pythons *Python sebae* (attack of pregnant ♀ observed by A. Galat-Luong), Spotted Hyenas *Crocuta crocuta* and African Wild Dogs *Lycaon pictus* are the main predators. Striped Jackals *Canis adustus*, Caracals *Felis caracal*, Servals *Felis serval*, Domestic Dogs *Canis familiaris* and large eagles probably prey on young. Green Monkeys recognize individually the dogs that herd sheep and have a different flight distance for each dog (that seems to depend on how much of a threat each dog is). For example old, rheumatic dogs evoke flight at <5 m, whereas faster, more dangerous dogs evoke alarm calls and flight at >100 m (A. Galat-Luong pers. obs.). Brewer (1978), under semi-captive and reintroduction conditions, recorded the Robust Chimpanzee *Pan troglodytes* as a predator. Pruetz & Bertolani (2007) saw a wild Robust Chimpanzee feeding on a Green Monkey. Excessive dry periods can cause blindness due to vitamin A deficiencies, high adult mortality, and increased rates of stillbirths and miscarriages (Galat & Galat-Luong 1977). Penile and scrotum necrosis also occurs (A. Galat-Luong pers. obs.).

Identified intestinal parasites include Nematoda *Strongyloides* sp. (69% of faecal samples), *Necator* sp. (6%), *Physaloptera* sp. (6%); Protozoa *Entamoeba coli* (75%), *Iodamoeba butschlii* (25%) (Assirick, n = 16 faecal samples; McGrew *et al.* 1989b). *Entamoeba coli* (49%), Nematoda (32%), *Strongylidae* (20%), *Strongyloides stercoralis* (11%), *Trichuris trichura* (3%), *Ascaris lumbricoides* (9%) (n = 94 faecal samples from various sites in Senegal; Pourrut *et al.* 1997). Nematode infection in Green Monkeys is lower where *A. nilotica* is a staple food. *Acacia nilotica* is used by the local people against intestinal parasites, but the low rainfall in those areas also thwarts nematode development (overall infestation W, N and SE Senegal was 79%, n = 94 faecal samples; Pourrut *et al.* 1997).

Green Monkeys are healthy carriers of the simian immunodeficiency virus (SIV), which is similar to human immunodeficiency virus (HIV), and thus are used as biomedical models. Prevalence is 46% in wild populations in Senegal (n = 352; Galat & Galat-Luong 1997). Prevalence is higher in adults (51–81%) than in immatures (20%), indicating sexual transmission (Galat-Luong *et al.* 1994b, 1995), and implying other possible infection routes such as bites (Galat & Galat-Luong 1997). Comparing these values with those for Patas

(6% of the population, 10% for adults, 4% for immatures), Galat-Luong *et al.* (1994b) showed the importance of differing strategies in the choice of sexual partners for the transmission of SIV (multiple partners among Green Monkeys and single-male groups among Patas). Transmission of Green Monkey's SIVagm to Patas in the wild occurs (Bibollet-Ruche *et al.* 1996, Galat-Luong *et al.* 1996). Infection with SIV or STLV-I (Simian T-cell Lymphotropic Virus) increases the risk for a second retroviral infection (Durand *et al.* 1995).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Only some populations are threatened, such as at Île à Morfil, Senegal, where an 85% reduction of the *A. nilotica* forest resulted in the disappearance of 83% of the Green Monkeys. Here the number of ♀ ♀ per ♂ dropped from 3.0 in 1975 and 2.5 in 1976 (wet season data) to 1.4 in 1988 as a result of increased mortality among adult ♀ ♀. Likewise, the number of young per adult, which was 0.96 in 1975 and 0.76 in 1976, declined to 0.67 in 1988 (Galat-Luong & Galat 1994).

Measurements

Chlorocebus sabaeus

HB (♂ ♂): 540 (470–650) mm, n = 7

HB (♀ ♀): 420, 460 mm, n = 2

T: n. d.

HF: n. d.

E: n. d.

WT (♂ ♂): 6.3 (4.7–7.5) kg, n = 17

WT (♀ ♀): 4.4 (3.4–5.9) kg, n = 20

Body measurements: HB: Senegal and Côte d'Ivoire (A. Galat-Luong pers. obs.)

WT: Senegal (Galat-Luong *et al.* 1996)

Chlorocebus pygerythrus VERVET MONKEY

Fr. Vervet; Ger. Südliche Grünmeerkatze

Chlorocebus pygerythrus (F. Cuvier, 1821). Histoire Naturelle Mammifères, pl. 139, pt. 24: 2. 'Africa'.

Vervet Monkey *Chlorocebus pygerythrus* adult male.

Taxonomy Polytypic species. Dorst & Dandelot (1969), Kingdon (1971), Haltenorth & Diller (1977), Napier (1981) and Grubb *et al.* (2003) considered the Vervet to be a subspecies (*Cercopithecus aethiops pygerythrus*) within the *C. (aethiops)* Group. Hill (1966), Dandelot (1974) and Kingdon (1997) treated *C. pygerythrus* as a distinct species with 13, 14 and 6 subspecies, respectively. Groves (2001, 2005c) also viewed the Vervet as a full species (with five subspecies), but places this taxon within the genus *Chlorocebus*. Here we adopt the taxonomy of Groves (2001, 2005c), but with reservations over the use of the genus name '*Chlorocebus*' as we believe current evidence supports '*Cercopithecus*' as the more appropriate genus for the *C. (aethiops)* Group (see our comments in the *Chlorocebus* genus profile). Only cases of hybridization in the wild are of one Zanzibar Sykes's

Monkey *Cercopithecus mitis albogularis* × *C. pygerythrus* hybrid at Diani, SE Kenya, and of one Kolb's White-collared Monkey *Cercopithecus mitis kolbi* at Nairobi, SC Kenya (De Jong & Butynski 2010b). Synonyms: *arenaria*, *callida*, *centralis*, *?circumcinctus*, *cloetei*, *contigua*, *ellenbecki*, *erythropysga*, *excubitor*, *flavidus*, *rubellus*, *rufoniger*, *rufoviridis*, *glaucus*, *helvescens*, *hilgerti*, *johnstoni*, *lalandii*, *luteus*, *marjoriae*, *nesiotes*, *ngamiensis*, *pembae*, *pusillus*, *silaceus*, *tumbili*, *voeltzkowi*, *whytei*. Chromosome number: 2n = 60 (Sineo *et al.* 1986).

Description Medium-sized, semi-terrestrial, long-tailed monkey with grizzled light brown, greyish-brown, tawny, olive-brown, olive-green or brownish-yellow dorsum and sides. Adult ♀ weighs about 70% as much as adult ♂. Adult ♂ and adult ♀ similar except for colouration over anogenital region. Face black with white cheek-whiskers and brow forming ring around face. Eyes and ears black. Ventrums white or off-white. Limbs greyish-brown to grey outside, white inside. Feet and hands black. Tail light to dark brown dorsally, light brown ventrally, with tip dark brown to black. Ischial callosities grey. Adult ♂: scrotum turquoise blue surrounded by white hairs. Adult ♂ with patch of red hairs under base of tail, perianal skin and penis red, perineal stripe white. Adult ♀: perineum pink, clitoris red, vulvar area blue, no perineal stripe. Infants: face pink, pelage black or dark brown. By the third month, the face is black, the brow white and the cheek-hairs obvious. By six months, the back has acquired adult colouration (Struhsaker 1971b). Photographs of *C. pygerythrus* from many sites in Kenya and Tanzania available at: www.wildsolutions.nl

Geographic Variation Five subspecies recognized:

C. p. excubitor Manda Vervet Monkey. Manda I. and Patta I., north coast of Kenya. Pale brownish-yellow; smaller than *C. p. hilgerti*.

Lateral, palatal and dorsal views of skull of Vervet Monkey *Chlorocebus pygerythrus* adult male.

- C. p. hilgerti* Hilgert's Vervet Monkey. E Uganda through Kenya to S Ethiopia east of the Rift Valley, S Somalia and N Tanzania. Similar to *C. p. excubitor* but larger.
- C. p. nesiotis* Pemba Vervet Monkey. Pemba I. and Mafia I., Tanzania. Brownish-fawn; whiskers long, speckled; ventrum often reddish; smaller than *C. p. rufoviridis*.
- C. p. pygerythrus* Southern Vervet Monkey. South of Zambesi R. in Botswana, Zimbabwe, Mozambique and South Africa. Grey or olive-green; greyer in west, greener in east.
- C. p. rufoviridis* Reddish-green Vervet Monkey. S Uganda west of L. Victoria, through Tanzania, south to Zambesi R. east of Luangwa R., Zambia. Similar to *C. p. nesiotis* but larger.

Similar Species

- Chlorocebus aethiops*. East of White Nile R. and south of Khartoum, Sudan, to C Eritrea, C Ethiopia into Djibouti. Hybridizes with *C. p. hilgerti* at Omo R., Ethiopia. Cheek-hair long and fluffy; face often with white moustache; back yellower; feet and hands pale grey; base of tail with tufts of white hair to either side; tail tip whitish; scrotum sky blue.
- Chlorocebus djamdjamensis*. Parapatric on the Bali Massif, SC Ethiopia. Only in bamboo forest above 2400 m. Temples black. Brow-band absent or narrow. Thin white moustache. Tail short. No red patch under base of tail in adult ♂.
- Chlorocebus tantalus*. Nigeria to S Sudan, N and C Uganda and NW Kenya. Hybridizes with *C. p. rufoviridis* along northern and western shores of L. Victoria, Uganda. Cheek-hair long and yellow with short black tips; white facial ring broken by black line from eyes

Chlorocebus pygerythrus

to temples; white above eyes more sinuous than rounded; back and crown gold to greenish; base of tail with tufts of white hair to either side; tail tip whitish; perineal area orange; scrotum sometimes with light covering of orange hairs.

Chlorocebus cynosuroides. Distribution relative to *C. pygerythrus* is unclear. Through S DR Congo and Angola to N Namibia, eastward to west of Luangwa R. and southwards to north of Zambezi R., Zambia, and L. Kariba, Zimbabwe. Face pinkish, blotched. Dorsum olive-buff to olive-grey. Bare skin of palms and soles pinkish. Ischial callosities rose-pink. Scrotum slate blue to violet.

Distribution Endemic to eastern and southern Africa. Somalia—Masai Bushland, Zambezian Woodland, Coastal Forest Mosaic, South-West Arid and Highveld BZs. Occurs in S Somalia, S Ethiopia, E and S Uganda, Kenya (including Manda I.), Tanzania (including Pemba I., Zanzibar I., Mafia I.), Malawi, Zambia, Mozambique, N and E Botswana and South Africa. See Geographic Variation.

Habitat Primarily along water-courses, swamps, lakeshores, and the coast of the Indian Ocean in savanna-woodlands. In Amboseli N. P., S Kenya, until the 1990s when groves of *Acacia xanthophloea* declined, Vervets live in habitats dominated by *A. xanthophloea* near water and *Acacia tortilis* away from water. On the Laikipia Plateau, C Kenya, Vervets feed and sleep along rivers dominated by *A. xanthophloea*, and also feed in non-riverine habitat dominated by *Acacia drepanolobium* (Isbell *et al.* 1998b). In Samburu-Isiolo National Reserves, Kenya, Vervet habitats along the Ewaso Nyiro R. are dominated by *Acacia elatior*, *Hyphaene coriacea* and *A. tortilis* farther away from the river (Whitten 1983, 1988). On Lolui I., L. Victoria, Uganda, Vervets live in areas dominated by *Alchornea cordifolia* and *Antiaris schweinfurthii* (Hall & Gartlan 1965, Gartlan & Brain 1968). At Windy Ridge Game Park, Natal Province, South Africa, they are found in mixed *Acacia* woodland (Baldellou & Henzi 1992). In the Karkloof area of Natal, Vervets live in mature montane forest

edged with Black Wattle *Acacia mearnsii* commercial plantations and cultivated crops, e.g. yams *Dioscorea* sp. (Bruerton *et al.* 1991). Near L. Sibayi, KwaZulu Province, South Africa, they live in strips of dune forest that include *Celtis africana*, *Acacia karroo* and *Acacia kraussiana* (Van der Zee & Skinner 1977). In Ndumu G. R., NE South Africa, Vervets live along the Usutu R. and Pongola R. where *A. xanthophloea* and *Ficus sycomorus* dominate. Some groups here range mainly in habitats dominated by thickets of *Acacia burkei*, *Acacia nigrescens* and *Dicrostachys cinerea* (De Moor & Steffens 1972). Along the Milk R., Klein Karoo Region of Western Cape Province, South Africa, Vervets are found with *A. karroo*, *Rhus lancea* and *Schinus molle* (McDougall 2011).

Mean annual rainfall in eastern Africa ranges from 330 mm (Amboseli) to 1524 mm (Lolui I.), but tends to be low. At four Vervet sites in Kenya, annual rainfall ranges from ca. 200–400 mm (Kimana), 350–400 mm (Samburu), 400–600 mm (Mosirot) and >600 mm (Naivasha) (Whitten & Turner 2004). Annual rainfall in southern Africa is more extreme. In Klein Karoo, mean annual rainfall is 300 mm (McDougall *et al.* 2010), but near Windy Ridge, just nine months spanning 1987–88 (excluding Jul–Sep 1988) yielded 9920 mm (490 mm in Dec 1987 to 2000 mm in Mar 1988) (Baldellou & Adan 1998). Rainfall patterns are variable, with two distinct wet seasons (Nov–Dec and Mar–Apr) in Amboseli (Cheney *et al.* 1988), two wet seasons (Apr–Jun and Oct–Nov) at Segera (Isbell *et al.* 2009), and year-round rainfall on Lolui I. (Gartlan 1969). At Ndumu there is one wet season (Nov–Apr; De Moor & Steffens 1972). Minimum and maximum daily temperatures are ca. 9 and ca. 32 °C, respectively, in Amboseli (Struhsaker 1967c). Annual mean monthly minimum and maximum temperatures from Jan 1993 to Feb 2002 were 11.3 and 29.6 °C, respectively, at Segera (L. A. Isbell pers. obs.). Near Windy Ridge, mean monthly minimum temperatures for Oct 1987 to Jun 1988 ranged from 13.3 °C in Jun to 22.6 °C in Mar, while mean monthly maximum temperatures ranged from 21.9 °C in Jun to 29.3 °C in Feb (Baldellou & Adan 1998). Altitudinal limits are from sea level in coastal areas (e.g. coastal East Africa) to >2000 m at Naivasha (Whitten & Turner 2004; T. Butynski & Y. de Jong pers. comm.), to >2000 m at Mt Hanang, N Tanzania (Y. de Jong & T. Butynski pers. comm.), to 1900 m in the Udzungwa Mts, SC Tanzania (Rovero *et al.* 2009).

Abundance Widespread but patchy and prone to local extinction. Densities 9–>104 ind/km². In Amboseli the density of Vervets in the Kitirua/Ol Lengia area declined from 79–104/km² in 1977 to 29–56/km² in 1983, continuing a decline that began in the early 1970s (Struhsaker 1973, 1976, Cheney *et al.* 1988). By 1988, six groups became so small that they joined other groups (Hauser *et al.* 1986, Isbell *et al.* 1991). This population decline is attributed to a die-off of *A. xanthophloea*, exacerbated by a period of heavy predation (Cheney *et al.* 1988, Isbell 1990). Vervet densities on Segera also declined, from 80/km² in 1992 to 9/km² by 2002 (L. A. Isbell pers. obs.). This decline is attributed to poor recruitment of ♀♀ and heavy predation (Isbell & Enstam 2002, Isbell *et al.* 2009). The density of Vervets on Lolui I. is ca. 50–88/km² (Hall & Gartlan 1965, Gartlan & Brain 1968) and in Samburu, 39/km² along the river and 1.6/km² in the Reserve as a whole (Whitten 1982). At Burman Bush Nature Reserve, South Africa, where Vervets are provisioned by humans, the density is 59–89/km² (Henzi & Lucas 1980).

Adaptations Diurnal and semi-terrestrial. Compared to the sympatric, more arboreal, Gentle Monkeys *Cercopithecus mitis*, Vervets possess more traits associated with terrestrial locomotion, i.e. shorter trunk length relative to body weight, shorter humerus relative to the femur, and higher brachial (i.e. longer forearm relative to arm) and crural (i.e. longer crus relative to thigh) indices (Anapol *et al.* 2005). Vervets also have traits that are associated with arboreal locomotion, including wider humeral and talar heads, a shorter tibia, a longer ischium and a longer tail than expected of terrestrial primates (Taylor 1976, Rodman 1979, Anapol *et al.* 2005). In Amboseli, Vervets spend equal amounts of daytime on the ground and in trees overall but there is considerable variation among groups (Cheney & Seyfarth 1990, L. A. Isbell pers. obs.). Similarly, at Segera, one group of Vervets spent more time on the ground than another (L. A. Isbell pers. obs.). At Segera, when Vervets are not in *A. xanthophloea*, ca. 60% of their time is spent on the ground (Enstam & Isbell 2002). Vervets at Segera climb nearly four times as often as sympatric Patas *Erythrocebus patas*, reflecting their greater use of tall trees, but they do not leap more often (Isbell *et al.* 1998a). At Naivasha, where Vervets are terrestrial only 20% of the time, leaping constitutes 10% of their locomotion (McGraw 2002). At Ngezi Forest, some groups of Vervets live well within the forest where they are strictly arboreal. No other guenon is present on Pemba I. That Vervets live within forest at Ngezi, and are arboreal, is probably attributable to ‘competitive release’ (T. Butynski & Y. de Jong pers. comm.).

Foraging and Food Omnivorous. Vervets forage both arboreally and terrestrially, typically beginning the day by feeding within their sleeping trees. By mid-morning they descend to forage on shrubs and herbaceous plants. After a mid-day rest, Vervets continue foraging, either on the ground or in trees, until dusk when they climb back into sleeping trees. At Segera seven adult ♀♀ in one group maintained a mean 6.6 m from their nearest neighbour. This is close to the mean of 6.1 m between feeding sites (Isbell & Enstam 2002). In Amboseli, individuals in six groups spent 30–40% of their time feeding and 15–20% of their time moving (Isbell & Young 1993b). Two groups with mean group sizes of 17.2 and 16.4 in Amboseli travelled a mean 950 m and 1440 m/day, respectively (135–2558, n = 114 days; Struhsaker 1967c). Daily travel distances of two groups at Segera were 1025 m (n = 44 days) for a group averaging eight members and 1632 m (n = 144 days) for a group averaging 27 members (based on straight-line distances of the groups during 30-minute periods; Isbell *et al.* 1999b, Enstam & Isbell 2007). Larger groups and groups in poorer habitats travel farther per day than smaller groups and groups in higher-quality habitats (Struhsaker 1967c, Isbell *et al.* 1999b).

Vervets use hand-to-mouth movements to eat leaves, flowers, fruits, seeds and arthropods, but apply the mouth directly to scrape gum off trees. They rely heavily on *Acacia* spp. In Amboseli, flowers, gums, leaves and pods of *A. xanthophloea* and *A. tortilis* account for ca. 50% of total time spent feeding (Lee & Hauser 1998). At Segera, *A. drepanolobium* and *A. xanthophloea* account for ca. 35% and ca. 22% of the diet, respectively (Pruetz & Isbell 2000). In Samburu, *A. tortilis* and *A. elatior* account for >60% of total time spent feeding (Whitten 1988). Other important food species are the woody shrubs *Azima tetracantha* and *Salvadora persica*, the herbs *Abutilon mauritanium* and *Lycium europaeum*, and the grasses *Pennisetum mezianum*, *Cynodon*

dactylon and *Cynodon plectostachyus* in Amboseli (Struhsaker 1967c, Lee & Hauser 1998), *Acacia gerrardii*, *Acacia seyal*, *Commelina* spp., *L. europaeum* and *Euclea divinorum* at Segera (Pruetz & Isbell 2000), and *H. coriacea*, *Boerhavia erecta*, *Abutilon hirtum*, *F. sycamorus* and *Aphania senegalensis* in Samburu (Whitten 1983).

With the exception of gums, which are available year-round, foods are eaten as they come into season. Flowers are preferred over other foods in Amboseli and Samburu. In Amboseli, *A. tortilis* flowers are most abundant in Jan–Mar, Oct–Dec (Wrangham & Waterman 1981, Isbell 1995, Lee & Hauser 1998). In Samburu Vervets spend 43% of their feeding time eating flowers (Whitten 1988). At Segera, which has no *A. tortilis*, gums are eaten more frequently (37%) than flowers (8%). Other foods eaten at Segera are fruits (10%), seeds and grasses (8% each), and leaves and swollen thorns (2% each). Small, unidentified items account for 23% of the diet; most of these are probably arthropods (L. A. Isbell pers. comm.), e.g. termites, beetles, moths, butterflies, grasshoppers, spiders and army worms *Spodoptera exempta*. Though percentages are not available for the diet of Vervets in the southern part of their range, foods of Vervets in the dune forests near L. Sibayi include floral parts of *C. africana*, fruits of *Mimosa affra*, *Ziziphus mucronata*, *Sideroxylon inerme*, *Ficus natalensis*, *Grewia* sp. and *Cucumis* sp., seeds of *A. karroo*, *A. kraussiana* and *Albizia adiantifolia*, and leaves of *C. africana*, *A. karroo*, *A. kraussiana*, *Vepris undulata* and *A. adiantifolia* (Van der Zee & Skinner 1977). Although omnivorous, Vervets in southern Africa eat leaves less often than Samango Monkeys *Cercopithecus mitis labiatus* and have gastrointestinal tracts that are less specialized for digesting foliage (Bruerton *et al.* 1991). Vervets sometimes eat the eggs and young of birds (Struhsaker 1967c, Skinner & Skinner 1974, Lee & Hauser 1998), and they drink regularly when water is available (Wrangham 1981). In Amboseli, Vervets visited waterholes, on average, about once every two days, and drank most often in the early afternoon ($n = 53$ in 1677 h) (Struhsaker 1967c). At Segera, Vervets are no longer able to drink throughout the year because irrigation practices upstream have caused the Mutara R. to dry up entirely from Mar–Jul in recent years, e.g. 1999 and 2000 (L. A. Isbell pers. obs.). Young Vervets acquire adult food habits as they mature. During their first two months infants feed asynchronously with their mothers. At three months, infants begin to feed synchronously with their mothers on the same food items (Hauser 1993). Adult ♂♂ and adult ♀♀ eat the same foods (L. A. Isbell pers. obs.).

Vervets live in home-ranges of 5–103 ha ($n = 27$) (Struhsaker 1967d, De Moor & Steffens 1972, Whitten 1982, Cheney & Seyfarth 1987, Isbell *et al.* 1990, 2002, Lee & Hauser 1998). Large group size, low density of food trees and absence of neighbouring groups all increase home-range size (Struhsaker 1967d, De Moor & Steffens 1972, Isbell *et al.* 1990, L. A. Isbell pers. obs.). Vervets use all parts of their home-range throughout the year, and invariably defend the boundaries of their home-ranges against incursions by neighbouring groups (Struhsaker 1967d, Gartlan & Brain 1968, De Moor & Steffens 1972, Cheney 1981, L. A. Isbell pers. obs.). Home-range overlap in Amboseli was 11–33% in 1963–64, 26–42% in 1977–80 and 4–57% in 1986–88 ($n = 15$) (Cheney 1987, Isbell *et al.* 1990). The wider range of overlap in the latter time period occurred because some neighbouring groups ceased to exist and larger groups expanded into the home-ranges of smaller groups.

Vervets prefer to sleep in trees that are tall and large. In Amboseli, Vervets prefer *A. xanthophloea* over *A. tortilis* (Struhsaker 1967c), and prefer groves rather than isolated trees (Struhsaker 1967c, L. A. Isbell pers. obs.). The same few sleeping sites are repeatedly used (De Moor & Steffens 1972, L. A. Isbell pers. obs.). Small groups often share the same sleeping tree. Larger groups may split into subgroups and spread out to sleep within a small number of trees. Individuals typically sleep on the highest branches and as far along the distal ends of branches as will bear their weight (Andelman *et al.* 1985, L. A. Isbell pers. obs.).

Social and Reproductive Behaviour Social. Vervets live in cohesive groups of 2–10 adult ♀♀ and their offspring, usually accompanied by multiple adult ♂♂ (Struhsaker 1967c, Whitten 1983, Young & Isbell 1994, Whitten & Turner 2004). In Amboseli, maximum group size declined over 30 years from 53 ($n = 4$) to 4 ($n = 2$) (Struhsaker 1967b, Cheney & Seyfarth 1987, L. A. Isbell pers. obs.). At Segera group sizes declined over ten years in two groups from 10 and 30 to one group of 9 (Isbell *et al.* 2009). On Lolui I., group sizes ranged from 6 to 21 ($n = 46$) (Gartlan & Brain 1968). In Samburu group sizes were 37 and 40 ($n = 2$) (Whitten 1983). In Mosi-Oa-Tunya N. P., Zambia, group sizes ranged from 23 to 47 ($n = 4$) (Tembo 1994). At Burman Bush Nature Reserve, where groups are provisioned by tourists, three groups ranged in size from 8 to 37 (Henzi & Lucas 1980). At Windy Ridge one group had a maximum of 23 individuals (Baldellou & Henzi 1992). At Nduma, South Africa, two groups comprised ca. 22 and 37 members (De Moor & Steffens 1972). Along the Milk R., two groups had 48 and 69 members (McDougall *et al.* 2011).

Females remain in their natal groups throughout life, except under unusual circumstances, e.g. group fusions. Males disperse from their natal groups around sexual maturity (ca. 5–6 years). Most dispersing natal ♂♂ do not become solitary but immediately join adjacent groups (Henzi & Lucas 1980, Cheney & Seyfarth 1983, Isbell *et al.* 2002). In Amboseli, over a five-year period, 22 of 23 (96%) natal ♂♂ in three groups dispersed to adjacent groups (Cheney & Seyfarth 1983). At Segera, over a ten-year period, five of six (83%) ♂♂ in two groups joined neighbouring groups and stayed an average of 16 months (Isbell *et al.* 2002). Males also disperse with siblings and join groups that former groupmates previously joined (Cheney & Seyfarth 1983, Isbell *et al.* 2002). The tendency of Vervets to live along narrow strips near rivers limits the number of adjacent groups to two in most areas. When this is coupled with the high risk of mortality that Vervets face while moving into unfamiliar areas (Isbell *et al.* 1990, 1993), dispersal options become more limited and, thus, likely result in shorter dispersal distances and greater relatedness among Vervet ♂♂ than among ♂♂ of other species of primates. Limited dispersal options may contribute to the social system of Vervets, which is unusual among the Cercopithecini in having a permanent multimale presence in most areas (Isbell *et al.* 2002). Vervets do form single-male multifemale groups in some areas, e.g. along L. Naivasha and in the dune forests near L. Sibayi (Van der Zee & Skinner 1977, Whitten & Turner 2004, T. R. Turner pers. comm.). Solitary ♂♂ must exist in such places but they have not been reported.

Adult ♂♂ and adult ♀♀ both have easily detectable, linear dominance hierarchies (Struhsaker 1967d, Whitten 1983, Isbell &

Pruetz 1998). Males assert their dominance over subordinate ♂♂ with vocalizations and displays, e.g. the red-white-and-blue display, in which the dominant ♂ holds his tail high while walking back and forth or circling the subordinate ♂, thereby exposing his red perianus, blue scrotum and white stripe of fur that connects the scrotum and perianus (Struhsaker 1967b). Female hierarchies are more stable than those of ♂♂, with daughters occupying ranks near their mothers (Cheney 1983, Lee 1983b). The female dominance hierarchy also influences grooming and coalitionary support during agonistic interactions (Seyfarth 1980).

Young Vervets begin interacting with group members other than their mothers within the first week of life, often through play with other immatures. Time spent playing increases during the first three months of life (Lee 1984), more so in ♂♂ than ♀♀ (Lee 1983c). Males become more socially peripheral as they mature, whereas ♀♀ remain active in social life, maintaining grooming bonds and handling infants of other ♀♀ (Lee 1983a). It is not always apparent that infant handlers are helpers. In most cases infants are handled gently when they are taken from the mother (Lee 1983a); rarely, infants are mistreated (e.g. bitten). Mothers continue to carry their infants for up to one year, but the frequency tapers off after one month (Struhsaker 1971b, Lee 1984). In their first three months infants are carried for 30–100% of the time mothers are moving. By the time infants are four months old they are carried only 1–20% of the time (Whitten 1982).

Vervets produce at least 33 acoustically distinct vocalizations (e.g. 'squeals', 'screams', 'grunts', 'chutters', 'wrrs', 'waas' and 'aarrs') (Struhsaker 1967a). Some (e.g. grunts and 'loud aarr' calls) convey information about the identities of group members and members of other groups (Cheney & Seyfarth 1980, 1982a, b, 1990). Vervets also give different alarm calls to mammalian predators, raptors, snakes and humans (Struhsaker 1967a, Seyfarth *et al.* 1980b). Alarms to Leopards *Panthera pardus* of adult and subadult ♂♂ differ from those of adult ♀♀ and juveniles (Struhsaker 1967a, Seyfarth *et al.* 1980b, Enstam & Isbell 2002). Because Vervets give alarm calls to some species but not others, they effectively categorize species into predators and non-predators. Adults are the most selective, and give alarm calls to their most dangerous predators (Seyfarth *et al.* 1980a). Though infants are able to distinguish between general classes of predators, they are more likely to direct alarm calls at inappropriate stimuli (Seyfarth & Cheney 1980).

Vervets respond differently to different alarm calls (Struhsaker 1967a, Seyfarth *et al.* 1980b). They respond to 'eagle alarms' primarily by looking up and to 'snake alarms' by looking down and approaching the snake (Struhsaker 1967a, Seyfarth *et al.* 1980b, Cheney & Seyfarth 1990, Enstam & Isbell 2002). In areas with tall trees, Vervets respond to 'leopard alarms' primarily by climbing or remaining in trees. In areas with shorter trees, Vervets respond by descending trees, running away and scanning while bipedal (Enstam & Isbell 2002). Vervets also attend to alarm calls of other animals, e.g. Superb Starling *Lamprolornis superbus*, Helmeted Guineafowl *Numida meleagris*, Crowned Lapwing *Vanellus coronatus*, Impala *Aepyceros melampus*, Plains Zebra *Equus quagga*, Common Warthog *Phacochoerus africanus* and Yellow Baboon *Papio cynocephalus* (Struhsaker 1967c, Cheney & Seyfarth 1990). They are mobbed by birds, e.g. Lilac-breasted Roller *Coracias caudata*, Fork-tailed Drongo *Dicrurus adsimilis*, Northern White-crowned

Vervet Monkey *Chlorocebus pygerythrus* adult female.

Shrike *Eurocephalus rueppelli* and Hildebrandt's Starling *Lamprolornis hildebrandti* (Struhsaker 1967c).

Vervet groups do not form polyspecific associations with other primate species, though occasionally they are found in proximity to baboons *Papio* spp., Sykes's Monkeys, Patas and Northern Lesser Galagos *Galago senegalensis*. One exception appears to occur in Ngezi Forest, where preliminary observations suggest that the Zanzibar Red Colobus *Procolobus kirkii* (an introduced species) is frequently, if not almost always, in association with Vervets (T. Butynski & Y. de Jong pers. comm.). Vervets react variably to Yellow Baboons, Olive Baboons *Papio anubis* and Patas, sometimes moving away and other times ignoring them. Juvenile Vervets sometimes play with juvenile Yellow Baboons and Patas (Struhsaker 1967c, L. A. Isbell pers. obs.). Individual Vervets may temporarily, at least, join groups of Yellow Baboons or Patas (Struhsaker 1967c, Enstam & Isbell 2007, L. A. Isbell pers. obs.).

Vervets have no elaborate courtship behaviour. Males and ♀♀ do not form consortships (Andelman 1987). Males are single-mount ejaculators (Struhsaker 1967b) and matings are brief. Female Vervets do not have obvious indicators of reproductive state, other than a willingness to copulate more during some months of the year than others. None the less, ♂♂ initiate copulations most frequently around the period of conception (Andelman 1987), suggesting that ♀♀ provide some cue(s). Vaginal secretions perhaps indicate reproductive state. Males frequently sniff the perineum of ♀♀, and may obtain information about reproductive state in this way. Chest-rubbing (i.e. apparent scent-marking) occurs but perhaps not in all populations (Gartlan & Brain 1968, De Jong & Butynski 2010b, Freeman *et al.* 2012).

Reproduction and Population Structure Vervets are seasonal breeders. In Amboseli ♀♀ copulate from Apr–Oct, but conceptions occur about two months after the onset of mating. Females normally conceive on the first ovulatory cycle of the year (Andelman 1987). Most births (87%) occur in Oct–Dec ($n = 75$; Cheney *et al.* 1988). In Samburu copulations occur in Mar–Jun ($n = 22$); most births (88%) occur in Nov–Dec ($n = 16$; Whitten 1983). Timing of matings and births in Amboseli and Samburu associated with seasonal abundance of flowers, especially those of

Acacia spp. (Whitten 1983, Butynski 1988). At Segera, copulations observed in all months except Jan, Mar and Apr, but most often in Jun–Oct (L. A. Isbell pers. obs.). Over a ten-year period, 30 of 40 births (75%) that could be assigned to a particular month occurred in Jan–Mar. The percentage of births that occurred outside these peak birth months was nearly double (25%) that of Amboseli (13%) (Cheney *et al.* 1988, L. A. Isbell pers. obs.). Segera's less distinct birth seasonality may be related to its less seasonal rainfall (Butynski 1988). Females also copulate during pregnancy (Gartlan 1969, Andelman 1987). Mean length of gestation in captivity is 163.2 days \pm 6.2 S.D. ($n = 38$) (Johnson *et al.* 1973). In the wild, gestation length for one ♀, based on hormonal analyses of urine, was 156–161 days (Andelman *et al.* 1985).

Females give birth to one infant every 1–2 years, depending largely on habitat quality and the survival of preceding infants. In Amboseli, mean inter-birth intervals for ♀♀ in three groups ranged from 13.8 to 21.3 months, with the longer inter-birth interval occurring in a group without access to permanent water (Cheney *et al.* 1988). At birth, infants weigh 300–400 g (Smithers 1971, Nowak 1999). Weaning begins at around three months and is complete by around 18 months, or earlier if the mother reproduces the next year (Whitten 1983). Infants orphaned at six months can survive. The earliest age at first reproduction is ca. 3.5 years (Isbell *et al.* 2009). In Amboseli mean age at first reproduction was earlier (4.4 years) in a group with better access to food and water than in two groups with poorer access (5.1 and 5.7 years) (Cheney *et al.* 1988). At Segera, where water is no longer always available year-round, the mean age at first reproduction was 5.1 years (3.5–6.1) for the three ♀♀ born during the ten-year study that survived long enough to reproduce. The youngest ♀ to reproduce gave birth unusually during the mating season after an extraordinarily wet El Niño event. This female's two subsequent births were also six months off the peak birth season and well into the mating season (L. A. Isbell pers. obs.).

During the mating season ♀♀ mate with multiple ♂♂. High-ranking ♂♂ do not monopolize matings during the most probable week of conception. Females refuse most attempts by ♂♂ to copulate (Andelman 1987). Males can commit infanticide, but incidence appears to vary with habitat structure, costs of dispersal, and corresponding degree of relatedness between immigrants and members of the groups they join. Where Vervets are restricted to linear home-ranges along rivers (e.g. Segera), high costs of dispersal limit movement to one of two adjacent groups and increases genetic relatedness between immigrants and the groups they join. In such groups infanticide is rare, if it occurs at all. In nine years of observation no attempts at infanticide were observed at Segera (Isbell *et al.* 2002). In areas with more dispersal options (e.g. a greater number of adjacent groups in Amboseli), genetic relatedness between immigrants and members of non-natal groups declines, and infanticide is more common. In Amboseli, where each group shared home-range boundaries with up to five other groups, three infants were victims of immigrating ♂♂, at a rate of 0.03 infanticides/100 immigration events (Isbell *et al.* 2002). No data are available for Vervets at Naivasha where genetic relatedness between immigrant ♂♂ and non-natal groups must be lower because groups are limited to only one adult ♂. The rate of infanticide in Green Monkeys *Chlorocebus sabaeus* living in single-male groups in Barbados is 4.5/100 immigration events (Horrocks & Baulu 1988, Isbell *et al.*

2002). Infanticide is normally attributed to intense male–male competition for reproductive success, but there is no *a priori* reason to expect competition to be less intense in multimale groups unless ♂♂ are more closely related to each other.

Sex ratios at birth are biased toward ♂♂. In Amboseli the birth sex ratio of 41 (56%) ♂♂ and 32 (44%) ♀♀ was 1 : 0.8 (Cheney *et al.* 1988). Of 50 unambiguously sexed infants at Segera the birth sex ratio of 31 (62%) ♂♂ and 19 (38%) ♀♀ was 1 : 0.6 (L. A. Isbell pers. obs.). This is not an artefact of easier identification of ♂♂ in the first weeks of life; in fact, ♀♀ were initially sexed incorrectly more often than ♂♂. The sex ratio becomes more biased toward ♀♀ in adulthood. In Amboseli the adult sex ratio per group varied from 1 : 0.8 to 1 : 7.0 ($n = 3$) over five years (Melnick & Pearl 1987, Cheney *et al.* 1988). In Samburu the mean adult sex ratio for two groups was 1 : 1.0 (Melnick & Pearl 1987). On Lolui I. the adult sex ratio was 1 : 1.4 (Hall & Gartlan 1965). At Segera the mean monthly adult sex ratio of two groups was 1 : 1.2 ($n = 101$ months) and 1 : 1.5 ($n = 73$ months) (L. A. Isbell pers. obs.).

At Segera mean annual birth rate was 0.62 offspring/adult ♀ over ten years. Mean annual infant mortality rate for two groups over ten years was 48%; mean annual adult ♀♀ mortality rate over 11 years was 15% (Isbell *et al.* 2009). In Amboseli, 57% of individuals died during their first year, on average. Vervets can live to about 30 years in captivity (Nowak 1999) and to at least 18 years in the wild (Cheney & Seyfarth 1990).

Predators, Parasites and Diseases Predation accounted for at least 69% of all Vervet deaths and only 27% of ♀♀ survived to adulthood in Amboseli (Cheney *et al.* 1988). Such high losses to predators may account for the large percentage of time (30–40%) Vervets devote to scanning the environment ($n = 54$ individuals in six groups) (Isbell & Young 1993a). Similarly, at Segera, at least 7 of 15 adult ♀♀ (47%) died of suspected or confirmed predation (Isbell & Enstam 2002, Isbell *et al.* 2009). Only 16% (3/19) ♀♀ born during the study survived to adulthood (Isbell *et al.* 2009).

Confirmed predators of Vervets include Leopards, African Crowned Eagles *Stephanoaetus coronatus*, Martial Eagles *Polemaetus bellicosus*, Central African Rock Pythons *Python sebae*, Yellow Baboons and Domestic Dogs *Canis familiaris* (Struhsaker 1967c, Cheney *et al.* 1988, Baldellou & Henzi 1992, Isbell & Enstam 2002, T. Butynski pers. comm.). Potential predators include Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta*, Cheetahs *Acinonyx jubatus* and Black-backed Jackals *Canis mesomelas*, based on alarm calls or greater vigilance of Vervets toward those animals. Though large enough to attack Vervets, African Hawk-eagles *Hieraaetus spilogaster*, Black-chested Snake Eagles *Circaetus pectoralis*, Tawny Eagles *Aquila rapax* and Giant Eagle-owls *Bubo lacteus* are not likely predators, based on their dietary preferences and the indifference of Vervets to those animals. Egyptian Cobras *Naja haje*, Black Mambas *Dendroaspis polylepis* and Puff Adders *Bitis arietans* are not predators but Vervets give alarm calls to them (Struhsaker 1967a, L. A. Isbell pers. obs.) and bites can, undoubtedly, be fatal. Estimated annual predation rates range from 6% in Samburu to 15% in Amboseli (Cheney & Wrangham 1987, Cheney *et al.* 1988). Predation rates occasionally spike. In Amboseli the estimated predation rate was at least 45% in 1987, largely from a brief period of intense predation by Leopards (Isbell 1990). Similarly, brief but intense Leopard

predation over a seven-month period at Segera resulted in the loss of 21 of 28 (75%) study animals (Isbell & Enstam 2002, Isbell *et al.* 2009). Predators depress Vervet populations periodically, even to the extent of decimating local populations. Evidence from carcasses, scratch marks on tree trunks and footprints indicates that Leopard predation often occurs at night while Vervets are in their sleeping trees, and that multiple Vervets can be killed in one night, especially when ♀ Leopards hunt with cubs (Isbell *et al.* 2009). Leopard predation is less likely to occur when humans are nearby (Isbell & Young 1993a).

Vervets sometimes develop an unidentified seasonal malady. In Amboseli, in at least two consecutive years during Nov–Jan, 16 of 51 (34%) adults and subadults, and four of 22 (18%) juveniles, lost hair on their abdomens, knees, elbows and/or inner thighs, and developed hyperpigmentation of the exposed skin. Males also developed scrotal hyperpigmentation (Isbell 1995). Hair loss occurs more rarely at Segera, in May–Jun (L. A. Isbell pers. obs.). In no case has this disease progressed to scrotal bleeding or bursting as observed in Amboseli (Struhsaker 1967c). At Segera, infants may have been more susceptible than adults to respiratory illnesses. Those that died within their first year (n = 17, excluding those dying of predation and after losing the mother) were, on average, born in significantly wetter months (mean 45 mm rainfall) than infants that survived their first year (mean 24 mm rainfall, n = 24) (Isbell *et al.* 2009).

Vervets harbour a variety of viruses, protozoa, bacteria and helminths. Viruses include HTLV-like STLV-1, Papillomavirus SA-12, Spumavirus Simian Foamy Virus, Lentivirus SIV agm, Alphavirus-SFV Complex Chikungunya and Polyomavirus SAV-12. Protozoa include *Babesia macaci* and *Babesia pitheci*. Bacteria include *Salmonella* sp., *Shigella* sp., *Borrelia harveyi*, *Chlamydia* sp., *Leptospira* sp. and *Rickettsia cornorii*. Helminths include *Schistosoma matthei*, *Schistosoma mansoni*, *Cercopithifilaria vervezi*, *Dirofilaria aethiops* and *Enterobius bipapillatus* (Nunn & Altizer 2005). Vervets are implicated, along with Olive Baboons, in Kenya's first recorded outbreak of Yellow Fever among humans in 1992–93 in the Kerio Valley (Reiter *et al.* 1998). The effects of parasites and diseases on Vervet populations are unknown.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Though Vervets are geographically widespread and can tolerate a wide range of habitats, they are none the less patchily distributed. In the two areas where Vervets were studied for at least ten years (Amboseli and Segera), the Vervet populations suffered severe declines (Cheney *et al.* 1988, Isbell *et al.* 2009). More limited surveys at Kasoje in the Mahale Mts, Tanzania (Uehara & Ihobe 1998) and L. Naivasha (L. A. Isbell pers. obs.) also suggest local declines. In the

latter case the decline is likely the result of human encroachment and habitat destruction along the lake shore. Though it is difficult to determine overall population trends from a few studies of this widespread species, reported declines, combined with the absence of studies reporting increases in numbers of Vervets, suggest that Vervet populations are declining, particularly where habitat change (e.g. tree die-offs, river water depletion and human encroachment) is occurring. The tendency for Vervets to live in small, isolated populations probably makes them particularly susceptible to local extinction. Detailed surveys of the extent of isolation are needed throughout their range.

Measurements

Chlorocebus pygerythrus pygerythrus

HB (♂ ♂): 490 mm, n = 30

HB (♀ ♀): 446 mm, n = 30

T (♂ ♂): 652 (600–750) mm, n = 30

T (♀ ♀): 575 (485–653) mm, n = 30

HF (♂ ♂): 144 (133–170) mm, n = 30

HF (♀ ♀): 125 (115–137) mm, n = 30

E (♂ ♂): 38 (31–42) mm, n = 30

E (♀ ♀): 35 (30–40) mm, n = 30

WT (♂ ♂): 5.5 (3.9–8.0) kg, n = 29

WT (♀ ♀): 4.1 (3.4–5.3) kg, n = 30

N Botswana (Smithers 1971). Range for HB not given.

Chlorocebus cynosuros MALBROUCK MONKEY

Fr. Malbrouck; Ger. Malbrouck-Grünmeerkatze

Chlorocebus cynosuros (Scopoli, 1786). *Deliciae Faunae et Florae Insubricae* 1: 44, pl. 19. No locality, but fixed at Banana, right bank lower Congo R., DR Congo, by Schwarz (1926).

Malbrouck Monkey *Chlorocebus cynosuros* adult male.

Taxonomy Monotypic species. Classically considered as a subspecies of the *Cercopithecus (aethiops)* Group or Superspecies (Schwarz 1926, Hill 1966, Thorington & Groves 1971, Dandelot 1974, Napier 1981, Lervold 1988). A recent revision by Groves (2001) elevated and reassigned the savanna monkeys to *Chlorocebus* and gave species status to most of the subspecies, including *C. cynosuros*. Unfortunately, a planned alpha taxonomy of the group was left uncompleted (Grubb *et al.* 2003). Given the extensive overlap of characters used to distinguish the different types (i.e. species and subspecies; Napier 1981), neither the specific validity of *C. cynosuros* nor the varieties contained within the species of *Chlorocebus* are certain. Grades imperceptibly into the Vervet *Chlorocebus pygerythrus* at the north-eastern, eastern and south-eastern ends of distribution (Schwarz 1926, Smithers 1971, Ansell 1978, Napier 1981, E. E. Sarmiento pers. obs). No obvious biogeographic barrier exists between *C. pygerythrus* and *C. cynosuros*.

Classification of *C. cynosuros* is therefore problematic (Ansell 1978) and little agreement exists as to whether some varieties are subspecies of *C. pygerythrus* or synonyms of either species (Ellerman *et al.* 1953, Hill 1966, Dandelot 1974, Ansell, 1978). The last author considered all animals in Zambia (except those east of the upper Zambezi R. in extreme SW Zambia) to be *C. cynosuros*, but there is no proven continuity between the W Angolan animals and those in Zambia.

In regard to species, if a cline is geographically narrow with relatively few animals participating in the clinal interzone then, in the here and now, the populations at either end can be regarded as true species (species can be defined only in narrow time horizons). On the other hand, if the cline is geographically wide with more animals in the interzone than exist at either end of the cline, then, in the here and now, the entire population can more realistically be treated as a single species. In the past it may have been different and in the future it will

no doubt differ yet again, but in the present the status of populations, especially within this section of the *Chlorocebus* complex, remains uncertain. We need to recognize that many blanks in knowledge will need to be filled in before the decision as to what is or what is not a species can be asserted with any confidence. In this case most of the data for making such a decision are in Angola waiting to be tapped. For the sake of both simplicity and convenience, *C. cynosuros* is tentatively treated here as a monotypic species, although given its extensive range it probably contains more than one variety.

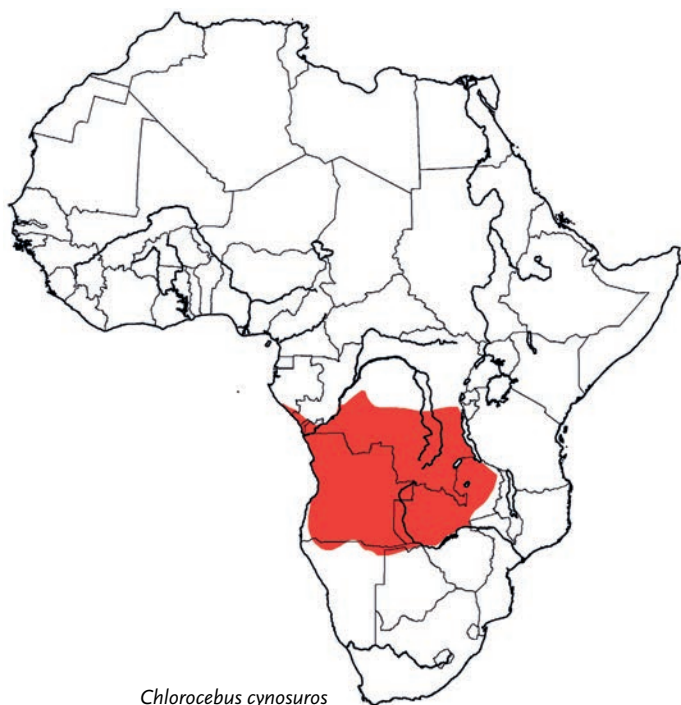

It is a little suspicious that *C. cynosuros* occurs on both sides of the lower Congo R., supposedly with animals from both sides being indistinguishable (Schwarz 1926). Given that this river is a formidable biogeographic barrier for so many primate species, human transportation of these animals as pets must be considered as a distinct probability (Van der Kuyl *et al.* 1996). In yet another complication, the type of *C. cynosuros* may not have come from Banana, on the right bank of the Congo R. The type locality was fixed as such because *cynosuros* is supposedly similar to *weynsi* from Banana (Matschie 1912).

This has resulted in a highly atypical distribution that further confounds our efforts to classify *cynosuros* to species or subspecies. To complicate matters still further, many *C. cynosuros* diagnostic characters (i.e. facial skin, ischial callosity and genital colour) can only be clearly documented in living animals and not in the museum specimens that most taxonomies are based on (Dandelot 1959).

Note that the species name applied to the Malbrouck is misspelled '*cynosurus*' in some taxonomic works. The name that Scopoli (1786) provides is '*cynosuros*'.

Synonyms: *cynosurus*, *katangensis*, *lukonzolwae*, *tholloni*, *weynsi*. Chromosome number: $2n = 60$? All savanna monkeys karyotyped from East, West and southern Africa show a diploid number of 60 chromosomes (Dutrillaux *et al.* 1988b). Although the chromosome number for *C. cynosuros* is unknown, the chances are it shares this number with other *Chlorocebus* species.

Description Medium-sized, semi-terrestrial, olive-buff monkey with flesh-coloured facial skin, often splotched and darker on nose and ears. Sexes similar in appearance but adult ♀ smaller, being ca. 70% weight of adult ♂. Lips and chin with short white hairs. Frontal (brow) band white with some interspersed black hairs delimited below by a thin line of long stiff black hairs. Cheek-whiskers short, white, sweep backwards and upwards but not covering ears. Whiskers progressively darken around temple blending in colour with hair on crown. Ears naked, brown and lack tufts. Jowls and throat largely white. Dorsum of head, neck and body covered in yellow-tipped black-banded grey hairs, producing a dark olive-buff with varying brown to yellow highlights. Ventrums and inner limbs light grey to dirty white. Outer limbs, hands and feet with white-tipped grey hairs that produce a grey wash. Tail dorsum mottled grey and black. Dorsum of tail tip dark grey to black with a greater proportion of

Chlorocebus cynosuros

fully black hairs than remainder of tail. Tail underside light grey to dirty white with reddish tuft of hair at base. Ischial callosities flesh-coloured or pallid pink. Scrotum described as slate-blue (Elliot 1913b), lapis lazuli blue (Dandelot 1974) or violet (Schwarz 1926), presumably contrasting with the turquoise blue of other *Chlorocebus* spp. Exposed skin (i.e. facial, plantar, palmar, genital) is pink. Newborn infants have soft dark-brown pelage. Infants with complete milk dentition already show adult colour pattern.

Geographic Variation Newborn infants in Angola with light grey pelage while those in Zambia have dark brown pelage. Otherwise, *C. cynosuros* requires study to determine if patterns in geographic variation exist (see Taxonomy).

Similar Species To the east, *C. pygerythrus rufoviridis* in Malawi and Tete Province, Mozambique, are in all respects indistinguishable from animals in Zambia that Ansell (1978) classified as *C. cynosuros*. As such, there is disagreement as to where *C. cynosuros* ends and *C. pygerythrus* begins, and to which of the two species synonyms should be referred (Ellerman *et al.* 1953, Hill 1966, Dandelot 1974, Ansell, 1978, Groves 2001). *C. pygerythrus* has black skin on face, palms and soles, grey ischial callosities, and turquoise blue scrotum.

Distribution Endemic to Africa south of Equator, north of Tropic of Capricorn, west of Luangwa R., and north of Zambezi R. Southern Rainforest-Savanna Mosaic and Zambezian Woodland BZs. Distribution poorly known but believed to occur across Africa west of the Rift Valleys between the Congo Basin forests, DR Congo, in the north, and Zambezi R., Zambia, and lower Cunene R., Angola, in south. In north-west (ca. 12° E) in savannas and at the edge of grasslands as far north as Banana, just north of Congo R. (i.e. right bank) at 06° S. Eastwards, right bank of Congo R., reaches Brazzaville at 04° 15' S (Matschie 1912, E. E. Sarmiento pers. obs.). In central Africa, reaches northwards slightly past 02° S on eastern

and western shores of L. Mai-Ndombe (L. Leopold in Schouteden 1944a). Northern extent probably limited by Lukeka R. at ca. 06° S. Eastern limit supposedly L. Tanganyika (ca. 30° W) and the Malawi Highlands (ca. 33° W) but, as discussed above, species allocations are far from secure in this region. Unlikely to extend north-eastwards into Tanzania between L. Tanganyika and Malawi. Animals from close to border in Mbeya and Sumbawanga Districts, Tanzania, are unequivocally of *C. pygerythrus* appearance (see Swynnerton & Hayman 1951 and colour plate illustrating *C. pygerythrus*). Eastwards towards W Malawi and Tete Province Mozambique, *C. cynosuros* and *C. p. rufoviridis* are more or less indistinguishable (Schwarz 1926, Ansell & Dowsett 1988). Authors differ as to which biogeographic barriers separate the two species (Hill 1966, Dandelot 1974, Ansell 1978, Groves 2001). Southern limit appears to be the Zambezi R. and L. Kariba (Ansell 1978) at 16–18° S, although this is not certain (Hill 1966). Towards the west, along the Cunene R., Okavango R. and Caprivi Strip, *C. cynosuros* supposedly comes into contact with *C. p. helveticus* (Smithers 1971). Here the aridity of the Etosha Plains and the Kalahari Desert prevent southward movement of *C. cynosuros*.

Within its geographic range, *C. cynosuros* absent from Lukulu and Zambezi Districts of W Zambia and from montane areas (Ansell 1978). Poorly known from Angola, especially the eastern half (from where no museum specimens have been collected). In summary, the distribution of *C. cynosuros* extends deep into S DR Congo, Angola, Zambia and depending on authors or diagnosis, into W Malawi, W Mozambique, N Botswana, N Namibia and N Zimbabwe.

Habitat Woodlands and riparian forests running through savanna, grassland and scrub. Always close to year-round water sources. Usually at sites that lack other guenon competitors. Appears to prefer edge, utilizing trees or large shrubs for sleeping and shelter, and more open areas for foraging. A large part of the geographic range includes miombo woodlands (*Brachystegia* spp., *Julbernardia* spp. and *Isoblerina* spp.) and mopane woodlands (*Colophospermum mopane*) between 500–1000 m. Also in areas from near sea level (4 m) at mouth of Congo R. to 1400–1600 m on Angolan Plateau, NE Zambia. To 1850 m in Upemba N. P., DR Congo. If the savanna monkey on the Nyika Plateau, Malawi, is *C. cynosuros* (Ansell 1978), then this species occurs to at least 1950 m. Mean annual rainfall in *C. cynosuros* habitat varies from 1750 mm near the equator to ca. 450 mm along the Namibia–Angola border. Over most of the range there is one long dry season with little or no rain during Jun–Sep. Temperatures are generally between 18 and 24° C year-round and even at the highest altitudes never dip below freezing, reaching lows of only 5° C.

Abundance No data on population density. Avoidance of montane areas and affinity for water-courses suggests that *C. cynosuros* is much less common in the hilly country west of L. Tanganyika than in Katanga, DR Congo (Frechkop 1954) or on the plains of Zambia. Absence of *C. cynosuros* museum specimens from N and E Angola (Seabra 1908, Hill & Carter 1941, Machado 1969) probably reflects their relatively low abundance in these regions. *C. cynosuros* avoids areas with other (competing) guenons and may show high density in human-modified environments that provide sleeping sites, water and food, especially cultivated areas.

Adaptations Diurnal and semi-terrestrial. An opportunistic forager capable of moving long distances on the ground in search of food and water. Uses trees and shrubs as sleeping sites and for protection, but most food gathering is linked to ground movement. On the whole, adaptations and life-style, including a markedly varied diet, allow for exploitation of undependable and widely varying food sources in areas with long dry seasons and seasonal flooding.

Foraging and Food Omnivorous. Diet not systematically studied. Information presented here is based largely on the author's observation in Zambia and Angola, including reports by local people and the examination of stomach contents from museum specimens. Preferentially a frugivore, *C. cynosuros* eats the fruit of the Sugar Plum *Uapaca kirkiana*, Buffalo-thorn *Ziziphus mucronata*, African Ebony (or Monkey-guava) *Diospyros mespiliformes*, Marula Plum *Sclerocarya birrea* and various figs *Ficus* spp. Shoots and stems of *Euphorbia* spp. and gum, seeds and seed pods of *Acacia* spp. also eaten. Commonly raids maize, sorghum and fruit orchards, although typically much less destructive than baboons *Papio* spp. Stomach contents in museum specimens usually show fruit and some vegetative material, and sometimes a high proportion of locusts and termites. Consumption of small vertebrates, eggs and tubers have not been verified for *C. cynosuros*, although this is likely.

Chlorocebus cynosuros, like other savanna monkeys, is diurnal and forages in large multimale/multifemale groups. Smallest groups include one adult ♂, one adult ♀ and immatures, or can be composed solely of ♂♂. Movement between food sources is generally on the ground. Feeding begins at daybreak with movement of animals towards food sources and ends at sunset with movement to sleeping sites. Reported to move nearly 18 km overnight (Brain 1965).

Social and Reproductive Behaviour Social. No systematic studies conducted on *C. cynosuros*. Social and reproductive behaviour expected to be similar to other members of the *C. (aethiops)* Group. *Chlorocebus cynosuros* is territorial and has a flexible social system. Territories are defended by all members of the group except the youngest individuals. Inter-group interactions may be friendly with temporary merging of groups, or antagonistic ending in fights. Uses vocalizations, facial expressions and body postures to communicate. 'Splaylegged' displays exhibiting adult ♂ genitals warn ♂ members of encroaching groups. Alarm calls warn group members of predators. Grooming, agonistic behaviours and social play are all part of this species' intra-group interactions (E. E. Sarmiento pers. obs.).

Reproduction and Population Structure Little studied. Not clear if *C. cynosuros*, like other *Chlorocebus* spp., is a seasonal breeder, museum records indicate most offspring are born Aug–Oct in the middle of the dry season (Frechkop 1954, E. E. Sarmiento pers. obs.). Given a 5.5 month gestation (Eley *et al.* 1989b), most conceptions occur in Mar–Apr at the end of the rainy season. One infant is born, weighing ca. 400 g ($n = 2$). All ♀♀ in the group may partake in the care of each other's infants (E. E. Sarmiento pers. obs.).

Malbrouck Monkey *Chlorocebus cynosuros* adult male.

Predators, Parasites and Diseases Hunted in Angola and Zambia as a pest and often eaten when captured. Infants and young juveniles often kept as pets. Humans, Yellow Baboons *Papio cynocephalus kindae* and Domestic Dogs *Canis familiaris* are documented predators of *C. cynosuros*. Lions *Panthera leo*, Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, Servals *Felis serval*, Caracals *Lynx caracal*, Brown Hyenas *Hyaena brunnea*, Spotted Hyenas *Crocuta crocuta*, Black-backed Jackals *Canis mesomelas*, Martial Eagles *Polemaetus bellicosus*, African Crowned Eagles *Stephanoaetus coronatus*, pythons *Python* spp. and Nile Crocodiles *Crocodylus niloticus* likely prey on *C. cynosuros*.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

A crop pest in some areas. *Chlorocebus cynosuros* populations probably increasing and expanding along with human cultivation, the related increase in water availability and the reduction of competing guenon species.

Measurements

Chlorocebus cynosuros

HB ♂♂: 496 ± 60.7 (342–697) mm, $n = 81$

HB ♀♀: 440 ± 35.8 (379–540) mm, $n = 92$

T ♂♂: 643 ± 59.1 (440–785) mm, $n = 82$

T ♀♀: 570 ± 44.9 (460–742) mm, $n = 94$

HF ♂♂: 141 ± 12.1 (89–178) mm, $n = 85$

HF ♀♀: 125 ± 11.8 (95–183) mm, $n = 94$

E ♂♂: 36 ± 4.8 (25–46) mm, $n = 83$

E ♀♀: 34 ± 3.4 mm, 20–40 mm, $n = 91$

WT ♂♂: 5.4 ± 0.87 (5.4–7.4) kg, $n = 80$

WT ♀♀: 3.7 ± 0.68 (2.0–5.1) kg, $n = 88$

Various localities. Field-collected animals in AMNH, USNM, MCZ, RMCA, NMZB, TM, AM

Chlorocebus djamdjamensis DJAM-DJAM MONKEY (BALE MONKEY)

Fr. Cercopithèque du Balé; Ger. Bale-Grünmeerkatze

Chlorocebus djamdjamensis (Neumann, 1902). Sitzb. Ges. Naturf. Fr. Berlin, p. 51. Bamboo forest at 3300 m near Abera, east of L. Abaya, Ethiopia.

Djam-djam Monkey *Chlorocebus djamdjamensis* adult male.

Taxonomy Monotypic species. Member of the Savanna Monkeys Group *Chlorocebus (aethiops)*. Djam-djam was initially given the status of a species by Neumann (1902) based on one study skin and an incomplete description. This designation was accepted by Pocock (1907) and Elliot (1913b). Subsequently, however, this taxon was variously treated as a synonym of Matschie's Grivet *Chlorocebus aethiops matschiei*, Ellenbeck's Vervet *Chlorocebus pygerythrus ellenbecki* and Hilgert's Vervet *Chlorocebus pygerythrus hilgerti* (Schwarz 1926, de Beaux 1943, Dandelot 1959, Hill 1966, Yalden *et al.* 1977, Groves 2001, Grubb *et al.* 2003), all three subspecies of which were also described by Neumann (1902) at the time he described *C. djamdjamensis*.

On the basis of seven additional specimens from three new localities, Dandelot & Prévost (1972) redescribed *djamdjamensis* and resurrected *C. a. djamdjamensis*. This taxonomy was widely accepted (e.g. Lernoùld 1988). Yalden *et al.* (1996) and Kingdon (1997) independently resurrected *djamdjamensis* to species rank. This taxonomy was followed by Groves (2001, 2005c), but not by Grubb *et al.* (2003). Although *C. djamdjamensis* has phenotypic characters of *C. aethiops*, it is distinctly different (Dandelot & Prévost 1972, Yalden *et al.* 1996, Kingdon 1997, Groves 2001, J.-M. Lernoùld pers. comm., T. Butynski pers. obs.). Photographs of *C. djamdjamensis* are presented in Dandelot & Prévost (1972), Carpaneto & Gippoliti (1994), Rowe (1996) and Yalden *et al.* (1996). Kingdon (1997: 62) suggests that, since *C. djamdjamensis* is so distinctive, 'it seems likely that it is the montane relict of an older regional population belonging to the earliest dispersal of savanna monkeys'.

Synonyms: none. Chromosome number: $2n = 60$? Chromosome number not known, but diploid number likely 60 as for all other *Chlorocebus* spp. for which the karyotype has been studied (Dutrillaux *et al.* 1988b, Romagno 2001).

Description Medium-sized, short-tailed, grizzled-brown, semi-terrestrial monkey of bamboo forest on the Bale Massif, SC Ethiopia. Adult ♂ like adult ♀ but larger. Pelage long and woolly. Face below

eyes covered with short black hairs. Brow and broad (temple) band from eyes to ears, black. Brow sometimes with faint white line. Cheek-whiskers short, dense and white. Moustache white, narrow, variable, from well-defined to diffuse and nearly absent. Beard short, bushy, white. Ears black and exposed. Sides of neck and throat to chest white. Neck and shoulder pelage long and thick, almost forming a mane. Crown, shoulders, back and front of thighs with long, thick, grizzled dark brown to yellowish-brown pelage. Upper half of arms, and upper half of legs, brown to dark grey. Lower limbs greyish. Hands and feet dark grey or blackish-brown. Ventrums white, creamy-white, or off-white sometimes mixed with grey on chest. Upper tail dark grey to blackish-brown. Underside of tail pale grey. Base of tail with inconspicuous red-brown tufts at base (Kingdon 1997). Tail tip black with tuft nearly absent. Tail held out straight behind body when moving. Tail noticeably short, being much shorter than HB (Pocock 1907). This is also the observation in the field (T. Butynski pers. obs.) and of a live captive individual (J.-M. Lernoùld pers. comm.), but three adult ♀♀ obtained from the north-west extreme of the geographic range have tails that are slightly longer than HB (see Measurements; Dandelot & Prévost 1972). Relative to HB, *C. djamdjamensis* may have the shortest tail of any guenon. Scrotum blue.

Geographic Variation None recorded.

Similar Species Not reported to be sympatric with any other guenon, including *Chlorocebus* spp.

Chlorocebus aethiops. Parapatric to the north-west and west. Temples and brow-band white. Whiskers long and sickle-shaped. Distinct white moustache. Tail long, tipped white. White tuft under and to sides of base of tail.

Chlorocebus pygerythrus. Parapatric to the north-east, east and south (J.-M. Lernoùld pers. comm.). Temples and brow-band white. No white moustache. Tail long. Red patch under base of tail in adult ♂♂.

Distribution Endemic to the bamboo zone of the Bale Massif and other areas in the Southern Ethiopian Highlands, SC Ethiopia. The Bale Massif covers an area of ca. 5550 km². Afro-montane–Afroalpine BZ. Known from eight localities, but about 60% of the potential range has never been surveyed (Mekonnen *et al.* 2010b). The known extremes of the range are as follows: east (Odobullu): 06° 52' N, 40° 10' E; south and south-west (Abera): 06° 27' N, 38° 28' E; west (Wando = Wendo = Wondo = Uondo): 06° 37' N, 38° 24' E; north (ca. 25 km south-east of Goba): 06° 57' N, 40° 10' E; A. Mekonnen pers. comm.) Distance across the range from west to east is ca. 210 km. Distance across the range from north to south is ca. 55 km. Extent of occurrence ca. 8000 km². Since much of this area lacks bamboo, *C. djamdjamensis* probably occupies but a small portion of this 8000 km² area.

*Chlorocebus djamdjamensis*

Habitat Bamboo forest with scattered large trees on the Bale Massif. About 21% (15 km²) of the Odobullu Forest (71 km², 06° 50' – 06° 56' N; 40° 07' – 40° 12' E, 2250–3020 m) is Mountain Bamboo *Sinarundinaria alpina* forest. Of 43 encounters with groups of *C. djamdjamensis* in Odobullu Forest, all were within bamboo forest (Mekonnen *et al.* 2010b). The larger species of trees here include *Hagenia abyssinica*, *Dombeya torrida*, *Schefflera volkensii*, *Schefflera abyssinica* and *Manilkara butugi* (A. Mekonnen pers. comm.). Species richness for plants >2 m tall in the home-ranges of two study groups here was poor, comprising *S. alpina*, 13 tree species, 1 shrub, 5 liana, 1 epiphyte and 2 herbs within the vegetation quadrats. *Sinarundinaria alpina* accounted for 90% of the total stems (Mekonnen *et al.* 2010a).

At another site where *C. djamdjamensis* is present, Katcha (2400 m in Harenna Forest on the south slope of the Bale Massif), the dominant plant is 7–10 m tall *S. alpina*. The most common large trees here are *S. abyssinica* and *H. abyssinica*. Also present: Giant St John's Wort *Hypericum revolutum*, Croton *Croton macrostachyus*, Red Stinkwood *Prunus africana*, Pillar Wood *Cassipourea malosana*, *Lepidotrichilia volkensii*, *Erica* spp., *D. torrida*, *Galiniera saxifraga*, *Rhamnus prinoides*, *Maytenus* sp. and *Lobelia* sp. The ground cover in open areas is dense and includes *Rubus* sp., *Discopodium penninervium*, *Urera hypselodendron*, *Impatiens* spp., *Plectranthus* spp. and *Bothriocline* sp. There is an extremely heavy cover of moss, ferns and other epiphytes on the larger trees, especially on *S. abyssinica* (Carpaneto & Gippoliti 1994, T. Butynski pers. obs.). In Harenna Forest, as in Odobullu Forest, *C. djamdjamensis* confined to areas of tall (6–10 m) bamboo, often where there are scattered, large, trees (e.g. *S. abyssinica*, *H. abyssinica*, *D. torrida*). Here, *C. djamdjamensis* present from 2200–3400 m (Wakjira *et al.* 2011). *Chlorocebus djamdjamensis* not known to occur anywhere below 2200 m as bamboo is short (<6 m) or absent below this altitude. Known upper altitudinal limit is 3400 m as this is the upper limit of the treeline (Mekonnen

et al. 2012). Mean annual rainfall limits over the range of *C. djamdjamensis* ca. 1300–1800 mm. Wet season is Mar–Oct and dry season is Nov–Feb. During much of the wet season the Bale Massif is covered by a thick fog (Mekonnen *et al.* 2010b, A. Mekonnen pers. comm.).

Guerezas *Colobus guereza* are common in Harenna Forest and in Odobullu Forest. Olive Baboons *Papio anubis* are also present here along the roads and in the vicinity of agriculture (Carpaneto & Gippoliti 1994, A. Mekonnen pers. comm., T. Butynski pers. obs.). No other non-human primates are present.

Abundance Harenna Forest appears to be one of two strongholds for *C. djamdjamensis* (Hillman 1986). None the less, *C. djamdjamensis* is uncommon here. Two observers, working alone, each encountered *C. djamdjamensis* but once during 2.5 days of field surveys in 2003 (Q. Luke & T. Butynski pers. obs.). In Harenna Forest, based on 79 km of foot surveys, there are roughly 1437 (S.E. = 1315) *C. djamdjamensis* (ca 9.6 ind/km² [S.E. = 8.8] in ca. 149 km² of suitable habitat; Wakjira *et al.* 2011). Mekonnen *et al.* (2010b) conducted 280 km of foot surveys in Odobullu Forest, of which 76.8 km were in bamboo forest. Whereas they encountered no groups of *C. djamdjamensis* in grassland, bushland, forest and tree-dominated habitats, they encountered 43 groups within bamboo forest (0.58 groups/km ± 0.08). Within bamboo forest there were ca. 7.0 groups/km² and ca. 132 ind/km². The estimated total number of *C. djamdjamensis* in Odobullu Forest is 1700–2000.

Adaptations Diurnal and arboreal. Whereas the other five species of savanna monkeys are generalists, *C. djamdjamensis* is a bamboo forest specialist (Mekonnen *et al.* 2010a). As noted by T. Butynski (pers. obs.), where one or more *Cercopithecus* spp. are present, *Chlorocebus* do not enter the forest and barely even make use of the forest edge (e.g. along the lower Tana R., Kenya, where *C. p. hilgerti* is present in woodlands and Pousargues's White-collared Monkey *Cercopithecus mitis albitorquatus* is confined to gallery forest). However, *Chlorocebus* is found well within forest in the absence of any species of *Cercopithecus* (e.g. the Pemba Island Vervet *Chlorocebus pygerythrus nesiotes* on Pemba I., Tanzania, and Common Grivet *Chlorocebus aethiops aethiops* in Eritrea). Utilization of forest habitats by *Chlorocebus* in the absence of *Cercopithecus* appears to be a good example of 'competitive release'. T. Butynski (pers. obs.) is of the opinion that *C. djamdjamensis* in the highlands of Ethiopia represents another such case of competitive release where, in the absence of *Cercopithecus* (perhaps especially the Gentle Monkey *Cercopithecus mitis*), a *Chlorocebus* sp. has been able to adapt to at least the more open, lower stature, forest habitat that the mix of large bamboo and trees offers.

Data from the study of two groups of *C. djamdjamensis* in Odobullu Forest yielded the following diurnal activity budget over an 8-month period: feeding (66%), moving (14%), resting (11%), social (7%), other behaviours (2%) (n = 11,393 scans; Mekonnen *et al.* 2010a).

Unlike other *Chlorocebus* spp., *C. djamdjamensis* rarely comes to the ground. *Chlorocebus djamdjamensis* moves into large trees during periods of rain and to sleep at night (A. Mekonnen pers. comm.). This is an alert, cryptic and relatively quiet monkey that is difficult to detect and observe in its typical bamboo forest habitat.

Foraging and Food Omnivorous ('bambooivore'). T. Butynski (pers. obs.) encountered one group at Kacha (2400 m). The members of this group were foraging in thick bamboo (with a dense herbaceous ground cover) at ca. 4 m above the ground. They were breaking down newly sprouted ca. 4 m tall bamboo and eating the pith from the top ca. 1.5 m. At Kacha it is fairly common to find small piles of young bamboo leaves and pith. These piles, which represent *C. djamdjamensis* feeding sites, appear identical to the piles that Golden Monkeys *Cercopithecus mitis kandti* make while feeding on bamboo shoots in the Virunga Mts, SW Uganda.

The diet of two *C. djamdjamensis* groups at Odobullu Forest comprised young leaves (80%), fruits (10%), flowers (3%), animals (2%), shoots (2%), stems (1%), mature leaves (1%) and roots (1%) (n = 7223 items). Only 11 plant species were eaten, with the top five accounting for 94% of the diet. *Sinarundinaria alpina*, provided 77% of the food items, with 95% of these being young leaves. Other important food plants were *Psychotria orohila* (11% of food items) and *D. torrida* (3%; Mekonnen *et al.* 2010a). Foraging for young leaves of bamboo occurred to a height of 8 m, while the highest food items (flowers of *D. torrida* and leaves of *U. hypselodendron*) were up to 25 m (A. Mekonnen pers. comm.). See Wakjira *et al.* (2011) for a preliminary list of foods eaten in Harenna Forest.

The two focal groups at Odobullu Forest had home-ranges (during 8 months of study) of 12.3 ha and 18.1 ha. These groups were adjacent to one another but exhibited only 3–4% home-range overlap. Mean daily distance moved was 898 m (724–1207, n = 13 days) and 956 m (759–1288, n = 25 days; Mekonnen *et al.* 2010a).

Social and Reproductive Behaviour Social. One group at Kacha was comprised of at least two young juveniles, three juveniles and three adult ♀♀ (T. Butynski pers. obs.). At this same site, a group of about nine individuals was observed in 1986 (Yalden *et al.* 1996). In one study in Odobullu Forest, group size counts during surveys ranged from 13 to 41 (mean 19.1 ± 5.43 , n = 41; Mekonnen *et al.* 2010a, b). However, two research groups at this site comprised 46–50 and 55–60 individuals. In another study, group size counts during surveys ranged from 9–29 (mean 19.5 ± 4.5 , n = 37; Mekonnen *et al.* 2012). Solitary individuals occur. Most groups have at least two adult ♂♂. One group had no fewer than three adult ♂♂ (A. Mekonnen pers. comm.). Vocalizations include warning 'chirps', long 'screeches' and 'wavering growls'. All three of these vocalizations sound similar to those given by *C. pygerythrus* and *C. mitis* (T. Butynski pers. obs.). A. Mekonnen (pers. comm.) believes that the vocal repertoire of *C. djamdjamensis* does not differ from that of *C. aethiops*. *C. djamdjamensis* and *C. guereza* form polyspecific associations in areas where large trees are present within bamboo (Carpeneto & Gippoliti 1994, Mekonnen *et al.* 2012). Such associations are, however, uncommon (A. Mekonnen pers. comm.).

Reproduction and Population Structure Not studied. Apparently only one infant born at a time. Twins not observed (A. Mekonnen pers. comm.).

Predators, Parasites and Diseases No observations of predation or disease. Both African Crowned Eagles *Stephanoaetus coronatus* and Leopards *Panthera pardus* are present over the range of *C.*

Frontal portrait of Djam-Djam Monkey *Chlorocebus djamdjamensis* adult male.

djamdjamensis. They are probably the two most important predators of this species.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Chlorocebus djamdjamensis lives in a region of great biogeographic importance where many other species of plants and animals are also threatened. Most notable among these are the two 'Endangered' flagship species of the Bale Massif; Mountain Nyala *Tragelaphus buxtoni* and Ethiopian Wolf *Canis simensis*. The main threat to *C. djamdjamensis* in Odobullu Forest is habitat loss and degradation as a result of the collection of bamboo for local consumption (Mekonnen *et al.* 2010a, b, 2012). Harenna Forest, although within the Bale Mountains N. P., is under threat from an expanding human population, fire, agriculture, including livestock grazing, and the taking of forest products such as bamboo, lumber, fuelwood and charcoal (Oates 1996a, Wakjira *et al.* 2011, T. Butynski & A. Atickem pers. obs.). More than 8000 households (ca. 55,000 people) are located within the Bale Mountains N. P. (Flintan 2005). The human population in this region is growing at the rapid rate of 3.1% per year (WWF 2001).

Hybridization may be a threat as forest clearance for agriculture at the lower levels of montane forest presumably brings *C. aethiops* and *C. pygerythrus* closer to the range of *C. djamdjamensis* (Kingdon 1997). Apparent hybrids recently reported at three sites (Mekonnen *et al.* 2012, J.-M. Lernoould pers. comm.). Another result of the loss of habitat and proximity of people is that crop raiding by *C. djamdjamensis* is now common, with *C. djamdjamensis* being hunted at many sites (Mekonnen *et al.* 2012).

The African Buffalo *Syncerus caffer* and the Savanna Elephant *Loxodonta africana* have been extirpated from the Bale Massif. The loss of the two largest herbivores must have had a significant impact

on the ecology of this ecosystem, perhaps resulting in a far more closed bamboo forest and fewer and smaller short-grass glades. The impact on *C. djamdjamensis* is likely to have been significant, but remains unknown. Haremma Forest, with the adjacent Forest Priority Areas, encompasses an area of >4000 km², making this the second largest forest in Ethiopia (Williams 2002). Top priorities for the conservation of *C. djamdjamensis* are (1) to survey this region to determine the distribution and abundance of *C. djamdjamensis* and (2) to provide improved management and protection to those areas where this species occurs, especially Haremma Forest and Odobullu Forest.

Measurements

Chlorocebus djamdjamensis

HB (♀ ♀): 442 (430–455) mm, n = 3

T (♀ ♀): 488 (470–505) mm, n = 3

HF (♀ ♀): 121 (117–125) mm, n = 3

E (♀ ♀): 32 (30–33) mm, n = 3

WT (♀ ♀): 3.4 (3.0–3.6) kg, n = 3

GLS (♀ ♀): 91 (87–96) mm, n = 3

GWS (♀ ♀): 63 (61–65) mm, n = 3

Two specimens from 18 km west-south-west of Koffolé and one from the road between Koffolé and Goba (Dandelot & Prévost 1972)

GENUS *Allochrocebus*

Mountain Monkeys

Allochrocebus Elliot, 1913. Review of the Primates 1: xl, 2: 296.

L'Hoest's Monkey *Allochrocebus lhoesti*
adult male.

Preuss's Monkey *Allochrocebus preussi*
adult male.

Sun-tailed Monkey *Allochrocebus solatus*
adult male.

Polytypic genus endemic to equatorial Africa. The *Allochrocebus* (*preussi*) Group embraces three species; Preuss's Monkey *Allochrocebus preussi*, L'Hoest's Monkey *A. lhoesti* and Sun-tailed Monkey *A. solatus*. Although allocation of *A. lhoesti* to the subgenus *Allochrocebus* dates back to 1913 (Elliot 1913b), the profiles presented here represent one of the first of contemporary works to return formal recognition for the distinctness of this group. Until recently this group had usually been placed in *Cercopithecus*. Indeed, Gautier *et al.* (2002), while acknowledging that the three species cluster with savanna monkeys *Chlorocebus* and the Patas *Erythrocebus patas*, still consider that the three species in the *A. (preussi)* Group possess sufficient characters to keep them in the genus *Cercopithecus* (J.-P. Gautier pers. comm.). Our reasons for taking *Allenopithecus*, *Miopithecus*, *Erythrocebus*, *Chlorocebus* and *Allochrocebus* out of *Cercopithecus* are founded upon robust, molecular studies that are discussed in other genus profiles. The affinities of *Allochrocebus* are revealed by molecular analysis (Dutrillaux *et al.* 1980, 1982a, 1988a,

b, Muleris *et al.* 1986, Purvis 1995, Disotell 2000, Disotell & Raaum 2002, Tosi *et al.* 2005, Xing *et al.* 2007, Tosi 2008, Perelman *et al.* 2011, Hart *et al.* 2012) as well as analysis of vocalizations (Gautier 1988, Gautier *et al.* 2002), biogeography and behaviour (Kaplin & Moermond 2000, Kaplin 2001), and comparison of the morphology of hands and feet (Kingdon 1988a) and of the postcranial skeleton (Gebo & Sargis 1994, Sargis *et al.* 2008). All these studies concur in associating members of the *A. (preussi)* Group with *Erythrocebus* and *Chlorocebus*. Dutrillaux, Muleris and their colleagues showed that the ancestor of these three groups branched away to form a radiation that was quite distinct from all the arboreal guenons as well as being earlier. Gautier (1988) showed that vocalizations allied *A. preussi* more closely with *Chlorocebus* than with *A. lhoesti* and *A. solatus*, which clustered more closely with one another.

The skull of *Allochrocebus* is similar to *Cercopithecus* and *Erythrocebus*, but the postcranial skeleton strongly differs from *Cercopithecus*.

L'Hoest's Monkey *Allochocebus lhoesti*.

Allochocebus has a shorter supraspinatus fossa of the scapula, narrower head of the humerus with more proximally extended greater and lesser tuberosities, reduced deltopectoral crest, flatter capitulum, smaller trochlea, smaller radial facet on the ulna, narrower patella facet, narrower medial condyle of the femur, taller and narrower head of the talus, narrower tuber calcanei and longer cuboid (Gebo & Sargis 1994, Sargis *et al.* 2008). These provide more stable limb joints with less mobility, as befits a terrestrial life-style, and resemble *Erythrocebus* more than *Chlorocebus*. Kingdon (1988a) noted the exceptionally long, narrow feet of *A. lhoesti*, *Erythrocebus* and *Chlorocebus*, but both of the latter have much shorter toes, and neither have the robust first digit of *A. lhoesti*. The shallow calcaneo-cuboid facet of *A. lhoesti* resembles that of *E. patas*, suggestive of terrestrial traits, while the astragalo-calcaneal facet approximates more closely to that of the Grivet *Chlorocebus aethiops*. A relatively short and lightly built calcaneum suggests that the lever-arm of the Achilles tendon is less developed in *A. lhoesti* than in the more consistently cursorial *Chlorocebus* and *Erythrocebus* (Kingdon 1988a).

Although it was noted that *A. lhoesti* spend much of their time on the ground, and that the leaves of various herbs, shrubs and trees were common foods (Kingdon 1971), it took the detailed studies of Kaplin & Moermond (2000) and Tashiro (2006) to reveal that terrestrial forest herbs comprise as much as 78% of the diet in undisturbed forest habitats, especially those on steep terrain. Kaplin (2001) argues that reliance on terrestrial forest herbs may be the limiting factor in their distribution and the link with broken terrain is also suggestive.

The *A. (preussi)* Group has been associated with many *Cercopithecus* species, including Gentle Monkey *C. mitis* (Pocock 1907, Eisentraut 1973, Ruvolo 1988), Owl-faced Monkey *C. hamlyni* (Schwarz 1928b, Allen 1939, Ruvolo 1988), Groves 1989), Putty-nosed Monkey *C. nictitans*, Red-bellied Monkey *C. erythrogaster* (Groves 1989, Kingdon 1971), Diana Monkey *C. diana* and De Brazza's Monkey *C. neglectus* (Dandelot 1974), as well as with talapoin *Miopithecus* spp. (Disotell & Raaum 2002). Ruvolo (1988) followed earlier precedents in allying the *A. (preussi)* Group with *C. mitis* but she also suggested an affinity with *C. hamlyni*. Most of these authors partly based their association of the *A. (preussi)* Group with arboreal forest species on resemblances in colour and pattern. This similarity is, in fact, greater than with their actual sister-species among savanna monkeys and Patas.

According to Tosi *et al.* (2005) and Perelman *et al.* (2011), the common ancestors of *Allochocebus*, *Chlorocebus* and *Erythrocebus* branched off from the other guenons ca. 8 mya (late Miocene) and could not, of course, have been as specialized as any of the surviving species. Tosi (2008) estimates that *A. solatus* separated from the ancestral stock at 2.1 mya, and that *A. preussi* and *A. lhoesti* bifurcated at ca. 0.5 mya (but see Page *et al.* 1999) when a montane forest dispersal corridor is posited to have connected the highlands of east central and west central Africa. This mini-radiation seems to have involved *Allochocebus* adapting to denser, more heavily forested areas of the equatorial forest belt while *Chlorocebus* and *Erythrocebus* specialized in the drier, more open ends of the climatic and ecological spectrum both to the south and to the north of the Equator.

Allochocebus are long-legged, dark, strongly patterned monkeys with minimal sexual dimorphism in colour but substantial differences in body size between adult ♂♂ and adult ♀♀; adult ♀♀ weigh about 60% as much as adult ♂♂ (T. Butynski pers. comm.). Males have particularly large canines, set in robust, narrow, elongated muzzles. The oval nose-pad in *A. lhoesti* is covered in a deep black plush. The facial skin of the ♂ is purple. The naked, sky-blue testicles strongly contrast against the dark black fur of the buttocks. The limbs have subtle anatomical modifications that render the relatively unspecialized hands and feet particularly flexible at wrist and ankle. The three species in the *A. (preussi)* Group can be distinguished from one another by the colour of the tail and by the distribution of white on the face and throat.

Until the discovery of *A. solatus* in lowland forest in Gabon in 1984 (and named in 1988), the two other species were popularly known as 'mountain monkeys' because of the predominantly montane distribution of *A. lhoesti* and *A. preussi*. It should be noted, however, that *A. preussi* descends to ca. 900 m (i.e. lower montane forest, on Bioko I., Equatorial Guinea) but T. Butynski (pers. comm.) suggests that this is a case of 'competitive-release' as no other medium-sized semi-terrestrial primate occurs on Bioko. It now seems likely that *Allochocebus* is less of a montane genus than a semi-relictual array of semi-terrestrial monkeys that are adapted to living mainly off terrestrial herbs (Kaplin 2001) in well-drained, but densely vegetated forest, perhaps during cooler climatic periods of the past. Most other medium-sized, forest-living, semi-terrestrial primates, such as the drill-mangabeys *Cercocebus* spp., Allen's Swamp Monkey *Allenopithecus nigroviridis*, *C. hamlyni* and *C. neglectus* tend to prefer swampy and riverine areas in warm, wet lowland forests. This probably left a niche for *Allochocebus*, not only in the cool, wet, montane forests, but also in the deeply-cut, mainly well-drained areas south of the Ogooué R., Gabon, where *A. solatus* occurs.

For semi-terrestrial animals a likely advantage of living in swamp-forest is decreased vulnerability to predation and, perhaps, reduced

competition. If this is so, it can be predicted that *Allochocebus* spp. suffer higher levels of predation from Leopards *Panthera pardus* and Golden Cats *Profelis aurata* (and possibly greater competition from other ground-feeders) than the swamp-dwellers. It is certain that they suffer more than other monkeys from trapping by humans (J.-P. Gautier & T. Butynski pers. comm.). Susceptibility to predators is probably mitigated by exceptional alertness, quietness, fast pace (over the ground, and even through heavily obstructed undergrowth), and an ability to take to the trees.

Extrapolating from *C. lhoesti* (the best known of the three species), *Allochocebus* spp. live in tightly knit groups of a single adult ♂ and one or more adult ♀♀ and their offspring. These apparently range widely through well-defined and routinely travelled home-ranges. Confrontations between groups of *A. lhoesti* involve all members. Adult ♂♂ make frequent threats and forward rushes, then posture with chin thrust forward and tail raised, frequently turning to display lateral, rear and frontal views. The adult male's brilliant blue testicles against a jet black rear end make for a highly conspicuous display. These confrontations are usually followed by a sudden and silent withdrawal (Kingdon 1997). Their otherwise low-key types of communication imply that individuals can easily get isolated or lost and this would encourage tight social formations.

The limited distribution of *Allochocebus* spp. could be explained by a reluctance to move across more open habitats, even an inability to cross river barriers. For whatever reasons, a limited geographic range suggests that they are poor dispersers. Dependence on continuity of experience possibly makes it difficult for *Allochocebus* species to regain lost ground after major disturbance or local extirpation. This poses special problems for their conservation in the face of extensive agricultural expansion into their habitats (Kingdon 1997).

Jonathan Kingdon & Colin P. Groves

Allochocebus preussi PREUSS'S MONKEY

Fr. Cercopithèque de Preuss; Ger. Westliche Vollbartmeerkatze

Allochocebus preussi (Matschie, 1898). Sitzb. Ges. Naturf. Fr. Berlin, p. 76. Victoria, Cameroon.

Preuss's Monkey
Allochocebus preussi
adult male.

Taxonomy Polytypic species. Preuss's Monkey *Allochocebus preussi* is a member of the *Allochocebus (preussi)* Group (Grubb *et al.* 2003) or the *Allochocebus (lhoesti)* Group (Gautier *et al.* 2002, Groves 2005c). Until recently, often considered a subspecies of L'Hoest's Monkey *Allochocebus lhoesti* (Rahm 1970, Thorington & Groves 1970, Dandelot 1974), but now widely regarded as a full species that differs considerably from *A. lhoesti* (Tappen 1960, Hill 1966, Napier & Napier 1967, Napier 1981, Harrison 1988b, Kingdon 1997, Gautier-Hion *et al.* 1999, Groves 2001, 2005c, Butynski 2002b, Gautier *et al.* 2002, Grubb *et al.* 2003, Tosi 2008). Synonyms: *crossi*, *insularis*. Chromosome number: $2n = 60$ (Groves 2001).

Description Medium-sized, semi-terrestrial monkey with white throat, grizzled grey cheeks, chestnut-red back and rump, and blue scrotum. Distal ca. 15% of the tail sharply curved towards the underside of the tail. Adult ♀ like adult ♂ in colouration but smaller, being ca. 65% as heavy. Cheeks, crown, nape, shoulders and upper arms blackish, grizzled-grey. Throat and front of neck white.

Iris amber. Nose and ridge of muzzle black. Sides of muzzle greyish. Ears slaty, hidden by hair of crown. Flanks grey with buff banding. Back with large, chestnut-red patch, beginning narrowly between shoulders and becoming increasingly broad over rump. Forearms black. Outside of thighs black and/or speckled grey. Wrists, hands, shanks, ankles and feet black. Callosities brownish-black. Ventrums dark grey. Scrotum skin is blue. Tail chestnut-red on dorsal surface for proximal 10–20%, then dark grey above and light grey below, then black over distal 25–35%. As for *A. lhoesti* and Sun-tailed Monkey *Allochrocebus solatus*, when moving (either on ground or in trees), tail stretched-out behind the body and curved gradually downwards with distal ca. 15% curved sharply downwards. When standing, tail often held vertical or over back with distal ca. 15% pointing backwards. When tail is dangling (e.g. when sitting in a tree), the tip curves distinctly forwards. *Allochrocebus* spp. are the only African monkeys to carry the tail in this manner. Infant with mostly yellowish-brown hairs tipped blackish. Skin of face, ears, hands and feet pale pink. Young juvenile with yellowish-brown pelage that is longer and more shaggy/fluffy than infant. Skin of face pinkish. Skin of hands and feet blackish. Hair of chin, throat and upper chest whitish with distinct yellow-gold tinge. Chestnut on dorsum less extensive than for adult. Almost no chestnut on tail. Tip of tail blackish (T. Butynski pers. obs.).

Geographic Variation

A. p. preussi Mainland Preuss's Monkey. Cameroon–Nigeria border region. Larger (see Measurements). Dorsal saddle brighter chestnut. Limbs black with grizzle-grey on front of hindlimbs. Chestnut covering ca. 20% of dorsal surface of tail. Tail lighter grey (Eisentraut 1973).

A. p. insularis Bioko Preuss's Monkey. Bioko I., Equatorial Guinea. Smaller, HB and T ca. 80–85% as long as for *A. p. preussi* (see Measurements). Dorsal saddle duller chestnut. Limbs grizzled-grey. Chestnut covering ca. 10% of dorsal surface of tail. Tail darker grey (Eisentraut 1973, T. Butynski pers. obs.).

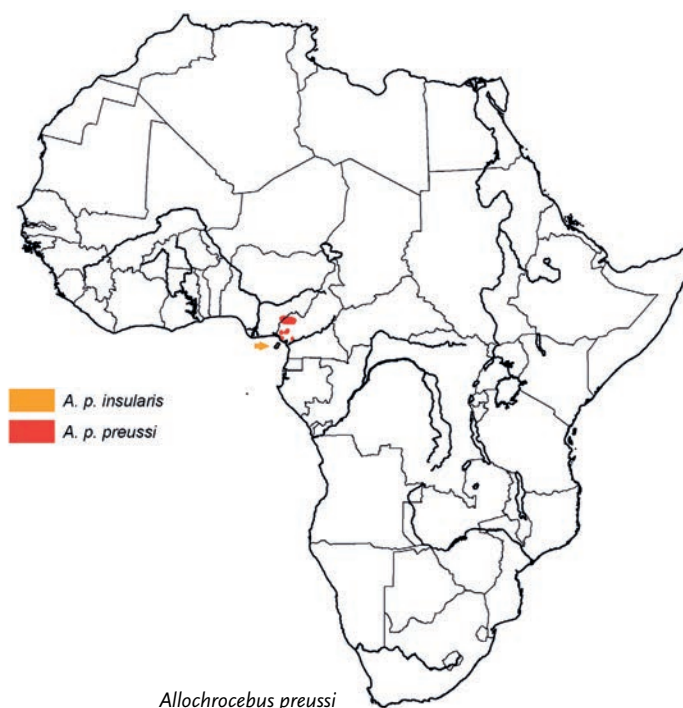

Similar Species None within geographic range.

Distribution Endemic to SE Nigeria, W Cameroon and Bioko I. Rainforest BZ; *A. p. preussi* in highlands of SE Nigeria–W Cameroon border region from Cross R. drainage (Cross River Highlands and Obudu Plateau) south to south side of Mt Cameroon and Sanaga R. Present in Bamboutos Mts, Mt Oku, Mt Kupé, Rumpi Hills, Oban Hills F. R., Bamenda Highlands, Takamanda Reserve, Boshi-Okwangwo and Mt Cameroon (including Etinde F. R.) (Wolfheim 1983, Oates *et al.* 2004). Northern limit ca. 07° N (Tappen 1960). Western limit ca. 08° E (Booth 1958b). In Cameroon found in an area of less than 120 km × 120 km (14,400 km²; Gartlan 1973). *A. p. preussi* on Bioko I. in Pico Basilé N. P. (330 km²) and Gran Caldera and Southern Highlands Scientific Reserve (510 km²) (Butynski & Koster 1994, Hearn *et al.* 2006).

Habitat Moist forest. Both on the mainland and on Bioko I., occurs in primary and secondary lowland, submontane and montane forest, but attains highest densities in montane forest. Also in isolated forest patches in montane grasslands. From 100–3000 m on the mainland, but primarily above 1000 m (Gartlan & Struhsaker 1972, Gartlan 1973, Beeson *et al.* 1996). From ca. 450–2800 m on Bioko

Lateral and palatal views of skull of Preuss's Monkey *Allochrocebus preussi* adult male.

I., but uncommon below 900 m (Butynski & Koster 1994, Hearn *et al.* 2006). Mean annual rainfall ca. 2000–9000 mm. Lives in some of the wettest sites in Africa.

Abundance No estimates of numbers for *A. p. preussi*, but the most common guenon in montane forest on Mt Kilum in the early 1990s (Beeson *et al.* 1996). *Allochrocebus p. insularis* at low densities over much of its range. Encounter rate during an island-wide primate census on Bioko I. in 1986 was 0.03 groups/km (373 km of census), but this survey underestimated density as it included sites below 450 m where *A. p. insularis* probably does not occur due to unsuitable habitat (Butynski & Koster 1994). In 2008, encounter rate of 0.09 groups/km along 44 km of transect in Gran Caldera

de Luba, and 0.14 groups/km on south slope of Pico Basilé along 49 km of census. Highest rate of encounter during censuses on south Pico Basilé in 2008 was 3 groups/km (T. Butynski, G. Hearn & J. Owens pers. obs.). Both the Gran Caldera de Luba and the south slope of Pico Basilé are remote and receive relatively low levels of hunting. Also, there has been little to no anthropogenic impact on the habitats at these sites. As such, these encounter rates are likely close to what is expected for undisturbed populations of *A. p. insularis*. In 1986, *A. p. insularis* may have been the most common monkey on Pico Basilé (Butynski & Koster 1994), but numbers have probably declined considerably since as a result of commercial hunting over the more assessable parts of this mountain. Number of *A. p. insularis* unlikely to be >1000. This may be the rarest species of monkey on Bioko I. (Hearn *et al.* 2006).

Adaptations Diurnal and semi-terrestrial. Spends much time foraging on the ground and within a few metres of the ground, but also climbs well and is often seen in trees. Runs on the ground when fleeing from people (Struhsaker 1969, Gautier-Hion 1988). May be more arboreal on Bioko I. than on the mainland. Preliminary observations of groups in the most remote areas (where hunters do not go) suggest that *A. p. preussi* travels and forages primarily above ground. Where hunted on Bioko I., and where the tree canopy is continuous, they flee through the trees, not on the ground (T. Butynski pers. obs.). More active during the first few hours after dawn and last few hours before dusk than during the middle part of the day.

Foraging and Food Omnivorous. An opportunistic feeder on the mainland (Struhsaker 1969). Studied for 15 months at Mt Kilum, Cameroon, where diet comprised 52% seed/fruit, 26% tree shoot, 14% herb, 4% pith, 1% tree leaf, 1% flower (n = 1284). Invertebrates comprised only 1% of the diet. Shoots, herbs and pith comprised 44% of the diet, which is far more than for most species of guenons. The invertebrate component of the diet is far less than for most guenons. Thirty-one items from 18 plant species were eaten. Small aquatic animals (possibly frogs and crabs) caught from streams were eaten in the middle of the dry seasons (Beeson *et al.* 1996). On Bioko I., eat ripe fruits of *Ficus sur* (J. Owens pers. comm.) and *Tiliacora funifera*, flowers of Giant St John's Wort *Hypericum revolutum*, and search foliage and moss for invertebrates (T. Butynski pers. obs.).

Social and Reproductive Behaviour Social. *A. p. preussi* groups on Mt Cameroon range in size from 2 to 9, with a mean of 5.6 individuals (n = 10; Struhsaker 1969). Group size is considerably smaller than for most other forest-living species of guenon. Groups typically include one adult ♂ and one or more adult ♀♀ and their offspring. Solitary individuals occur but seem to be uncommon. On Mt Kilum the largest group observed had 19 individuals and groups of >10 were often encountered. Here, groups often have more than one adult ♂. Ratio of adult ♂♂ to adult ♀♀ was ca. 1:3. Solitary (single) adult ♂♂ often observed but never solitary adult ♀♀ (Beeson *et al.* 1996). There are few data on group size on Bioko I. Hunters claim *A. p. insularis* live in groups of 4–5 individuals but most groups probably considerably larger than this (Butynski & Koster 1994). J. Owens (pers. comm.) obtained a complete count of one group in a remote area where hunters do not go. This group

comprised seven individuals (one adult ♂, one subadult ♂, two adult ♀♀, two juveniles and one infant). A second group in this area comprised at least six individuals. The impression is that most groups comprise 5–10 individuals (T. Butynski pers. obs.).

A relatively quiet monkey (Gautier-Hion 1988, Gautier *et al.* 2002, T. Butynski pers. obs.). Adult *A. p. preussi* ♂ gives loud, two-part, booming 'oop-uuh' (or 'oop-weur') calls in the late afternoon (17:50–18:40h; Struhsaker 1969, 1970, Gautier *et al.* 2002). Dowsett-Lemaire & Dowsett (2001) refer to this as the 'ouou-owe' dusk call. This call is 'contagious' in that several adult ♂♂ give the oop-uuh call once the first adult ♂ gives this call. Struhsaker (1969) heard as many as five adult ♂♂ give this call within a 1.5 minute period, and Gautier *et al.* (2002) report up to ten adult ♂♂ responding to each other. The function of the oop-uuh call is not known, but its contagious effect and marked diurnal periodicity implies that it provides information about the number and distribution of adult ♂♂ and, therefore, aids in group spacing (Struhsaker 1969, Gautier *et al.* 2002). It is important to note that neither *A. lhoesti* nor the Sun-tailed Monkey *Allochrocebus solatus* has a loud call, and that the structure of the oop-uuh call differs from the loud calls of all other cercopithecines or colobines (Gautier 1988, Gautier *et al.* 2002). The strong periodicity of this call and the large number of adult ♂♂ that participate is unique, at least among African primates. Interestingly, the oop-uuh call is not known for *A. p. insularis* on Bioko I. (even in areas where this subspecies is most common at a density of 3 groups/km of transect; T. Butynski pers. obs.).

Other calls of *A. p. preussi* are warning/alarm 'chirps', which are given by adult ♀♀, subadults and juveniles, and unity/alarm/warning 'hacks' and 'hack-trains', which are given by adult ♂♂. *Allochrocebus p. preussi* not heard to give contact 'trills' (Struhsaker 1969, 1970, Gautier 1988, Gautier *et al.* 2002, T. Butynski pers. obs.). One call given by *A. p. insularis* (probably adult ♀♀), but that has not been reported for any other species of guenon, is the 'purr' (T. Butynski pers. obs.). The purr appears to be a cohesion/contact call and may represent a much modified 'grunt' (i.e. 'type 2 quavered call' of Gautier *et al.* 2002).

Allochrocebus p. preussi forms polyspecific associations with other monkeys, including Mona Monkeys *Cercopithecus mona*, Putty-nosed Monkeys *Cercopithecus nictitans*, Red-eared Monkeys *Cercopithecus erythrotis*, Crowned Monkeys *Cercopithecus pogonias* and Red-capped Mangabey *Cercocebus torquatus*. In Cameroon, 7% of *A. p. preussi* groups encountered were in polyspecific associations (n = 27; Gartlan & Struhsaker 1972, Struhsaker 1981a, Gautier-Hion 1988).

Allochrocebus p. insularis not often in polyspecific association, but this may be because (1) few other monkey species occur at the higher altitudes, and (2) these other species are usually at low densities. Observed in association only with *C. erythrotis*. When *A. p. insularis* adult ♂ gives hacks, adult ♂♂ in *C. erythrotis* groups (to >100 m away) may give hacks in response (T. Butynski pers. obs.).

Adult ♂♂ give the 'blue balls and tail display' in a manner that appears to be identical to that *A. lhoesti* and *A. solatus* (Gautier *et al.* 2002). During this ritualized visual (threat/dominance) display, the ♂ stands on all four legs and faces the opponent. He then, in one continuous movement, turns 180° while raising the tail high over his back. He then stops and displays his blue testicles for ca. 2–4 seconds while facing away from the opponent. On Bioko I., a ♂ may give this

display towards a human observer several times in a matter of a few minutes (T. Butynski pers. obs.). *Allochrocebus p. preussi* may be unique among cercopithecines in possessing both a loud call and a highly ritualized visual display.

Reproduction and Population Structure No information available. Live to at least 19 years and 4 months of age in captivity (Jones 1962).

Predators, Parasites and Diseases No information available. Two of the primary predators of monkeys on mainland Africa, Leopards *Pantherus pardus* and African Crowned Eagles *Stephanoaetus coronatus* are absent from Bioko I. (Struhsaker 2000a, T. Butynski pers. obs.). Humans are the main predator for *A. preussi* both on the mainland and on Bioko I.

Conservation IUCN Category (2012): Endangered as *A. preussi*, *A. p. preussi* and *A. p. insularis*. CITES (2012): Appendix II.

Main threats are habitat loss and fragmentation due to logging and clearance for agriculture, and commercial hunting. Amount of habitat available to *A. p. preussi* has been greatly reduced (Wolfheim 1983, Oates 1996a, Lee *et al.* 1988). Significant populations thought to exist in Nigeria in the Oban Hills F. R. and in the mountains near Obudu (Oates 1986). Still locally common in Ndokbou Forest (>1000 km²) and Ebo Forest (1400 km²), W Cameroon, but hunting is a major threat here and some populations have apparently been extirpated (Dowsett-Lemaire & Dowsett 2001). Surveys needed to better assess abundance, distribution and conservation status, especially in the Oban Hills, Mamfe-Obudu area on the Cameroon–Nigeria border, Etinde Reserve on Mt Cameroon, and Ndokbou Forest and Ebo Forest. All populations should be strictly protected, in particular Okwangwo Division of Cross River N. P., Afi River F. R. and Obudu Plateau, Nigeria, and Takamanda F. R., Mone River F. R., Etinde Reserve and forests of Bakossiland, Mt Kube and Mt Oku (= Mt Kilum), Ndokbou Forest and Ebo Forest, Cameroon (Oates 1996a, Butynski 2002a). Six threatened primate species are sympatric with *A. p. preussi* (IUCN 2012); Drill (Endangered), Preuss's Red Colobus (Critically Endangered), Red-capped Mangabey (Vulnerable), Red-eared Monkey (Vulnerable), Western Gorilla *Gorilla gorilla* (Critically Endangered) and Robust Chimpanzee (Endangered). These species, and hundreds of others, would benefit from conservation actions focused on *A. p. preussi*.

The number of *A. p. insularis* killed by hunters each year has increased from roughly 50 in 1998–2000 to ca. 300 in 2005, when the price paid per adult was ca. US\$31 (Hearn *et al.* 2006). In October 2007 a Presidential Decree banning the hunting and possession of primates in Equatorial Guinea (including Bioko I.) was signed. For a few months after the signing of the Decree the killing of monkeys on Bioko was reduced by >95%. The Decree was, however, never effectively enforced and by early 2009 the number of monkeys killed on Bioko was back to pre-October 2007 levels. Conservation priorities include surveys of Pico Basilé N. P. and much improved management and protection of Pico Basilé N. P. and of the Gran Caldera and Southern Highlands Scientific Reserve (Butynski 2002a). Effective protection of these two areas would provide for the long-term survival, not only of *A. p. insularis*, but also of the six other species of monkeys on Bioko I., four of which are threatened at the

species level and all of which are threatened at the subspecies level (IUCN 2009, Butynski *et al.* 2009).

Measurements

Allochrocebus preussi

A. p. preussi

HB (♂ ♂): 575 (550–605) mm, n = 5

Allochocebus lhoesti L'HOEST'S MONKEY

Fr. Cercopithèque de L'Hoest; Ger. Östliche Vollbartmeerkatze

Allochocebus lhoesti (Sclater, 1899). Proc. Zool. Soc. Lond. 1898: 586 [1899].

Restricted to Tschopo R. (Tschepo R.), near Stanleyville, 'Congoland' (DR Congo) by Pocock (1907).

L'Hoest's Monkey *Allochocebus lhoesti* adult male.

Taxonomy Monotypic species. Most easterly distributed member of the *Allochocebus* (*preussi*) Group. Following Groves (2001), treated here as a monotypic species, although given the allopatry of the three main *Allochocebus* types (Preuss's Monkey *A. preussi*, L'Hoest's Monkey *A. lhoesti* and Sun-tailed Monkey *A. solatus*), their specific status is subjective and unresolved. Resolution would entail showing that the differences among *Allochocebus* species are as great as those that separate other guenon species (but see Gautier *et al.* 2002). Dutrillaux *et al.* (1988a, b) found the same chromosome number in *A. lhoesti* and *A. solatus* but noted differences in the banding patterns of chromosomes 11 and 17. *Allochocebus lhoesti* has classically been considered a species of *Cercopithecus*, the nominate subspecies of *C. lhoesti* (Allen 1939, Hill 1966, Thorington & Groves 1970, Dandelot 1974), and grouped with Owl-faced Monkey *Cercopithecus hamlyni* (Schwarz 1928b, Allen 1939, Groves 1989). Other authors have grouped L'Hoest's Monkey with savanna monkeys *Chlorocebus* spp. (Pocock 1907), Gentle Monkey *Cercopithecus*

mitis (Matschie 1898, Sclater 1898, Pocock 1907, Elliot 1913b, Eisentraut 1973, Ruvolo 1988), Putty-nosed Monkey *Cercopithecus nictitans* and Red-bellied Monkey *Cercopithecus erythrogaster* (Pocock 1907, Kingdon 1971, Groves 1989), Diana Monkey *Cercopithecus diana* and De Brazza's Monkey *Cercopithecus neglectus* (Dandelot 1974).

Elevation of Elliot's (1913b) subgenus to a genus gives specific status to all three known types (Groves 2001), but unnaturally separates them from *C. hamlyni* and from the other semi-terrestrial guenons all of which appear to share a special relationship with *Allochocebus*. Blood protein analyses by Ruvolo (1988) support classic taxonomies that show *Allochocebus* is uniquely related to *C. hamlyni*. If this relationship is true, recognition of *Allochocebus* would require either elevating *C. hamlyni* to its own genus or transferring it to *Allochocebus*. Further complicating matters, morphology (Kingdon 1988a, Gebo & Sargis 1994, Sargis *et al.* 2008), chromosome banding (Dutrillaux *et al.* 1988a, b) and recent DNA analyses (Tosi *et al.* 2003, Xing *et al.* 2007, Tosi 2008, Hart *et al.* 2012) all show that *Allochocebus* shares a unique relationship with *Chlorocebus* and *Erythrocebus* not shared by the more arboreal guenons. Considering that *Cercopithecus* encompasses a greater variety of types than *Chlorocebus*, it could be argued that *Allochocebus* is more properly a subgenus of *Chlorocebus*. Since most arboreal guenons, regardless of their diversity, have been placed in *Cercopithecus*, it is inconsistent to place all the main types of terrestrial (or semi-terrestrial) guenons into separate genera. To maintain taxonomic consistency, recognition of *Allochocebus* appears to merit a general reworking of guenon taxonomy. Affinities between *A. lhoesti* and *A. solatus* in vocal communication systems, but significant differences of both to *A. preussi*, further suggest that a three-species classification of *Allochocebus* is far from clear-cut (Gautier *et al.* 2002).

Synonyms: *rutschuricus*, *thomasi*. Chromosome number: $2n = 60$ (Romagno 2001, Moulin *et al.* 2008).

Description Medium-sized, semi-terrestrial, long-tailed monkey with a well-developed white beard (enveloping the throat, jowls and sides of neck), which contrasts with the dark head, body and limbs. Sexes similar in colouration but average adult ♀ weight is ca. 57% that of adult ♂. Snout long. Snout, nose, chin and upper and lower lips covered in black to dark-brown hairs. Sides of eye orbits outlined by long white-banded black hairs, producing a grey colour bordering on the white beard below and the white-ticked black cap above. In some highland populations (i.e. Bwindi Impenetrable N. P., SW Uganda and Nyungwe N. P., SW Rwanda) short white hairs cover infraorbital area flanking nose and snout, resulting in light grey to white patches below each eye. Brow with sizeable bony torus. Crown and cap black, individual hairs variably exhibiting narrow white bands. White-banded black hairs just above the brow may produce a narrow frontal band. White beard hairs long, thick, directed upwards and backwards but fail to fully cover the mainly bare ear. White of throat continues downwards, tapering to a narrow white patch over the breastbone.

Lateral, palatal and dorsal views of skull of L'Hoest's Monkey *Allochrocebus lhoesti* adult male.

Remainder of body underside is black to dark brown. Back of neck and shoulders with white-ticked black hairs. Body dorsum with a chestnut-coloured 'saddle' extending from between shoulder blades to hips and downwards to flanks. Saddle composed of dark brown hairs with three orange bands that produce green highlights. At saddle periphery, the orange bands whiten, resulting in grey along flanks and over dorsal root of tail. Limbs, and dorsum of hands and feet jet black. Tail, both above and below, covered with black and white hairs that produce a grizzled grey colour. Tail black over distal 25% of underside, proximal ca. 15% of dorsum and distal ca. 20% of dorsum. Tail tip with modest tuft. Female and ♂ genitalia and perianal region marked by tuft of white hairs. Scrotum skin turquoise blue (similar to *Chlorocebus* spp., *C. hamlyni* and *Lesula Cercopithecus lomamiensis*). Newborns have uniformly brown pelage. Adult colour pattern develops by the time the deciduous dentition is fully erupted. When moving, tail carried in a downwards curve that bends upwards then downwards near the tip. Young wrap the tail around supports and each other showing prehensile tendencies (Dandelot 1974).

Geographic variation Differences in facial markings and altitudes at which different populations occur might further separate *A. lhoesti* populations into subspecies (Lonnberg 1919).

Similar Species None within geographic range.

Distribution Endemic to Burundi, E DR Congo, W Rwanda and SW Uganda. Afromontane–Afroalpine, and Rainforest BZs. In moist forest between the right banks of the Congo and Lualaba Rivers, and the forest flanking the eastern border of the Western Rift Valley. Northern, eastern and southern limits roughly coincide with

Allochrocebus lhoesti

the break-up of the forest in this region. Western-most extent (at nearly 25°E) limited by left bank of the Lindi R., whose arching course forms the western half of the northern boundary for *A. lhoesti*. In the east, however, found north of the upper Lindi and Aruwimi Rivers, in the Nepoko, Epulu and Ituri River valleys, reaching as far north as 02° 30' N. Eastward, *A. lhoesti* crosses the Western Rift as far east as 30° 30' E. Southwards, in Burundi, found to 30° 18' E, well east of L. Tanganyika and the Ruzizi R. Southern boundary is south of the Elila R., reaching roughly 04° S in the vicinity of Lualaba town, DR Congo (Colyn 1988). Geographic range ca. 474,000 km² (accounting for hilly terrain).

Habitat *Allochrocebus lhoesti* inhabits savanna woodlands, and bamboo, montane, mid-altitude, riverine, lowland gallery and mono-dominant (*Gilbertiodendron*) forests (Rahm & Christiaensen 1963, Hill 1966, Butynski 1985, Hart *et al.* 1986). Commonly ranges into disturbed land, i.e. lava fields, landslides on steep slopes and cultivated land (Hoier 1955, Rahm & Christiaensen 1963, Kaplin 2001, E. E. Sarmiento pers. obs.). Inhabits a wide altitudinal range from ca. 400 m (in forests flanking the Tshopo R. near Kisangani, DR Congo), to ca. 2700 m in bamboo and montane forests in the Western Rift mountains (Rahm & Christiaensen 1963, Butynski 1984, 1985, Kaplin & Moermond 2000, J. Hart pers. comm., museum records). Found at all altitudes (1160–2600 m), including bamboo forest, in Bwindi Impenetrable N. P. and (formerly) near Kisenyi, W Rwanda. Apparently absent from all other bamboo forests within its geographic range.

In Nyungwe N. P. 18% of one group's annual home-range comprised landslide slopes (Kaplin 2001). Although no *A. lhoesti* have been recorded at altitudes above 2700 m, it is possible that those inhabiting the Rwenzori Mts and Virunga Mts, on occasion, reach the ericaceous vegetation zone at 3000 m. Throughout its range mean annual rainfall is above 1400 mm and may be in excess of 3000 mm on mountain slopes facing L. Kivu. Mean annual temperatures at the

lowest (ca. 400 m) and highest altitudes (2700 m) at which *A. lhoesti* is found are roughly 26 °C and 8 °C, respectively. Only rarely, at the highest altitudes (>2500 m), may temperatures fall below freezing. Over that part of the geographic range close to the Equator there are two dry seasons, each roughly two months in duration. One progressively shortens and the other lengthens with distance from the Equator to form a single dry season that is about three months long at the limit of *A. lhoesti*'s southern extent.

Abundance In all areas where *A. lhoesti* have been studied they are more abundant along roads, in disturbed areas, and at the edge of forests than in the (less disturbed) forest interior (Rahm & Christiaensen 1963, Butynski 1985, Kaplin 2001, Plumptre *et al.* 2002), and seem to tolerate a high level of human disturbance. Occur at low density over most of their geographic range (i.e. forests below 1200 m), with so few sightings that accurate density calculations are not possible (Hart *et al.* 1986, Hall *et al.* 2003). *Allochrocebus lhoesti* are much more common in the montane forests of the Western Rift. In Nyungwe N. P. they are most abundant in open canopy forest and burned habitats (2180–2690 m), have low abundance (three- to eight-fold less) in closed canopy forest at lower altitudes in the north-western sector (1500–2150 m), and are absent or have undetectably low abundance in bamboo forest and in higher altitude closed canopy forest (2260–2450 m; Plumptre *et al.* 2002). In contrast, *A. lhoesti* are most abundant in the bamboo zone at Bwindi Impenetrable N. P. (>2300 m). Here density over the 115 km² used is ca. 10 ind/ km² (Butynski 1984, 1985). At ca. 4 ind/km² at Ngogo, Kibale N. P., SW Uganda (Mitani *et al.* 2001), and ca. 0.4 ind/km² in Ituri, DR Congo (Thomas 1991).

Adaptations Diurnal and semi-terrestrial. The ability of *A. lhoesti* to exploit food both in trees and on the ground enables it to inhabit forests with two or more other species of (competing) guenons. The ability to exploit herbaceous vegetation and tolerance to a wide altitudinal range enables it to live in disturbed and rapidly changing environments (i.e. burned forests, volcanic slopes) within or adjacent to forests that are not available to other forest-living guenons. This ability may be further enhanced by a small ♀ : ♂ body-size ratio, which optimizes habitat-carrying capacity for producing the next generation, allowing for quick expansion into disturbed habitats. The colobine-like molars, with relatively high cusps and wide occlusal surfaces, are advantageous for processing foliage, including terrestrial herbs on which it heavily depends (Hill 1966, Kaplin 2002). The stark black and white coat may serve as warning colouration that is linked to the terrestrial life-style. Kingdon (1971) interpreted their relatively quiet vocal repertoire and tendency to climb repeatedly onto vantage points as adaptations to the risks involved in ground-dwelling.

Foraging and Food Omnivorous. Most of what is known of the diet and foraging behaviour of *A. lhoesti* comes from animals living at altitudes above 1500 m, while practically nothing is known from lower altitudes. Leaves, seeds, fruit, flowers (including fern sporangium), insects, pith, bark, lichen, mushrooms and tree gum are all part of a varied diet (Rahm & Christiaensen 1963, Kaplin 2001, Tashiro 2006, Tolo *et al.* 2007). They raid bean, maize, rice, papaya, oil palm *Elaeis guineensis*, cassava *Manihot* and banana

L'Hoest's Monkey *Allochrocebus lhoesti* adult male.

plantations (Rahm & Christiaensen 1963, Carpaneto & Germi 1989, E. E. Sarmiento pers. obs.). Vertebrate consumption not reported. Diet varies greatly from area to area. In Kalinzu F. R., SW Uganda, they spend as much as 66% of feeding time on insects (Tashiro 2006). By contrast, in Nyungwe N. P., only 9% of feeding time is spent on insects, with most feeding time spent on terrestrial herbs (35%), fruits (24%) and seeds (17%). A sizeable percentage of time feeding on fruits (26%) and seeds (23%) is spent in canopy trees and colonizing trees, respectively (Kaplin & Moermond 2000). Fruits and seeds are more often eaten in early morning and afternoon, and insects (mostly gathered from tree leaves) throughout the day (Kaplin 2001). Fruits and insects are more frequently eaten during the dry season (accounting for 42% and 24% of feeding time, respectively). Fruit and insect feeding is positively correlated and inversely related to time spent eating seeds (Kaplin & Moermond 2000). *Macaranga* *Macaranga capensis* and *Beilschmiedia* sp. are the major source of seeds and fruits, comprising 23% and 10% of feeding time, respectively (Kaplin & Moermond 2000). In Bwindi Impenetrable N. P., *A. lhoesti* commonly feed on bamboo *Sinarundinaria alpina* shoots (E. E. Sarmiento pers. obs.). To the west of L. Kivu, *A. lhoesti* eat fruits of *Aframomum* sp. and seeds of *Eugenia* sp. (Rahm & Christiaensen 1963). In Bwindi Impenetrable N. P. they eat the gum and pods of the Australian Black Wattle *Acacia mearnsii* (Kingdon 1971, T. Butynski pers. comm.).

In Nyungwe N. P., at 2100–2700 m, a group of 29 *A. lhoesti* had a mean monthly home-range of ca. 44 ha, and an annual home-range of ca 117 ha. This group travelled an annual mean daily distance of 2029 m, with Aug (a dry month) averaging the highest (2439 m) and

Apr (a wet month) the lowest (1626 m; Kaplin 2001). Travelled less per day when seeds were a major food and travelled most when fruit was a major food. Feeding and moving made up most of the daily activity. Although 62% of daily activity and 66% of feeding occurred in trees, 53% of travel occurred on the ground. This group spent as much time feeding on the ground (16% of diurnal activity) as in the canopy of the highest trees. When in disturbed habitats, they spent 90% of feeding time eating herbaceous vegetation. Nevertheless, 59% of herbs eaten came from undisturbed forest. They used trees next to feeding sites to sleep in at night, but spent >25% of their diurnal rest time and nearly 40% of their social time on the ground (Kaplin & Moermond 2000, Kaplin 2001).

Social and Reproductive Behaviour Social. Solitary animals commonly seen venturing into open habitats or sitting along dirt roads or paths (Rahm & Christiaensen 1963, E. E. Sarmiento pers. obs.). Groups usually comprised of one adult ♂, numerous adult ♀♀ and immature animals. Rarely, a group contains more than one adult ♂. Adult ♂ tends to stay peripheral to the group and take up the rear when the group moves or is alarmed (Kingdon 1971, E. E. Sarmiento pers. obs.). In Kibale N. P., mean group size was ca. 17 animals (S.D. 8.0, $n = 25$; T. Butynski pers. comm.). At Ngogo, Kibale N. P., mean group size was ca. 18 animals and density was 0.24 groups/km² (Mitani *et al.* 2001). Groups of 5–8 animals in forest to the west of L. Kivu (Rahm & Christiaensen 1963). In Ituri Forest only solitary animals or groups of three or less were encountered (Thomas 1991). Groups as large as 29 at Nyungwe N. P. are not uncommon (Kaplin 2001). As in most guenons, it is likely that ♀♀ stay with groups they are born into, but ♂♂ transfer to another group when sexually mature. The latter seems to be supported by presence of solitary ♂♂ in areas of high *A. lhoesti* density (E. E. Sarmiento pers. obs.).

Polyspecific associations during feeding with other mammals occur, but are not common. At Bwindi N. P., they feed with Doggett's Silver Monkey *Cercopithecus mitis doggetti*, Schmidt's Red-tailed Monkey *Cercopithecus ascanius schmidtii*, Western Guereza *Colobus guereza occidentalis*, Black-fronted Duiker *Cephalophus nigrifrons* and Crested Guinea fowl *Guttera pucherani* (E. E. Sarmiento & T. Butynski pers. obs.). In Nyungwe N. P., *A. lhoesti* feeds with *C. m. doggetti* (Kaplin 2001). In Maramagambo Forest, SW Uganda, a three-species group (*A. lhoesti*, *C. a. schmidtii* and *C. guereza*) seen feeding in a single tree (Kingdon 1971). In Kalinzu F. R. observed on cultivated land feeding with Olive Baboons *Papio anubis* and, when fruit was abundant, fed in trees with Stuhlmann's Blue Monkeys *Cercopithecus mitis stuhlmanni* and *C. a. schmidtii* (E. E. Sarmiento pers. obs.).

Vocal communication is not as varied as in other guenons; warning calls consist of a single 'chirp' and there is no contact call or a loud rallying call from adult ♂♂ (Gautier 1988, Gautier *et al.* 2002). Although scent-marking by *A. lhoesti* may occur, as it does in at least some other semi-terrestrial guenons (e.g. *C. hamlyni*, *C. neglectus*, *Chlorocebus* spp. and Allen's Swamp Monkey *Allenopithecus nigroviridis*; De Jong & Butynski 2010b), it has yet to be reported (Gautier *et al.* 2002).

Reproduction and Population Structure There is little information on *A. lhoesti* reproduction in the wild. There are no data on ovulatory cycle length or gestation length, but these, as in

L'Hoest's Monkey *Allochrocebus lhoesti* adult male in alert lateral posture.

most other guenons, are likely to last 30–32 days and 140–187 days, respectively (Hill 1966). When ready to copulate, ♀♀ present their backside to the ♂. Females do not show external signs of ovulation. During a period of 13 years of research in Kibale N. P., all 46 observations of clinging infants were during Oct–Apr with a peak in Dec–Feb (Butynski 1988). December–Feb is in the longer of the two dry seasons when fruit and invertebrates are relatively abundant. Infant specimens collected in different months show similar dental ages, indicating year-round births over its geographic range (E. E. Sarmiento pers. obs.).

Predators, Parasites and Diseases *Allochrocebus lhoesti* is not commonly hunted. Mbuti pygmies (Bataka) have taboos against eating the flesh, but use the skin for arrow quivers and ceremonial hats (Carpaneto & Germe 1989). In Uganda, Bakonjo and Bakiga use the skin for shoulder-bags (Haddow 1952, Kingdon 1971, E. E. Sarmiento pers. obs.). Due to their terrestrial nature, *A. lhoesti* are sometimes caught in snares set for antelopes and pigs. At Kahuzi-Biega N. P., Robust Chimpanzees *Pan troglodytes* prey on *A. lhoesti* (Basabose & Yamagiwa 1997). In Kibale N. P., an African Crowned Eagle *Stephanoaetus coronatus* observed on the carcass of a freshly killed adult ♂ *A. lhoesti* (T. Butynski pers. com.). Because *A. lhoesti* uses forest upper storey less frequently than most other guenons and their density in trees when feeding is low, they are relatively rare prey of *S. coronatus* (Mitani *et al.* 2001). Nevertheless, juvenile and infant reluctance to feed on fruit high in trees in Kalinzu F. R. is attributed to *S. coronatus* presence (Tolo *et al.* 2007). One study in Ituri Forest found that *A. lhoesti* accounted for 8% of the prey items in the diet of Leopards *Panthera pardus* (Hart *et al.* 1996). Natives report African Golden Cats *Profelis aurata* and pythons *Python* spp. as predators of *A. lhoesti* in NE DR Congo (Carpaneto & Germe 1989).

At the high altitudes of the Western Rift from which *A. lhoesti* is best known, there are few insect vectors for disease transmission, so that most of the diseases attacking other guenons at lower altitudes are not found in *A. lhoesti* (Haddow 1952). Nevertheless, *A. lhoesti* carries simian immunodeficiency virus (Hirsch *et al.* 1999, Beer *et al.* 2000). The stomach of an *A. lhoesti* from Kibale N. P. contained the nematode *Trichuris trichura* (Allen & Loveridge 1942) and faeces contained eggs of *T. trichura*, *Oesophagostomum* sp. and *Strongyloides fuelleborni* (Gillespie *et al.* 2004). Life-span not documented but may be in excess of 30 years for captives (Weigl 2005).

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Allochrocebus lhoesti thrives in markedly disturbed areas within or adjacent to forests, with most individuals living outside protected areas. Given its habitat preferences, *A. lhoesti* is not immediately threatened and may actually benefit from human disturbance to habitats. The relatively small geographic range (ca. 474,000 km², accounting for hilly terrain), when compared to that of baboons *Papio* spp. and savanna monkeys, and its apparent inability to exploit extensively human-altered areas as effectively as these monkeys poses a threat to its survival.

Among sites important for the long-term conservation of *A. lhoesti* are Kibale N. P., Bwindi-Impenetrable N. P., Kalinzu F. R., Kasyoha-Kitomi F. R., and Maramagambo F. R. in Uganda, Nyungwe N. P. in Rwanda, Kabira N. P. in Burundi, and Kahuzi-Biega N. P., Itombwe Mts, Maiko N. P. and Okapi Faunal Reserve in DR Congo. Much more research is needed on the ecology and behaviour of this poorly known species, particular in mid-altitude and lowland forest.

Measurements

Allochrocebus lhoesti

HB (♂♂): 553 ± 29.28 (510–585) mm, n = 5

HB (♀♀): 487 ± 50.99 (425–600) mm, n = 8

T (♂♂): 715 ± 24.23 (695–755) mm, n = 5

T (♀♀): 568 ± 68.24 (480–670) mm, n = 8

HF (♂♂): 161 ± 23.42 (134–189) mm, n = 5

HF (♀♀): 136 ± 11.78 (120–160) mm, n = 8

E (♂): 42 mm, n = 1

E (♀): 30 mm, n = 1

WT (♂♂): 6.1 ± 1.37 (3.2–8.5) kg, n = 20

WT (♀♀): 3.5 ± 0.76 (1.6–5.2) kg, n = 51

Allochrocebus solatus SUN-TAILED MONKEY

Fr. Cercopithèque à queue de soleil; Ger. Sonnenschwanzmeerkatze

Allochrocebus solatus (Harrison, 1988). J. Zool. Lond. 215: 562. Forêt des Abeilles, Bali R., 00° 14' S, 12° 15' E, SE of Booué, C Gabon.

Sun-tailed Monkey *Allochrocebus solatus* adult male.

Taxonomy Monotypic species. *Allochrocebus solatus* belongs to the *Allochrocebus (preussi)* Group. Molecular evidence suggests that *A. solatus* is the oldest member of the *A. (preussi)* Group, from which

A. preussi and *A. lhoesti* split ca. 0.5 mya (Tosi 2008). In common with many other scientists (e.g. Groves 2001, 2005c, Grubb *et al.* 2003), the authors of this profile have reservations about the genus *Allochrocebus*, preferring to retain *solatus* in *Cercopithecus*. The Editors' reasons for instituting this significant taxonomic change are given in the generic profile. *Allochrocebus solatus* has the same chromosome number as *A. preussi* and *A. lhoesti*, but differs in the banding of chromosomes 11 and 17. This helps to validate their full species status (Dutrillaux, *et al.* 1988a, b). Synonyms: none. Chromosome number: 2n = 60.

Description Medium-sized, semi-terrestrial monkey with pale grey cheeks and throat, chestnut-orange back, and yellowish-orange tail tip. Adult ♀ similar adult ♂ but smaller (weighing ca. 60% as much as the adult ♂), colouring less bright, and pelage pattern exhibiting less contrast (Harrison 1988a). Muzzle, periorbital skin, ears and forehead black. In adult ♂, cheeks with speckled pale grey hairs that begin below the periorbital skin at mid-eye and reach the upper chest to form a pale grey throat-ruff. The pale grey throat-ruff poorly developed in adult ♀. Dorsum and flanks speckled chestnut-orange. Chest and belly greyish-black. Legs and feet black. Proximal ca. 20% of tail speckled blackish-grey becoming progressively lighter grey up to about two-thirds the length of tail. Distal about 45% of tail yellowish-orange. Scrotum bright blue. Pelage colouring and contrasts less developed in young. Neonate yellowish-brown, i.e. very different from adults (Gautier *et al.* 2002).

Geographic Variation None recorded.

Allochrocebus solatus

Similar Species None.

Distribution Endemic to forests of C Gabon. Rainforest BZ. Total geographic range is 11,000–12,000 km² encompassing Forêt des Abeilles. West of the Offoué R., within Lopé N. P., but not to the west of 11° 30' E. Known northern and eastern limits are the Ogooué R., 00° 03' S and 12° 33' E, respectively. Southern limit unclear, apparently to foothills of the Massif du Chaillu. Confirmed at 01° 24' S, but probably present as far south as 01° 35' S. Reports to the north of the Ogooué R. (in particular the Mokékou Mts, ca. 00° 10' N, 11° 40' E) and close to the border with Congo unconfirmed (Harrison 1988a, Gautier *et al.* 1992, White & Mackanga 1995, Brugière *et al.* 1998, Coad *et al.* 2010, Motsch *et al.* 2011).

Habitat Evergreen primary and secondary rainforests (Harrison 1988a, Gautier *et al.* 1992). Altitudinal range from 140 m (along Ogooué R.) to 980 m (Iboundji Mts). Seems to prefer mid-altitudinal zones (400 m) and densely overgrown gullies along the banks of water-courses (Gautier *et al.* 1992, Brugière *et al.* 1998). Lives in degraded vegetation close to villages (occasionally raiding crops) and in heavily-logged forests. Here the dense undergrowth provides relatively abundant food and protection against predators (Gautier *et al.* 1992). Mean annual rainfall from 1500 mm (north Lopé) to 2400 mm (Massif du Chaillu).

Abundance Suspected to be abundant throughout its range (according to opportunistic observations and hunter reports) except in the mountainous parts in the south and west (Gautier *et al.* 1992). Density estimates available for the Makandé Field Research Station (MFRS; 00° 40' S, 11° 54' E), Forêt des Abeilles, and in southern part of Lopé N. P. At Makandé *A. solatus* had the highest density (25 ind/km²) and highest biomass (73 kg/km²) among the seven species that made up the Cercopithecidae community (Brugière *et al.* 2002).

Lateral view of skull of Sun-tailed Monkey *Allochrocebus solatus* adult male.

In southern Lopé N. P., near the south-western limit for *A. solatus*, density is only ca. 10% that at Makandé (Brugière 2005).

Adaptations Diurnal and semi-terrestrial. Because of its semi-terrestrial habits, *A. solatus* has a specific anti-predator strategy based on crypticity (Gautier 1998). In contrast to arboreal species, few sounds are exchanged during foraging: cohesion calls possess weak intensity and are atonal in structure. Because the group can be totally silent while on the move, individuals risk losing contact with one another and isolation (lost) calls are more frequent than in arboreal species, being given even by adults. No loud-calls for spacing and rallying are produced. The most frequent calls are given under conditions that imply a warning function: loud 'barks' by adult ♂♂ and high-pitched 'chirps' by adult ♀♀ and immatures, followed by silent flight on the ground. In contrast with arboreal species, *A. solatus* was in polyspecific associations in only 14% of 224 encounters; 6% were proximity associations, while 8% were true mixed group associations. Mixed groups appeared only under conditions where no danger could be anticipated, presumably because large groups increase the risk of detection by predators. As for most semi-terrestrial primates, there is considerable size dimorphism between adult ♂♂ and adult ♀♀. This is attributed to the defensive role that ♂♂ play in an environment where predators are more numerous and less visible than in the trees. At the Centre International de Recherche Médicale de Franceville (CIRMF), Franceville, Gabon, the daily activity pattern of one semi-free-ranging group of 13 individuals in a 0.5 ha enclosure has two peaks: one soon after dawn and the other from mid-afternoon until nightfall, when the group retires to sleep in trees; there is a period of low activity and rest during the middle of the day (Peignot *et al.* 1999).

Foraging and Food Omnivorous. During daylight hours, *A. solatus* at CIRMF spent 86% of time on the ground and 89% below 2 m (Peignot *et al.* 1999). Food is mainly found on the ground and in the undergrowth. Foraging begins early in the morning (as soon as the group climbs down from the sleeping trees), there is a slight decrease in foraging activity at mid-day, and increases again during the afternoon. Mean daily travel distance at Makandé (two radio-collared groups) was 1–2 km (n = 139 days). Home-ranges 150–300 ha (n = 2 groups). At dusk the group climbs into trees at a new sleeping site. Composition of the annual diet of *A. solatus* at CIRMF was invertebrates 27.5%, grasses 27.5%, fruits 19.5%, mushrooms 6.7%, flowers 5.8%, seeds 5.8%, pith 4.2%, leaves 3.3% (Peignot *et al.* 1999). As with *A. lhoesti*, *A. solatus* exhibits predatory behaviours.

A young individual (initially hand-raised and then living free at MFRS until 28 months old) regularly ate invertebrates, birds' eggs and small birds. He displayed hunting behaviours (on the ground as well as in the trees), stalking reptiles, small galagos, larger birds (Guinea fowls, touracos) and even a Blue Duiker *Philantomba monticola* (Fleury & Gautier 1998).

Social and Reproductive Behaviour Social. Of 247 encounters with *A. solatus* at MFRS, 21% were with solitary individuals, of which 17% were adult ♂♂ and 4% were not sexed. Mean group size was 18 individuals (9–25, $n = 5$). Two exceptional counts of 40 and 46 individuals in a single group suggest possible fusion of two or more social groups. Sex ratio is close to one adult ♂ per five adult ♀♀. A group of 16 individuals comprised 1 adult ♂, 5 adult ♀♀ and their offspring, 1 subadult, 2 juveniles and 2 infants. Overlap of home-ranges of two radio-tagged groups was 15%. At CIRMF, one-male organization observed with prolonged ♂ tenure and expulsion of maturing ♂♂ to the periphery of the enclosure. Only dominant ♀♀ gave birth (17 births over 11 years). As only one ♂ sired offspring during his period of tenure, a decrease of fitness among the animals in this colony was observed (Charpentier *et al.* 2005a, Charpentier *et al.* 2008). Territorial behaviour is not supported by stereotyped vocal displays (as in sympatric arboreal monkey species) but territorial conflicts do occur, with aggressive interactions (including chases) between adult ♂♂.

Reproduction and Population Structure Length of gestation and age at weaning are not known. At CIRMF the birth season coincided with the two annual wet seasons (8 births out of 11; four in Oct–Dec and four in Mar–May). Mean interval between births was 18 months (Peignot *et al.* 1999, 2002). Mean birth-weight is 380 g ($n = 4$). One young born at a time (twins not reported). Captive ♂♂ sexually mature at 5–7 years. Captive ♀♀ sexually mature at about four years.

Predators, Parasites and Diseases Leopards *Panthera pardus*, African Golden Cats *Profelis aurata* and African Crowned Eagles *Stephanoaetus coronatus* are presumed predators. At Makande a subadult ♂ found dead with two small holes on the neck revealing the bite of an unidentified snake. Vigorous vertical jumps, displayed by captive and semi-captive *A. solatus* facing live snakes or snake models, suggests that this is one way to escape from snakes. A young ♂ caught in the wild was infected under the skin with three larvae of the fly *Cordylobia anthropophaga*. A new and specific simian immunodeficiency virus (SIVsun) identified from a wild-born 12-year-old captive ♂ (Beer *et al.* 1999, Liégeois *et al.* 2011). This monkey appeared healthy.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Until the 1990s the entire geographic range of *A. solatus* was virtually uninhabited by people, but within the last 20 years virtually all of the forests within the range have been logged (except forests in the southern part of Lopé N. P.). *Allochrocebus solatus* does well in logged forest, as the resultant dense undergrowth provides relatively abundant food. Where logging has occurred, however, there is a dense network of roads. As a result, commercial bushmeat hunting has increased dramatically in the Forêt des Abeilles. This will be the main threat for *A. solatus* for years to come. Hunters report that *A. solatus* is difficult to hunt as a result of its cryptic behaviour, but non-selective ground snares (usually set for duikers *Cephalophus* spp. and *P. monticola*) represent a particularly acute threat for this semi-terrestrial species.

About 10–20% of the geographic range of *A. solatus* lies within the southern part of the Lopé N. P. (4910 km²) but this includes those parts of the species' geographic range where density is at its lowest. Proposed conservation actions include the control of commercial hunting, the creation of a protected area in the Forêt des Abeilles (i.e. a part of their geographic range that exhibits high density), and minimization of human settlement in the Forêt des Abeilles (Gautier 1989b, Brugière & Gautier 1999). The CIRMF Colony of breeding *A. solatus* was founded in 1986 with four individuals; by 2012 this colony numbered 15 individuals (P. Motsch pers. comm.). Reintroduction into the wild of a young ♂ taken from hunters was successfully carried out at MFRS (Fleury & Gautier 1998).

Measurements

Allochrocebus solatus

HB (♂♂): 530 (460–580) mm, $n = 7$

HB (♀♀): 480 (450–540) mm, $n = 8$

T (♂♂): 680 (590–760) mm, $n = 7$

T (♀♀): 600 (560–680) mm, $n = 9$

HF (♂♂): 160 (150–160) mm, $n = 6$

HF (♀♀): 140 (130–140) mm, $n = 6$

E (♂♂): 46 (40–50) mm, $n = 4$

E (♀♀): 45 (40–50) mm, $n = 5$

WT (♂♂): 6.9 (5.8–8.7) kg, $n = 6$

WT (♀♀): 4.0 (3.7–4.3) kg, $n = 7$

Cercopithecus, as presented here, consists of 20 species of long-tailed, arboreal monkeys commonly referred to as the 'arboreal guenons'. Compared to most other Cercopithecidae they are slender and medium-sized. They have short faces and the skull is particularly short-muzzled in both sexes of the smaller arboreal species but more prominent in the adult ♂ of the Diana Monkeys Group *C. (diana)*, De Brazza's Monkey *C. neglectus*, Owl-faced Monkeys Group *C. (hamlyni)* and Nictitans Monkeys Group *C. (nictitans)*. Ischial callosities consist of two prominent pads that are separate and attached to the posterior extremities of the pelvis. Females lack the catamenial swellings typical of Papionini. They have agouti coats, often with bright colour contrasts on the face and/or limbs. Dentally, M_3 lacks a hypoconulid and M_2 and M_3 have no mesostylids. Molars without the flares that typify papionins and Allen's Swamp Monkey *Allenopithecus nigroviridis*. For detailed morphological diagnosis see Hill (1966).

In the present volume the genus *Cercopithecus* is more restricted than in any previous work. The rationale for this taxonomic contraction derives, in large part, from molecular work that has been unambiguous in separating the 'terrestrial' guenon lineages from the 'arboreal' ones (Dutrillaux *et al.* 1978, 1980, 1988a, b, Purvis 1995, Tosi *et al.* 2005, Tosi 2008, Perelman *et al.* 2011). Some recent molecular studies have gone still farther, suggesting that the talapoin *Miopithecus* lineage, a genus formerly associated with *Allenopithecus*, evolved after the 'terrestrial' Cercopithecini and clusters with *Cercopithecus* (Xing *et al.* 2007, Perelman *et al.* 2011). This finding serves to isolate the arboreal guenons still farther from their former congeners. Moulin *et al.* (2008), however, question this view, instead associating *Miopithecus* with *Erythrocebus* and allies.

Consistent with these studies, Groves (2000a) recognized that the savanna monkeys, formerly the *Cercopithecus (aethiops)* Group, should be treated as a distinct genus *Chlorocebus*, as should their sister-groups, the open-country Patas Monkey *Erythrocebus patas*, and now, given their known genetic affinity, the forest-dwelling Mountain Monkeys Group *Allochocebus (preussi)* (formerly the *Cercopithecus (preussi)* Group). All were previously lumped under *Cercopithecus*.

In this newly restricted sense, *Cercopithecus* embraces 20 species belonging to seven 'Groups' (sometimes also referred to as 'species-groups' or 'superspecies'), namely: the Dryad Monkey Group *Cercopithecus dryas* (1 sp.); Diana Monkeys Group *C. (diana)* (2 spp.); De Brazza's Monkey Group *C. neglectus* (1 sp.); Mona Monkeys Group *C. (mona)* (6 spp.); Owl-faced Monkeys Group *C. (hamlyni)* (2 spp.); Nictitans Monkeys Group *C. (nictitans)* (2 spp.); Cephus Monkeys Group *C. (cephus)* (6 spp.). These are, for the most part, medium-sized, long-tailed, arboreal forest monkeys. They include some of the

most colourful of all primates and their highly geometric signals are correlated with increased specialization in the visual communication channel of the species or group concerned (Kingdon 1980, 1988b, 2007; and illustration on p. 304).

The radiation of *Cercopithecus* has exercised many scientists, including Schwarz (1928b), Verheyen (1962), Hill (1966), Thorington & Groves (1970), Kingdon (1971, 1990, 1997), Dutrillaux *et al.* (1978, 1980, 1982, 1988b), Muleris *et al.* (1986), Ruvolo (1988), Groves (1989, 1993, 2000b, 2001, 2005c), Purvis (1995), Disotell & Raam (2002, 2005), Tosi *et al.* (2002, 2005), Grubb *et al.* (2003), Xing *et al.* (2007), Moulin *et al.* (2008), Tosi (2008) and Oates (2011). Schwarz's (1928b) assumption that the most arboreal species were the most conservative was generally accepted for more than 40 years, but Kingdon (1971, 1980) presented arguments that the smallest, most arboreal species were actually the most highly evolved and derived. The latter view has since been confirmed by molecular scientists (Dutrillaux *et al.* 1978, 1980, 1988b, Purvis 1995, Xing *et al.* 2007), but the assumption that the Cercopithecini had 'arboreal' origins is still made (Tosi *et al.* 2004). In fact, as discussed under Cercopithecinae, the ancestral condition for all Cercopithecini was probably semi-terrestrial, with the smaller-bodied types having a general tendency to be more arboreal.

Chromosome numbers range from 58 to 72 (Dutrillaux *et al.* 1988b, Romagno 2001).

Understanding the detailed relationships among species has been complicated by some genetic features unique to *Cercopithecus*. It would seem that the ancestral *Cercopithecus* had many polymorphic genetic elements and these remained during and after speciation; such elements seem to have become randomly fixed in some lineages or lost in others (Xing *et al.* 2007). Furthermore, hybridization in the wild occurs between species (Detwiler *et al.* 2005) and even between genera (De Jong & Butynski 2010b), further complicating the genetic heritage of species. This means that some taxa that are easily identified on external appearances may have hidden hybrid ancestry in some, many, possibly all members of a given population. That this can make for startling inconsistencies between external appearances and molecular profiles is demonstrated by Moulin *et al.* (2008) associating *C. hamlyni* with *C. (mona) pogonias*!

Molecular clocks suggest that ancestors of the seven major lineages all evolved during the late Miocene and Pliocene (6.2–2.2 mya; Tosi *et al.* 2005, Perelman *et al.* 2011). This rapid speciation into distinct ecological and dietary niches can be partly explained by the extreme climatic fluctuations that took place over this time. Periods of intense aridity would have fragmented populations along a latitudinal axis, isolating those in the far west ('Upper Guinea') from those in central West Africa (the 'Cameroon/Gaboon Centre of Endemism') and those in east-central Africa ('Central Refuge' or 'Haute Zaire'), and each of these regional forest refugia have been further subdivided. Furthermore, the Congo R. is one of the major biogeographic dividing lines in Africa, with populations readily differentiating north and south of the river.

OPPOSITE AND ABOVE: Two dimensional schematic charts of adult males of eight guenon species.

These charts 'map' the colour and pattern on the inner surface and the outer surface of the limbs, and of the head-on facial plate. Note the concentration of signals at the genital pole in the more terrestrial species (Owl-faced Monkey *Cercopithecus hamlyni* and Tantalus Monkey *Chlorocebus tantalus*), and at the facial pole in the more arboreal species (Moustached Monkey *Cercopithecus cephus* and Crowned Monkey *Cercopithecus pogonias*).

From top to bottom, left to right:

Putty-nosed Monkey *Cercopithecus nictitans*. Moustached Monkey *Cercopithecus cephus*.

Lowe's Monkey *Cercopithecus lowei*. Crowned Monkey *Cercopithecus pogonias*. De Brazza's Monkey *Cercopithecus neglectus*. Diana Monkey *Cercopithecus diana*.

Owl-faced Monkey *Cercopithecus hamlyni*. Tantalus Monkey *Chlorocebus tantalus*.

Taking the present distribution of species as a guide, Kingdon (1990) outlined a possible geographic scenario for the early emergence of four major *Cercopithecus* lineages during periods of forest fragmentation. In their studies of chromosomes, Dutrillaux *et al.* (1980, 1982, 1988b) were the first to reveal that the genus *Cercopithecus* (as used in this work) represents the more arboreal side of a primary bifurcation of the Cercopithecini. Dutrillaux's team was unable to secure material from the extremely localized and little-known *C. dryas* but this species can be tentatively extrapolated as a specialized relict close to the stem of this fecund radiation. The suggestion, based on genetic evidence, that *Miopithecus* might be closer to *Cercopithecus* than to *Allenopithecus* (Xing *et al.* 2007, Perelman *et al.* 2011), adds a new possibility to the little-known beginnings of arboreal guenon evolution: body-size. *Miopithecus*, at about 1.2 kg, is very small, while *C. dryas*, estimated at ca. 2.5 kg, is larger but is still a relatively small monkey. In coat pattern *C. dryas* has a close resemblance to 3–6 kg *C. (diana)*. According to Dutrillaux's team, *C. (diana)* (which were once locally successful, mainly canopy inhabitants of mature West African high forest) derive from a basal lineage of *Cercopithecus (sensu novo)*. Most molecular, morphological and behavioural studies agree that the other species subdivide into two distinct clusters, with *C. (mona) / C. neglectus* closest to *C. (diana)* and *C. (nictitans) / C. (cephus)* somewhat farther removed. *Cercopithecus hamlyni* occupies a rather ambiguous position in between the two, showing affinity with *C. neglectus*, *C. (nictitans)* and *C. (mona)* (see figure p. 245). While it has long been clear that the *mona/neglectus* complex antecedes the *nictitans/cephus* radiations,

a basal position for *C. (mona) campbelli* has been proposed by Moulin *et al.* (2008). This important conclusion is discussed further in the *C. (mona)* profile. Likewise, the *nictitans/cephus* radiation poses special taxonomic problems because (*cephus*) appears to nest within the putatively older (*nictitans*) group. It is therefore possible that *C. (nictitans)*, as described in this work, might eventually merit further subdivision.

A temporal framework for the *Cercopithecus* radiation was first offered by Purvis (1995) on the basis of molecular clock computations. This suggested that divergence of *Cercopithecus* from the other, less arboreal, cercopithecine genera took place just before or during the end of the Miocene Messinian, a period when tropical lowland forests would have been of minimal extent and scattered along an equatorial axis. A more recent estimate (Tosi *et al.* 2005; and figure p. 245), implies an earlier divergence between terrestrial and arboreal cercopithecines but agrees with Purvis in dating the main radiation of *Cercopithecus* between about 4.6 and 3 mya (early to mid-Pliocene). Perelman *et al.* (2011) place the start of the *Cercopithecus* radiation at 7–6 mya (late Miocene).

Central and West African equatorial forests have been the geographical focus for this radiation, and, if *C. dryas* represents the oldest form, it seems significant that it should occupy the centre of *Cercopithecus* range, a small area east of a former Pliocene lake, L. Congo (Beadle 1974). This understory, riverside species is now adapted to a uniquely local niche, and it seems likely that the survival of its lineage through the climatic vicissitudes of the later Pliocene and Pliocene was facilitated by the unusual ecological continuity of plant communities growing close to ground-water swamps and riverine forests in the central Congo Basin. The much larger and less specialized *C. neglectus* occupies a comparable habitat but over an extensive but patchy range, from the Atlantic to Ethiopia and Kenya (but this species evolved substantially later).

One influence that makes reconstructing the *Cercopithecus* radiation difficult is the relatively short period during which the founders of today's main lineages are thought to have diverged. Five lineages, *diana*, *neglectus*, *mona*, *hamlyni* and *nictitans/cephus*, all emerged from a common ancestral stock between 4.2 and 3.2 mya (mid-Pliocene). What is especially interesting is the timing of the emergence of the two most speciose lineages, *C. (mona)* and *C. (cephus)*. According to Tosi *et al.* (2005), ancestral *C. (mona)* diverged from *C. (diana)* and *C. neglectus* between 4.1 and 3.9 mya whereas the divergence of *C. (cephus)* from *C. (nictitans)* was about 1.3 million years later; when forests were particularly fragmented. Yet the fact that the location of tropical Africa's forest refuges corresponds well with the distribution of *C. (mona)* and *C. (cephus)* populations implies that their periodic fragmentation tended to follow the same general pattern over several, probably many, climatic fluctuations. Although fragmentary fossils have been allocated to *Cercopithecus*, none provides any guide to the evolution of modern species. None the less, their restriction to the African Plio-Pleistocene confirms their late and exclusively African provenance.

The species can generally be easily distinguished on the basis of body size and pelage patterns. Detailed diagnoses are presented in the species profiles.

Jonathan Kingdon & Colin P. Groves

Cercopithecus dryas DRYAD MONKEY (SALONGO MONKEY)

Fr. Cercopithèque Dryade; Ger. Dryadmeerkatze

Cercopithecus dryas Schwarz, 1932. Rev. Zool. Bot. Afr. 21: 251. Ikela Zone, Yapatsi, DR Congo.Dryad Monkey *Cercopithecus dryas* adult male.

Taxonomy Monotypic species. *Cercopithecus dryas* first described from a juvenile ♂ specimen thought to have been collected at Lomela (02° 20' S, 23° 12' E), but the type locality now in serious doubt (Schouteden 1946, Thys van den Audenaerde 1977, Colyn 1988, Sarmiento 2000). About 45 years after *C. dryas* was described, Thys van den Audenaerde (1977) described the Salongo Monkey *Cercopithecus salongo* from the incomplete skin of an adult specimen obtained in 1977 by T. Kano in Wamba Forest, near Wamba Village, Zone de Djolu, DR Congo (Kuroda *et al.* 1985, Sarmiento 2000, Groves 2001). The coordinates for the type locality of *C. salongo* are given as 00° 01' N–00° 01' S, 22° 31–33' E. In 1977 and 1978 the intact skins of a ♂ and ♀ were obtained near Wamba. These are described in detail in Kuroda *et al.* (1985). Wamba Village is ca. 255 km north-north-east of Lomela. Colyn *et al.* (1991) concluded that Thys van den Audenaerde had not described a new species of monkey, but rather the adult form of *C. dryas*. This conclusion has been generally accepted (Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003). Sarmiento (2000), however, questions the synonymy of *C. dryas* and *C. salongo*, arguing that they should be treated as separate species pending more data. S. Kuroda (pers. comm.) also questions the synonymy of *C. dryas* and *C. salongo*, pointing out that G. Idani photographed a juvenile Salongo Monkey with the same colour pattern as the adult, including the black-tipped tail – not the colour pattern of the juvenile described by Schwarz (1932) (see below).

Resolution of whether *C. dryas* and *C. salongo* represent one species or two species/subspecies is of high priority for those concerned with the taxonomy and conservation of Africa's primates.

Schwarz (1932), Napier (1981) and Lernoould (1988) consider *C. dryas* to be a central African representative of the Diana Monkeys Group *Cercopithecus (diana)* of West Africa. Similarly, Thys van den Audenaerde (1977) judged *C. salongo* to also be most similar to *C. (diana)*. Kingdon (1997) suggests that *C. dryas* might be a relict species sharing ancient affinities with *C. (diana)* and De Brazza's Monkey *Cercopithecus neglectus* in spite of differing from both in its small size. Kuroda *et al.* (1985) and Hurley & Lokasola (2007), however, found the ecology and behaviour of *C. dryas* to differ considerably from that of *C. (diana)* (see below). The dramatic juvenile to adult pelage colour change pattern (assuming *C. salongo* is a synonym of *C. dryas*), as well as the small upper lateral incisors, both suggest affinity with *C. neglectus* (Groves 1989, 2001). The triangular shape of the face, pattern of colour on the face and at base of the tail, and light blue scrotum, all recall the savanna monkeys *Chlorocebus* spp. (T. Butynski pers. obs.).

Hill (1966) placed *dryas* as a subspecies of Diana Monkey *Cercopithecus diana diana*. Thorington & Groves (1970), however, retained *dryas* as a separate species. Groves (quoted in Thys van den Audenaerde 1977: 1007) initially considered *C. dryas* to be most closely related to the Grivet *Chlorocebus aethiops*, but on the evidence of a photograph of an adult skull in Kuroda *et al.* (1985), stated the following (Groves 1989: 139):

'The figure of the skull makes it clear that it is indeed a *Cercopithecus*, not a *Chlorocebus*, with its oval orbits, nasals apparently not pointed, and so on; and nasals seem short and somewhat triangular, which would ally it to *C. cephus*, but its exceptionally small I² would place it near *C. neglectus*. On the other hand the interorbital pillar is not constricted unlike in *C. neglectus*; the premaxilla seems to be narrow, unlike in the *C. (mitis)*, (*preussi*), and (*hamlyni*) Groups; and the internasal suture is closed in the figured skull. The species is small in size, perhaps the smallest of the genus, and with very little sexual dimorphism.'

Of the skull of the holotype of *C. dryas*, a juvenile that he examined directly, Groves (1989: 140) wrote:

'The inferior mandibular border is not curved in the *C. diana* fashion ... There are a few features recalling *Chlorocebus*, such as the less-oval shape of the orbits than *Cercopithecus*, but at its immature age it is difficult to tell whether this is a true resemblance or only apparent. It does not have the V-shaped auditory tube, unlike *Chlorocebus*.'

Most recently, Groves (2000a: 96) wrote:

'It [*C. dryas*] is a thoroughly distinct species, not part of any of the well-known species-groups of the genus [*Cercopithecus*]. It appears to lack the character states of the *Chlorocebus/Erythrocebus* group, and to

Dryad Monkey *Cercopithecus dryas*.

possess those of true *Cercopithecus*: orbit not oval, upper incisors do not form a single unified bite surface, nasals not pointed at tips, small supraorbital torus.'

While there is no doubt that *C. dryas* is a member of *Cercopithecus*, it appears to be a very divergent species, possibly the sister to all other *Cercopithecus* spp. (Groves 2000a). Grubb (2006) points out that 'Dryad' is the accepted spelling for the vernacular of this species. Synonyms: *salongo*. Chromosome number: $2n$ = not known.

Description Small forest monkey with black face and jet black all around lower limbs, white around face, and white on chest and ventrum. Smallest *Cercopithecus* spp. Detailed descriptions provided by Thys van den Audenaerde (1977) and Koruda *et al.* (1985). Adult ♂ like adult ♀ but slightly larger with short, projecting, beard on chin. Face black, triangular. Temples with elongated, whitish horizontal tufts. Brow-band white. Cheeks, temples, sides of head, chin, beard, throat, front of shoulders, insides of upper arms and legs, ventrum, back of the thighs, and buttocks white or creamy-white. White of temples separated from brow-band by a posteriorly directed bare black line. Crown, back, sides, front of thighs and upper arms greyish-brown or dark olive-grey speckled with chestnut. The hairs here are grey over the basal half with the distal half alternating black and orange-brown rings. This mixing creates a general greyish-chestnut colour, which is much darker on crown than elsewhere. Lower limbs, including hands and feet, jet black all around. Tail of medium length, dirty white, with large black spot (i.e. inverted V) below at base and narrow grey line along

Cercopithecus dryas

upper surface. Distal ca. 10 cm of tail black with relatively long hairs. Scrotum light blue. White parts of the body sharply demarcated and strongly contrasting with black parts of the body, especially the white around the face, and on the chest and buttocks. See photos in Koruda *et al.* (1985: 327). In juvenile: brow-band, area around face, throat and ear tufts white; crown and dorsum greenish-gold with yellow ticking and rufous highlights; limbs duller than back, whitish medially (no black); dorsum of hands and feet dirty grey; ventrum mouse-grey; tail black at the base and rufous-green distally (Schwarz 1932, Napier 1981, Kuroda *et al.* 1985, Kingdon 1997, Groves 2001).

Geographic Variation None recorded.

Similar Species None within geographic range.

Distribution Endemic to one or a few small areas in DR Congo. Rainforest BZ. Distribution poorly-known. Although the provenance of the type *C. dryas* is given as Lomela (02° 20' S, 23° 12' E), it may be Yapatsi (01° 33' S, 23° 13' E) – or somewhere else (Thys van den Audenaerde 1977, Colyn 1988, Sarmiento 2000). Primate surveys in the Lomela area have failed to locate *C. dryas* (Hurley & Lokasola 2007). Only known from Kokolopori Forest, between right (north) bank of Maringa-Luo R. and left (south-west) bank of the Lopor R., Wamba region (Hurley & Lokasola 2007). There are, however, unconfirmed reports of *C. dryas* on the left bank of the Maringa-Luo R. (S. Koruda pers. comm.). Primate surveys have recently been conducted over a large region around Wamba, including the left bank of the Maringa-Luo R. and the right bank of the Lopor R. and *C. dryas* has not been encountered. While more intensive surveys may yield new populations of *C. dryas*, it now appears that *C. dryas* is a species with a very limited, fragmented, geographic range. Thus far, four, apparently isolated, populations of *C. dryas* have been located in the eastern part of Kokolopori Forest. Together, these four populations

Lateral, dorsal, frontal and palatal views of skull of Dryad Monkey *Cercopithecus dryas* adult male.

cover an area of ca. 500 km². The extent of occurrence is estimated at 3000 km² (Hurley & Lokasola 2007).

Habitat Main habitat is undergrowth (thicket) in secondary lowland moist forest, but also in swamp forest and old plantation (Kuroda *et al.* 1985). Primary forest is not used; indeed, primary forest may serve as a barrier among populations of *C. dryas* (Hurley & Lokasola 2007). J. Hart (pers. comm.) suggests that *C. dryas* is limited to small pockets of relatively high productivity in an otherwise oligotrophic region. The result is a localized and patchy distribution, not only for *C. dryas*, but also for humans, Gracile Chimpanzees (Bonobos) *Pan paniscus*, Tshuapa Red Colobus *Procolobus rufomitratus tholloni*, and probably numerous other species. Altitude ca. 380 m asl. Mean annual rainfall ca. 1900 mm.

Abundance Poorly known. Population density low in the Wamba region, but not considered rare (Kuroda *et al.* 1985). Recent surveys lead Hurley & Lokasola (2007) to suggest that the world population for *C. dryas* may be <200 individuals. Although S. Kuroda (pers. comm.) agrees that *C. dryas* is rare, he believes that the number remaining is >200 individuals. In 2006 he conducted one survey

along 1.5 km of transect through abandoned plantation to the south-west of Wamba. During this survey he encountered six groups of *C. dryas*. Although the visibility along the transect was poor, the number of individuals observed in these groups ranged from two to ten.

Adaptations Diurnal and arboreal. Highly secretive and cryptic in dense vegetation, usually close to the ground. Sometimes forages on the ground. When on the ground and threatened or surprised, moves quickly upward into dense undergrowth/thicket. Not observed in the middle canopy or upper canopy (S. Kuroda pers. comm.). Relatively large temporal muscles and large jaws. Dentition unusual in that the upper incisors are splayed, narrow and small (Kuroda *et al.* 1985, Kingdon 1997). Although the adaptive significance of these characters is not known, S. Kuroda (pers. comm.) suggests that the large jaw may be an adaptation for chewing foods that are more fibrous than are typically eaten by other *Cercopithecus* spp., especially food items from plant species in the families Zingiberaceae and Marantaceae.

Foraging and Food Omnivorous. Forages mostly in the lower stratum of secondary forest but also frequently on the ground. Diet poorly-known. Feeds on fruits supplemented with young leaves and shoots (Kuroda *et al.* 1985). S. Kuroda (pers. comm.) reports *C. dryas* feeding on the tips of shoots of arrowroot *Megaphrynium macrostachum* (Marantaceae), *Haumania liebrechtsiana* (Marantaceae), *Sarcophrynium schweinfurthii* (Caesalpinaceae) and ginger *Aframomum* spp. (Zingiberaceae), and the fruits of *Calancoma welwitschii* (Achariaceae). Dryas Monkeys appear to be most active early in the morning and late in the afternoon, becoming much more difficult to locate after ca. 10:00h (S. Kuroda pers. comm.). Preliminary studies on four groups indicate home-range areas of 2.8–7.0 ha (Hurley & Lokasola 2007).

Social and Reproductive Behaviour Social. According to Kuroda *et al.* (1985), group size is typically 2–15 individuals, but groups of up to 30 individuals occur. The four groups under study at Kokolopori comprise 15–31 individuals (Hurley & Lokasola 2007). Dryas Monkeys are polygynous, with one adult ♂ per group, occasionally with extra-group ♂♂. Solitary adult ♂♂ occur (Kuroda *et al.* 1985). Calls and vocal behaviour not yet described other than a ‘chirp’ alarm call that is given only once or a few times before group members flee. No loud-call described. Local people say that *C. dryas* does not have a loud-call (S. Kuroda pers. comm.). Forms polyspecific associations with other species of primates (Kuroda *et al.* 1985), including Red-tailed Monkey *Cercopithecus ascanius* (S. Kuroda pers. comm.).

Reproduction and Population Structure No information available.

Predators, Parasites and Diseases Humans appear to be the primary predator for *C. dryas*. Probable predators are African Crowned Eagles *Stephanoetus coronatus*, Leopards *Panthera pardus*, African Golden Cats *Profelis aurata* and Central African Rock Pythons *Python sebae*. No information on diseases and parasites.

Conservation IUCN Category (2012): Critically Endangered. CITES (2012): Appendix II.

The emerging picture from current field research is that *C. dryas* may be Africa's most threatened species of primate. The two main threats to *C. dryas* are hunting for the commercial bushmeat trade and loss of habitat to agriculture (Hurley & Lokasola 2007). While conducting research on *P. paniscus* at Wamba during the 1980s, S. Kuroda (pers. comm.) found *C. dryas* in most areas with secondary forest thicket. By 2006 this was no longer the case as *C. dryas* in the Wamba area now appears to be largely restricted to areas of old plantation. S. Kuroda (pers. comm.) has observed a general decline of the larger mammal fauna in this area as a result of hunting for bushmeat.

Cercopithecus dryas is one of the least studied species of primate in Africa. Priorities for the conservation of *C. dryas* are: (1) a study of age-related pelage change to determine whether *C. salongo* is the same as *C. dryas*; (2) additional surveys to better understand distribution, abundance and conservation status; (3) long-term research on habituated groups to determine ecology, behaviour and habitat requirements; (4) molecular research to assess taxonomic status; and (5) the rapid establishment of a well-managed, well-funded, protected area that encompasses the entire known geographic range of this species (Butynski 2002a, Grubb *et al.* 2003). The entire known geographic range for *C. dryas* falls within the

new, community-based Kokolopori Bonobo Reserve (ca. 4875 km²). Effective management of this Reserve is not only important to the conservation of *P. paniscus* in this region, it is critical to the survival of *C. dryas*. There is no captive population for *C. dryas*.

Thomas M. Butynski

Cercopithecus (diana) GROUP Diana Monkeys Group

Cercopithecus diana (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 26. Liberia.

The *Cercopithecus (diana)* Group embraces two species, the Diana Monkey *Cercopithecus diana* and the Roloway Monkey *Cercopithecus roloway*. Apart from Schreber (1774), who described and named the Roloway Monkey and Elliot (1913b), the Diana monkeys have been treated as subspecies of a single species. Here we follow Groves (2001), who emphasized that the differences between the two forms are absolutely clear-cut and that they stand as distinct species.

Both species are dark grey with white banding and a deep maroon lumbar saddle; most of underside black, except for the chest, throat and inner arms, which are white, sharply separated from the black of the underside; inner surfaces of legs are either red or yellow; characteristic white stripe across the haunch; facial skin jet black; prominent, narrow beard on the chin; and pale brow-band, shaped like a crescent moon (hence the species is named after Diana, the Roman moon goddess). The two species are separated by the shape and colour of the beard and brow-band, colour of the buttocks and inner surfaces of the thighs, and the number of agouti-bands on the hairs.

Cercopithecus diana ranges from Sierra Leone to the Sassandra R., Côte d'Ivoire; *C. roloway* originally ranged from the Sassandra R., Côte d'Ivoire, to the Pra R., Ghana, but is now close to extinction.

Both species are almost entirely arboreal and dependent on a continuous canopy. They show a strong preference for high canopy, primary rainforest but are also found in mature secondary, riverine and semi-deciduous forests and galleries. These are fast, highly vocal, conspicuous monkeys. Their foraging strategy seems to be that of coarse-grain foragers, moving rapidly over a relatively large range and relying upon good shared communication, rapid reaction times and fast escapes to mitigate predation.

Cercopithecus diana **DIANA MONKEY**

Fr. Diane (Capitaine); Ger. Diana-Meerkatze

Cercopithecus diana (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 26. Liberia.Diana Monkey *Cercopithecus diana* adult male.*Cercopithecus diana*

Taxonomy Monotypic species. *Cercopithecus diana* has long been regarded as one species with two subspecies, the Diana Monkey *C. diana* and the Roloway Monkey *C. roloway* (e.g. Kuhn 1967, Napier 1981, Oates 1988b, 2011), but Groves (2001, 2005c) treats *diana* and *roloway* as distinct species within the *Cercopithecus (diana)* Group (or Superspecies). Grubb *et al.* (2003) revert to the traditional two-subspecies taxonomy. Synonyms: *faunus*, *ignita*. Chromosome number: $2n = 58$ (Dutrillaux *et al.* 1988b).

Description A brightly coloured, long-limbed, long-tailed, arboreal monkey, with beard, white chest and white thigh stripe. Adult ♀ like adult ♂ in colouration but smaller, weighing about 75% as much. Face black. Brow-band white, not prominent. Throat, cheeks, chest and inner arms white. Beard square, ca. 20 mm long, blackish at base and white at tip. Ears tufted. Shoulders, anterior part of back, sides, outer arms and ventrum black or dark grey. Posterior part of back with a chestnut 'saddle'. Inner thigh russet-orange. Outer thigh black with white femoral (thigh) stripe. Feet and tail black. Neonate with head, shoulders, back, sides, ventrum, feet and tail dark grey. Chest white. Adult colouration develops within 12 months of birth.

Geographic Variation None recorded.

Similar Species Unlikely to be confused with any sympatric species.

Cercopithecus roloway. Allopatric (east of Sassandra R., Côte d'Ivoire; Oates 1988b). Beard much longer (80–100 mm), pointed, all white; ear-tufts absent; inner thighs creamy white or yellow; brow-band white, greater lateral extent, more prominent.

Distribution Endemic to Guinea, Sierra Leone, Liberia and Côte d'Ivoire. Rainforest BZ. Restricted to lowland rainforest from W Guinea eastwards through Sierra Leone and Liberia to Sassandra R., Côte d'Ivoire (the boundary with *C. roloway*; Oates 1988b, Grubb *et al.* 1998). Tappen (1960) noted the western limits of the range as 13°N, 17°W in Gambia, but this record is probably spurious. Most westerly recent record is from Kounounkan Forest, Forécariak Province, W Guinea, at about 12°30'W (Barnett *et al.* 1994).

Habitat Appears to prefer relatively undisturbed high moist forest but seen occasionally in regenerating farmbrush (Oates 1988b, Hill 1991, Fimbel 1994b). Mean annual rainfall at Diana Monkey study sites ranges from 1700 mm (Taï N. P., Côte d'Ivoire; McGraw & Zuberbühler 2007) to 2708 mm (Tiwai I., Sierra Leone; Oates & Whitesides 1990). This species occurs from just above sea level in S Sierra Leone to at least 1300 m in the Loma Mts, Sierra Leone.

Abundance Diana Monkeys were common at Tiwai I. (30–43 ind/km²; Whitesides *et al.* 1988), but their numbers were decimated during the 1991–2002 civil conflict (Stephan 2008). Common in Taï N. P.; of 70 ind/km² (calculated from group densities and mean group size cited in Holenweg *et al.* 1996), 48.2 ind/km² (Zuberbühler & Jenny 2002) and, for 2006–08, 1.45 groups/km², 16.9 ind/km², and total population of 97,000 (N'Goran *et al.* 2012). Density in Sapo N. P., Liberia, in 1988–89, was 11 ind/km² (calculated from group density and mean group size; Agoramoorthy 1989). Density in Gola Forest, Sierra Leone, ca. 71 ind/km² (Klop *et al.* 2008).

Diana Monkey *Cercopithecus diana* adult male.

Adaptations Diurnal and arboreal. Long limbs, narrow hands and feet, and long tail enable Diana Monkeys to travel and forage in all forest strata using a range of differently sized supports. Whilst not restricted to a particular forest stratum, and sometimes moving on the ground, they spend most of their time in the higher strata (Whitesides 1991, McGraw 1998a, McGraw & Sciulli 2011). Buzzard (2006b) found that this species spends 2% of its time on the ground, 18% at 0–5 m, 43% at 5–20 m and 38% in the canopy (i.e. >20 m). They are terminal branch feeders, adopting a range of postures to access foods, including the ‘stand/forelimb suspend’ posture and occasionally suspending themselves by both hindlimbs. They use the tail for additional support, curling it round tree branches and trunks (McGraw 1998c). Activity budget varies across studies. At Tiwai I., activity budget was: foraging and feeding 35%, travelling 25%, resting 21%, vigilance (scanning) 8%, social behaviour 6% (Hill, 1991), but Whitesides (1991) observed higher rates of foraging & feeding (48%) and substantially lower levels of resting (1%). At Tã, activity budget was: feeding 33%, travelling 28%, foraging 28%, resting 9% and social behaviour 1% (McGraw 1996).

Foraging and Food Omnivorous. Diana Monkeys feed mainly on fruits and arthropods. Most arthropod feeding occurs in the tops of emergent trees. Foraging and prey capture techniques suggest most prey is slow-moving or stationary. Animals search through leaves turning them over to inspect the underside, removing food items with fingers and occasionally lips. They scan the crowns of flowering emergent trees, making a sudden grabbing action with one and sometimes both hands. At Tã, dietary overlap is greater between Diana Monkey and Campbell’s Monkey *Cercopithecus campbelli* than between Diana Monkey and Lesser Spot-nosed Monkey *Cercopithecus petaurista*. Inter-specific feeding competition is reduced partly through occupation of different vertical strata (Buzzard 2006b).

Leaves, flowers and seeds are eaten to a lesser extent (Hill 1991, Whitesides 1991, Eckardt & Zuberbühler 2004). They occasionally raid bird nests for eggs or nestlings (Hill 1991), and eat foam nests

of the tree frog *Chiromantis rufescens* (Rödel *et al.* 2002). Like other guenons they exhibit dietary flexibility. A greater proportion of leaves and flowers, and less fruit, is eaten at Tiwai I. than at Tã (Galat & Galat-Luong 1985, Whitesides 1991, Wachter *et al.* 1997), possibly reflecting differences in food availability between sites. Ripe fleshy fruits are eaten when available, e.g. *Landolphia hirsuta* and *Uapaca guineensis* (Hill 1991). Fleshy arils encasing *Pycnanthus angolensis* seeds are also eaten at Tiwai I., as is fluid from the unripe pods of *Funtumia africana* and *Holarrhena floribunda* (Hill 1991, Whitesides 1991). Also eat fallen fruits (Buzzard 2006b).

Social and Reproductive Behaviour Social. Diana Monkeys live in groups of 15–30 individuals. Groups comprise 1–2 adult ♂♂ and 6–13 adult ♀♀ and young (Hill 1991, 1994, Whitesides 1991, Buzzard 2006b, Wolters & Zuberbühler 2003). Solitary adult ♂♂ observed travelling and feeding within group home-ranges at Tiwai I. (Oates & Whitesides 1990, Hill 1991). Adult ♀♀ and young groom each other regularly; the adult ♂ is rarely seen allogrooming but is groomed by adult ♀♀ (Hill 1991, Buzzard & Eckardt 2007). Few agonistic interactions seen among members of the same group at Tiwai, though some displacements over preferred food resources observed (C. M. Hill pers. obs.). Home-range sizes at Tã of 93 ha ($n = 1$; Galat & Galat-Luong 1985), 67 ha ($n = 1$; Holenweg *et al.* 1996) and 59 ha ($n = 2$; Buzzard & Eckardt 2007) are greater than those reported for Tiwai by Hill (1991) (Group W: 40 ha; Group E: 37 ha) and by Whitesides (1991) (Group W: 42 ha; Group E: 29 ha). Neighbouring groups’ ranges overlap by 16–29% at Tiwai (Hill 1991) and by 65–67% at Tã (Buzzard & Eckardt 2007). Diana Monkeys are active animals and travel extensively. Mean day range length at Tiwai (1668 m/day) differs between groups and across seasons (730–3125 m/day, $n = 103.5$ days, $n = 2$ groups). Mean day range significantly longer during the dry season (Hill 1991, Whitesides 1991). Conversely, at Tã, longest day ranges occur during the main wet season ($1,274 \pm 351$ m, $n = 8$ days, $n = 1$ group) and shortest day ranges occur during the main dry season (965 ± 368 m, $n = 8$ days, $n = 1$ group; Buzzard 2006c). Mean day range at Tã, 1215–1240 m/day ($n = 56$ days, $n = 1$ group), is comparable with Tiwai figures (Holenweg *et al.* 1996). At Tiwai group spread is typically >100 m and sometimes in excess of 200 m (Oates & Whitesides 1990); at Tã group spread is typically ca. 70 m (R. Noë, unpublished data, cited in Zuberbühler 2000c). This difference between the two sites may be a reflection of the much higher predation risk at Tã than Tiwai. Home-range use is strongly influenced by fruit availability and interactions with neighbouring conspecifics. Animals at Tiwai spend more time in boundary/overlap regions during the breeding season, a time when there is increased inter-group calling behaviour (Hill 1991).

Diana Monkeys defend exclusive territories against conspecifics. Inter-group encounters were rare at Tiwai but when groups met only adult ♀♀ and immature animals were seen chasing, threatening, biting and pulling members of the intruder group. Adult ♂♂ remained at the top of emergents, giving loud-calls and displaying by bouncing, stiff-legged, through the canopy, and producing additional noise by breaking twigs and small branches. Inter-group calling bouts were common; ♀♀ give ‘chatter-screams’ that incite the adult ♂ to give loud-calls (Hill 1994).

Several matings observed at Tiwai; the adult ♂ approached the adult ♀ and mounted her briefly. Infants are carried ventrally by the

mother. They are carried occasionally by immature animals during play (C. M. Hill pers. obs.).

Diana Monkeys have a rich repertoire of vocalizations comprising contact calls, alarm calls and inter-group calls. Contact calls are given almost exclusively by adult ♀♀ and immature animals, and comprise a range of whistles and trills, given during most group activities. All members of group give alarm calls. Research at Tāi indicates adult ♂♂ and adult ♀♀ give different, sex-specific alarm calls that convey information about the predator type (Zuberbühler *et al.* 1997, 1999). Animals modify their calling behaviour to avoid detection by specific predators, using calling and mobbing behaviour to warn off African Crowned Eagles *Stephanoaetus coronatus* and Leopards *Panthera pardus* (Zuberbühler 2000a, Bshary 2001). Male and ♀ Diana Monkeys also use calls to advertise territorial possession. Adult ♀♀ initiate inter-group calling bouts; the adult ♂ gives his loud-call after group ♀♀ have given several 'chatter-screams' (a short, quiet vocalization that is difficult to locate the source of) (Hill 1994). Males also use loud-calls to engage in male–male competition in the form of inter-male calling bouts (Hill 1991). Diana Monkeys respond to alarm calls of sympatric species (Oates & Whitesides 1990). Their response to alarm calls of Campbell's Monkeys suggest they understand the semantic context in which Campbell's Monkey alarm calls are given (Zuberbühler 2000b).

Diana Monkeys spend much of their time in association with other primate species. This is thought to be an anti-predator strategy (Oates & Whitesides 1990, Whitesides 1991). At Tiwai, Olive Colobus *Procolobus verus* groups are in permanent association with Diana Monkey groups; these associations are maintained by the Olive Colobus (Oates & Whitesides 1990). At Tāi, Diana Monkeys associate with Olive Colobus (Galat & Galat-Luong 1985), Campbell's Monkeys (Zuberbühler 2000b), Lesser Spot-nosed Monkeys (Buzzard 2010) and Western Red Colobus (Noë & Bshary 1997). Diana Monkeys were not observed in association with Western Red Colobus at Tiwai; this difference between the two sites may reflect the greater predation pressure at Tāi as compared with Tiwai (Holenweg *et al.* 1996).

Reproduction and Population Structure There are few data from wild populations on reproductive parameters. Diana Monkeys do not have sexual swellings. Average gestation in captivity is 180 days (Stevenson 1993). Diana Monkeys are seasonal breeders, giving birth to singletons. At Tiwai new infants observed from late Dec to early Feb (Hill 1991) and Jan–Apr (Whitesides 1989); at Tāi births reported from Oct–Jan (Uster & Zuberbühler 2001). Captives in UK show some seasonality with 50% of births during Mar–Jun ($n = 634$; G. Catlow pers. comm.). Birth season in the wild coincides with the early dry season, a period of relatively high abundance of flowers, fruits and seeds; thus the diet contains a high proportion of fruits and seeds during late gestation and early lactation, as in other guenon species (Butynski 1988, Hill 1991).

Birth-weights for wild Diana Monkeys not available. Mean birth weight for two captives is 475 g (R. D. Martin, A. McLarnon & R. Rudder pers. comm.). Mean inter-birth interval for captives is 590 days ($n = 150$; G. Catlow pers. comm.); average inter-birth intervals may be longer in wild populations if food quality and availability influences ♀ reproduction. Estimates from wild observations

suggest weaning is complete by ca. 12 months (C. M. Hill pers. obs.). Mean age at first reproduction in captivity is 87 months (ca. 24–147, $n = 167$) for ♀♀ and 105 months (ca. 105–185, $n = 143$) for ♂♂ (G. Catlow pers. comm.) Live to >25 years in captivity.

Using census data, group size and structure data from Tiwai ($n = 2$ groups), and taking into account solitary ♂♂, population sex ratios (adult ♂♂ : adult ♀♀) are ca. 1 : 3.0–3.5/km² and adults to immatures ratios are ca. 1 : 1.3–1.4/km².

Predators, Parasites and Diseases Humans have been, and continue to be, the most important predators of Diana Monkeys (Bshary 2001, Koné & Refisch 2007, McGraw 2007b). Robust Chimpanzees *Pan troglodytes*, Leopards *Panthera pardus* and African Crowned Eagles are also predators of Diana Monkeys (Hoppe-Dominik 1984, Boesch & Boesch 1989, Zuberbühler & Jenny 2002, 2007, Shultz & Thomsett 2007, Oates 2011).

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix I.

Populations affected by habitat loss through agricultural expansion and intensive commercial logging, and by hunting for bushmeat. In Gola F. R., Sierra Leone, Davies (1987) found the highest Diana Monkey densities where there was light hunting pressure, whereas none was encountered where hunting pressure was intense (Mahoi Forest, Gola East Forest). Where hunting pressure was light, he encountered Diana Monkeys at similar frequencies in selectively logged and unlogged forest. In a 1989–90 survey in Liberia, just before that country's civil war, Dunn (1991) found that Diana Monkeys were the third most vulnerable primate to hunting pressure, following Western Red Colobus and King Colobus *Colobus polykomos*. See also N'Goran *et al.* (2012). Important sites for the long-term survival of Diana Monkey are Tiwai Island Wildlife Sanctuary, the proposed Gola Forest N. P., the proposed Loma Mountains N. P., Sapo N. P. and Tāi N. P.

Cercopithecus roloway ROLOWAY MONKEY

Fr. Diane roloway (Palatine); Ger. Roloway-Meerkatze

Cercopithecus roloway (Schreber, 1774). Die Säugethiere 1: 186. 'Guinea' (= West Africa in general).*Cercopithecus roloway*ABOVE AND RIGHT: Roloway Monkey *Cercopithecus roloway* adult male.

Taxonomy Monotypic species. Recognized by some (e.g. Elliot 1913b, Groves 2001, 2005c) as a distinct species, but more often given subspecific status with the Diana Monkey *Cercopithecus diana* (e.g. Hill 1966, Napier 1981, Oates 1988b, 2011, Kingdon 1997, Grubb *et al.* 1998, 2003). Here the Roloway Monkey is treated as a full species within the *Cercopithecus (diana)* Group (or Superspecies). Colour of inner thighs white to pale yellow or orange in Ghana to rusty red at the Sassandra R., Côte d'Ivoire, making the Sassandra population identical to *C. diana* in this character (Oates 1988b), but beard length and colour, and brow-band width and colour distinguish the two species (Schreber 1774, Erxleben 1777, Allemand 1799, Schlegel 1876, Jentink 1898, Pocock 1907, Elliot 1913b, Booth 1956a, b, Groves 2001, 2005c). Synonyms: *palatinus*. Chromosomes: $2n = 58$ (Napier 1981, Dutrillaux *et al.* 1988b).

Description An elegant monkey, long-limbed and long-tailed, with richly coloured and complex markings, including pure white beard, chest and thigh stripe. Adult ♀ like adult ♂ in colouration but smaller. Face black, framed by broad white diadem and long (80–100 mm) all-white pointed or forked beard. Sides of throat, chest to nipples, and inner arms pure white. Crown black, shading into dark

grey on nape and sides. Ears lack tufts. Shoulders dark grey grading into a deep mahogany 'saddle' that widens over the rump and extends onto the base of the tail. Hairs of dorsum usually with more than four pairs of alternating light and dark bands (Groves 2001). White stripe on thigh extending from underside of tail and curving along outer thigh to knee, separating dark grey dorsal pelage from black pelage of outer thigh and lower leg. Ventrums, hands and feet black. Inner thighs and perineum cream to apricot in Ghana to rusty-red at the Sassandra R. Tail black, >130% length of HB. Pattern of natal pelage like adult but with paler colours.

Geographic Variation None recorded except as noted above.

Similar Species Unlikely to be confused with any sympatric species.

Cercopithecus diana. Allopatric (west of Sassandra R., Côte d'Ivoire; Oates 1988b). Brow-band a narrow white or cream crescent; not prominent. Beard short (ca. 20 mm), square, blackish at chin, white distally. Ears tufted. Hairs with four pairs only of alternating light and dark bands (Groves 2001). Inner thighs and perineum bright red-bay.

Distribution Endemic to Côte d'Ivoire and Ghana. Rainforest BZ. From Sassandra R., Côte d'Ivoire, north and east to Goaso in the Brong-Ahafo Region and east to Pra R., Ghana (Oates 1988b, Grubb *et al.* 1998, Oates *et al.* 2000a), but reported farther east in Kakum N. P., Ghana (P. Symonds pers. comm.).

Habitat Confined to wet evergreen, moist evergreen, moist semi-deciduous primary forest (Hall & Swaine 1981) and old secondary forest (Booth 1956b). In Bia N. P., Ghana, Roloway Monkeys are near sea level. Annual rainfall here 1441 mm in 1976 and 938 mm in 1977 (S. Curtin pers. obs.).

Abundance At low population densities throughout geographic range. Nowhere abundant at this time. About 8 ind/km² in Bia N. P., during 1976–77 (Curtin 2002).

Adaptations Diurnal and arboreal. Body slender, long limbs and long tail, long narrow hands and feet. An agile inhabitant of the middle and upper strata of mature rainforest. Exploits small, unstable terminal branches of emergent trees for insects, despite relatively large body size for a guenon. Bright coat colours and conspicuous markings may be related to social communication and associated with emphatic postures and displays (Kingdon 1997).

Foraging and Food Omnivorous. Diet largely ripe fruits and invertebrates. Eats significant proportion of seeds and, in the wet season, young leaves and flowers. Diet of one Roloway Monkey group in Bia N. P. over a nine-month period consisted of 31% mature fruit pulp, 25% invertebrates, 22% seeds of mature fruit, 7% new leaves and leaf buds, 6% flower buds and flowers, and 9% other (n = 3224 feeding scores). Pulp of mature fruit and invertebrates, especially small immobile insects in the terminal branches of *Piptadeniastrum africanum*, are the two most important food categories both in dry and wet seasons; seeds of mature fruit, especially the oil-rich seeds of *Pycnanthus angolensis*, is the third leading category in the dry season, replaced by new leaves and flowers in the wet season. They ate plant parts from >130 species of trees, climbers and epiphytes and took invertebrate prey (caterpillars, moths, ants, scale insects, beetles, grasshoppers, millipedes, spiders) from leaf, twig and bark surfaces of an additional 22 tree species (Curtin 2002).

One bisexual group in Bia N. P. comprised 15 animals and had a home-range of 189 ha.

Group members dispersed during foraging, often spread >100 m. Day ranges in the dry season averaged 2280 m (997–3038 m, n = 25 days), in the wet season 1505 m (939–2382 m, n = 25 days). Roloway Monkeys frequently forage in association with White-thighed Colobus *Colobus vellerosus*, especially in the wet season (May–Jul), the period of greater insect abundance (average daily association time: 4.63 h). They actively initiate and maintain these associations and apparently use the colobus to dislodge insects as they forage beneath, or to flush insects from arboreal pathways as they follow close behind (Curtin 2002).

Social and Reproductive Behaviour Social. A typical social group (n = 3 groups) contains 15–20 animals including only one adult ♂, although a second adult ♂ may be tolerated by the resident ♂ during non-breeding months (Nov–Jan). Groups are territorial and maintain spacing by long-calls that can be heard by the human ear to >1.5 km. Occasional incursions made by solitary extra-group ♂♂ are repelled by the resident ♂. No all-male groups observed. One territory 189 ha. Only the resident adult ♂ forms consortships and performs serial mounts and intromissions, although a subadult ♂ may steal single mounts with intromission. Roloway Monkeys form transient inter-specific associations with groups of *C. vellerosus*,

Lesser Spot-nosed Monkeys *Cercopithecus petaurista* and Lowe's Monkey *Cercopithecus lowei* (Curtin 2002).

Reproduction and Population Structure Births recorded at Bia N. P. in late Nov–early Dec (2) and in Mar (1). Copulations recorded Feb–Jul, peaking in Jul (n = 12; no observations Aug–Oct). Sex ratio: 4 ♂♂ to 7 ♀♀ (includes extra-group ♂♂). Adult to young ratio: 9 : 7 (Curtin 2002). Lives to at least 30.7 years in captivity (Jones 1962).

Predators, Parasites and Diseases Probably the same predators as for *C. diana*. Humans are the Roloway Monkey's most significant predator. African Crowned Eagles *Stephanoaetus coronatus* prey on other monkeys in Bia N. P. (Martin 1991) and presumably also prey on Roloway Monkeys. Diseases unknown.

Conservation IUCN Category (2012): Endangered (as *C. diana roloway*). CITES (2012): Appendix I as *C. diana roloway*.

Currently listed among the 25 most threatened primate taxa in the world (McGraw & Oates 2009). Together with the White-naped Mangabey *Cercocebus lunulatus* and Miss Waldron's Red Colobus *Procolobus badius waldroni*, the Roloway Monkey is among the three most threatened monkeys of the Upper Guinea Forest Block (Oates 1996a). Severely impacted throughout its geographic range by habitat loss due to logging, clearing of forest for subsistence farming and oil palm plantations, and by hunting for the bushmeat trade (Asibey 1978, Lee *et al.* 1988, Oates 1996a, 1999, McGraw 1998d, Oates *et al.* 2000a). Roloway Monkeys are especially vulnerable because their high canopy habits and long-carrying territorial calls advertise their presence to hunters. Highest priority should be given to protection of Krokosua Hills (L. Magnuson pers. comm.), Ankasa Reserve and Nini-Suhien N. P. in Ghana (Oates 1996a), and to the Tanoé Forest in Côte d'Ivoire (Koné & Akpatou 2005, McGraw & Oates 2009, Gondelé Bi *et al.* 2012).

Cercopithecus neglectus DE BRAZZA'S MONKEY

Fr. Cercopithèque de Brazza; Ger. Brazza-Meerkatze

Cercopithecus neglectus Schlegel, 1876. Mus. Hist. Nat. Pays-Bas. Simiae, p. 70. 'White Nile', SE Sudan.De Brazza's Monkey *Cercopithecus neglectus* adult male.*Cercopithecus neglectus*

Taxonomy Monotypic species. Age variation in pelage of a juvenile *Cercopithecus neglectus* specimen led Pocock (1908) to erroneously name *Cercopithecus ezrae*. Phylogenies inferred from blood proteins (Ruvolo 1988), chromosomes (Dutrillaux *et al.* 1988b) and vocal repertoires (Gautier 1988) agree in placing De Brazza's Monkey in the *Cercopithecus* (*mona*)–(*diana*) cluster. The geometry of colours and white beard resemble Diana Monkey *Cercopithecus diana* and Roloway Monkey *Cercopithecus roloway* (Pocock 1908). Phylogenies drawn from genetic analyses do not differentiate *C. neglectus* from the arboreal cercopithecines and its exact phylogenetic position remains unresolved (Disotell 1996). Synonyms: *brazzae*, *brazziformis*, *ezrae*, *uellensis*. Chromosome number: $2n = 62$ (Dutrillaux *et al.* 1988b).

Description Robust, semi-terrestrial, long-tailed monkey with rufous brow, long white beard and white thigh stripe. Strongly patterned monkey with dense pelage. Adults of both sexes similar in colour, but ♂ almost twice as heavy as ♀. Muzzle, throat and long 'beard' white. Diadem bright rufous topped by a black stripe. Black mask surrounds eyes. Cheek-whiskers, back and flanks greyish-olive speckled with black. Forearms, hands, feet, belly and tail black. Inner thighs and buttocks dazzling white. White stripe down leg. Tail slightly longer than HB (ca. 120%) but relatively shorter than in arboreal guenons. Scrotum of adult ♂ bright blue (Hill 1966). Perineum of adult ♀ pink. Newborn infants entirely yellowish with pink face, hands and feet. Infantile pelage retained up to 4–5 months. Adult pelage takes about four years to develop (Kirkevoold & Crockett 1987, A. Gautier-Hion pers. obs.). In between, fur gradually becomes speckled and turns brownish-grey; ventrum and tail become greyish. Bare skin on face becomes black; long white hairs grow on chin. At about two years, white beard becomes distinct, limbs and tail turn black, inner thighs and rump turn white and frontal diadem becomes more rufous. Upper black coronal bar appears at around four years.

Geographic Variation Some in eastern Africa have all-black forearms but this is not a common trait.

Similar Species Unlikely to be confused with any other monkey but juveniles may be difficult to identify on their own.

Distribution Endemic to equatorial Africa. Rainforest, Northern Rainforest-Savanna Mosaic, Eastern Rainforest-Savanna Mosaic, and Afromontane–Afroalpine BZs. From E Cameroon, Equatorial Guinea (Rio Muni), N Gabon and NE Angola eastwards through the Congo Basin to S Sudan, SW Ethiopia and C Kenya. Western limit is the Atlantic coast. North-western limit is Mbam & Djerem N. P., Cameroon, just north of the Sanaga R. (Maisels *et al.* 2007a). Northern limit is in gallery forests in N Central African Republic (08° 30' N; Fay 1988). Southern limit is 10° S in NE Angola. North-eastern limit is 07° 26' N, 35° 20' E in SW Ethiopia (Brown & Urban 1969). Eastern limit is in the Mathews Range F. R., C Kenya (01° 11' N, 37° 22' E; Mwenja 2007, De Jong & Butynski 2010a). The Mathews Range population, discovered in 2000 (Douglas-Dufresne 2005), is the only population east of the Eastern Rift Valley. Absent from western main Atlantic basins (except in Equatorial Guinea; Malbrant & Maclatchy 1949, Gautier-Hion *et al.* 1999). Found through most of Congo Basin except south of the Maiko R.

Historic Distribution: In East Africa, De Brazza's Monkeys were probably more regularly distributed in riverine forests in the past than at present. Noting the likelihood of some form of inter-specific intolerance limiting De Brazza's Monkeys in multi-species communities, Kingdon (1971) hypothesized that the species formerly 'must have

been very numerous to maintain a degree of gene-flow capable of sustaining the present homogeneity of the species over so vast an area of central and East Africa'. He also noted that De Brazza's Monkey is not limited to swamp forest throughout its range, being found in East Africa (where there are few other *Cercopithecus* species) in closed forests, in bamboo and along water-courses of dry montane forest. He suggests that, within eastern Africa, De Brazza's Monkey 'almost certainly ranged through all forest types in the past', an opinion that probably needs some qualification.

De Jong & Butynski (2010a) note that in central Africa, where primate communities in forests are typically comprised of at least four cercopithecine species, De Brazza's Monkey is an animal of lowland swamps and riverine forests (i.e. habitats with few cercopithecine species). In E Uganda and W Kenya, in the eastern part of the range, there are but one or two cercopithecine species in the forests and here De Brazza's Monkey appears to be less strongly associated with water and also occupies mid-altitude and dry montane forest (e.g. Mt Elgon to 2100 m; Kingdon 1971). At the eastern extreme of the range (Mathews Range), where there is no other forest cercopithecine species, De Brazza's Monkey is found >2 km from water and to an altitude of at least 2200 m in dry montane forest. These observations suggest that competition with other cercopithecine species (perhaps particularly Gentle Monkey *Cercopithecus mitis*) is a major factor in not only determining whether De Brazza's Monkey occurs, but also the habitats and altitudinal range occupied by this species. De Jong & Butynski (2010a) point out that the only site east of the Eastern Rift Valley where De Brazza's Monkey occurs (i.e. Mathews Range) is one of the few forested sites east of the Eastern Rift Valley in Kenya where *C. mitis* is absent.

Habitat Riverine species that inhabits periodically flooded forests, swamps, riverine forests and gallery forests. Found from 100 m up to 2200 m (Mathews Range; Mwenja 2007). Mean annual rainfall varies across the range from 700 to 4000 mm. In East Africa, De Brazza's Monkey occurs in forest pockets amidst expanding farmlands; occasionally found in secondary forests, *Acacia* woodlands and crops (Brennan 1985). Avoids primary forest with open understorey. In Central African Republic, Congo and DR Congo, group home-ranges always border or include a river (Gautier & Gautier-Hion 1969, Gautier-Hion & Gautier 1978, A. Gautier-Hion pers. obs.).

In undisturbed forest blocks in central Africa, De Brazza's Monkey depends on water-courses and is seldom observed farther than 300–400 m from a river and always selects dense undergrowth. Of 24 groups encountered in the Mathews Range during one study, all were <200 m from water except for one group that was ca. 1000 m from water (Mwenja 2007). However, of three groups encountered in the Mathews Range during another study, two groups were >2 km from a perennial stream (De Jong & Butynski 2010a).

Abundance In large forest blocks densities vary from 0.2 ind/ha (Central African Republic; Brugière *et al.* 2005b) to 0.3–0.6 ind/ha (NE Gabon; Quris 1976, Gautier-Hion & Gautier 1978). Among forest islands in E Uganda and W Kenya, density varies from 0.2 to 2.6 ind/ha (Brennan 1985, Wahome *et al.* 1993, Decker 1995). At low density in the Mathews Range, with only three groups encountered along 62 km of transect (62 h) in forest (0.05 groups/km, 0.05 groups/h; De Jong & Butynski 2010a).

Lateral, palatal and dorsal views of skull of De Brazza's Monkey *Cercopithecus neglectus* adult male.

Adaptations Diurnal and semi-terrestrial. De Brazza's Monkey terrestriality increases with increasing density of ground cover and thickness of undergrowth (Quris 1976, Gautier-Hion & Gautier 1978, Wahome *et al.* 1993). De Brazza's Monkeys spend >20% of daylight hours on the ground and >50% under 5 m in dense understorey vegetation. In areas with open understorey they move at a height of <5 m height for only 20% of time, and on the ground for <10% of time. Adult ♂♂ more terrestrial than adult ♀♀ and young. De Brazza's Monkeys sleep at night in crowns of high trees located on or close to rivers (Gautier-Hion & Gautier 1978).

De Brazza's Monkey has the broadest and most robust foot of any guenon, resembling that of Allen's Swamp Monkey *Allenopithecus nigroviridis*, but more arboreally than terrestrially adapted (Kingdon 1988a). Postcranial skeleton is similar to those of arboreal monkeys (Gebo & Sargis 1994). Excellent swimmers, De Brazza's Monkeys cross rivers >300 m wide, plunge into water to avoid predators, and can swim under water. Young De Brazza's Monkeys play together in water (Gautier-Hion & Gautier 1971). Scent-marking of branches and trunks includes serial rubbing that involves muzzle, throat and chest, with or without rubbing and licking palms of the hands. Sternal region has specialized cutaneous glandular area (Loireau & Gautier-Hion 1988). In captives, scent-marking occurs in all age and sex classes except infants less than one year old. Adult marking bouts are more frequent and last longer than those of juveniles. Most marking sequences provoke responses from other group members, especially inducing over-marking. 'Freezing' posture also characterizes the De Brazza's Monkey and

Schematic diagram (from film) of De Brazza's Monkey *Cercopithecus neglectus* adult male during one 'sweep' of his loud call display. Superimposed outlines of head and beard indicate positions (from right to left) during this 2.2 second traverse.

occurs in all age/sex-classes. When 'frozen' the monkey keeps still and remains curled up with head lowered so that white beard and rump are hidden. Freezing can last for at least 5 h (Gautier-Hion & Gautier 1978). This species lacks an alarm call in its repertoire (Gautier & Gautier-Hion 1977). 'Boom' calls of adult ♂♂ involve large vocal sacs in the throat that are inflated then deflated during booms (Gautier 1971).

De Brazza's Monkey is remarkable for its anti-predator behaviour. Monkeys respond to potential predators either by freezing or dropping into the undergrowth before fleeing silently. Adult ♂♂ may drop violently to the ground; the sound seems to act as a signal for congeners, which freeze. Harassing behaviour is mostly restricted to adult ♂♂, which may face off a predator (e.g. African Crowned Eagle *Stephanoaetus coronatus* or humans) at which time they utter impressive aggressive barks.

Foraging and Food Omnivorous. Forages mainly in trees. Contrary to strictly arboreal guenons, De Brazza's Monkeys handle food carefully and avoid wasting fruit. Both in Gabon and W Kenya, foraging for fruit is intensive and only a few fruiting sites are visited per day. For example, in Gabon a fruiting Apocynaceae liana was exploited on 14 days out of 20 consecutive observation days until most of the fruit was consumed (Gautier-Hion & Gautier 1978). In W Kenya one group used two neighbouring *Manilkara butugi* trees every day for two weeks (Chism & Cords 1998). Group home-ranges are small: 4–10 ha ($n = 16$ groups) in Gabon and 4–6 ha ($n = 3$ groups) in W Kenya. At both sites home-ranges of neighbouring groups overlap. Daily movements are short: mean 530 m (250–1010 m, $n = 24$ days) in Gabon and range is 330–1000 m in W Kenya. In Gabon 75% of the diet is comprised of fruit/seeds (from at least 27 species), 10% leaves, 5% mushrooms (genus *Mycera* and genus *Termitomyces*) and 5% animal prey (Gautier-Hion & Gautier 1978). In W Kenya diet comprised of 45% fruit/seeds (from 17 plant species), 30% leaves, 10% invertebrates and 2% mushrooms (Wahome *et al.* 1993). At both sites animal prey were mostly sedentary or slow moving insects (caterpillars, ants, cocoons, resting moths and termites). In East Africa, De Brazza's Monkeys raid crops (Maize *Zea mays*, green cotton *Gossypium* sp. bolls, avocados *Persea aguacate*, Guavas *Psidium guajava*; Mugambi *et al.* 1997, Chism & Cords 1998).

Social and Reproductive Behaviour Social. Most group counts give similar mean values. In NE Gabon the mean group size was 3.7 animals (2–6, $n = 16$ groups; Gautier & Gautier-Hion 1969, Quris 1976, Gautier-Hion & Gautier 1978); in W Kenya 3.8 ($n = 14$; Brennan 1985) and 3.7 (2–6, $n = 19$; Decker 1995); and in E Uganda 3.6 (2–6, $n = 16$) excluding four larger groups of 10, 12, 15 and 22 animals (Decker 1995). Groups in the Mathews Range numbered 2–18 ($n = 24$; Mwenja 2007). Three large groups of 11, 13 and 16 individuals in a small population in Kisere Forest, W Kenya (Wahome *et al.* 1993). Large groups, occurring in isolated small forests in East Africa (Kingdon [1971] noted groups of up to 35 individuals in E Uganda), could reflect sex differences in predation pressure (Kingdon 1997), aggregations of individuals within diminished forest patches (Decker 1995), or the difficulty facing animals who try to disperse from their natal groups because of insufficient or diminished suitable habitat (Chism & Cords 1998). Solitary animals, mainly adult ♂♂, observed at all sites. Three solitary adult ♂♂ present in a population of 38 monkeys in W Kenya (Wahome *et al.* 1993). One all-male group may have occurred in Kisere Forest but sexing of individuals was uncertain (Chism & Cords 1998). Groups are either families that include one adult ♂ and one adult ♀ and their offspring, or consist of small polygynous groups with one ♂ and up to four adult ♀♀ (Quris 1976, Gautier-Hion & Gautier 1978, Wahome *et al.* 1993). However, at least one multimale group observed in Uganda (Decker 1995).

Inter-group encounters are not aggressive but are accompanied by an increase in arousal and cohesion calls. The adult ♂ emits 'boom' calls that rally adult ♀♀ and regulate inter-group spacing (Gautier & Gautier-Hion 1977, Gautier-Hion & Gautier 1978). In captivity, courtship and mating are discrete events. In captivity, adult ♂ avoids his own offspring and rejects advances by the offspring after about two months of age, increasing rejections with time. Adult ♂ may play with an infant on rare occasions until it is seven months old, but between 11 and 18 months contacts between father and infant are neither positive nor aggressive (A. Gautier-Hion pers. obs.).

De Brazza's Monkeys in NE Gabon rarely occur in polyspecific associations (Gautier & Gautier-Hion 1969, Quris 1976). Aggressive chases of members of groups of sympatric arboreal monkeys, including Putty-nosed Monkeys *Cercopithecus nictitans*, Crowned Monkeys *Cercopithecus pogonias* and Moustached Monkeys *Cercopithecus cephus*, as well as against solitary adult ♂♂, observed several times (Gautier-Hion & Gautier 1978). Similarly, in East Africa Gentle Monkeys *Cercopithecus mitis* and Red-tail Monkeys *Cercopithecus ascanius* avoid De Brazza's Monkeys, which react aggressively towards them (Kingdon 1971, Wahome *et al.* 1993). In contrast, Guereza *Colobus guereza* may intermix peacefully with De Brazza's Monkeys in feeding trees (Wahome *et al.* 1993, Decker 1995, Mugambi *et al.* 1997). Observed feeding in the same trees with Guereza and Vervets *Chlorocebus pygerythrus* in Mathews Range (Mwenja 2007). Behavioural differences among semi-terrestrial De Brazza's Monkeys and arboreal guenons (shy and elusive nature vs. more extrovert nature) that appear both in foraging strategies (intensive vs. extensive) and in anti-predator strategies (freezing vs. fleeing) could explain inter-specific antipathy (Gautier-Hion & Gautier 1978).

The vocal repertoire of De Brazza's Monkey includes seven main call types. The vocal repertoire is distinguished by discrete non-

De Brazza's Monkey *Cercopithecus neglectus*.

graded calls, by non-quavered cohesion calls, by a copulatory call in adult ♀♀, and by the absence of high-pitched warning calls. Three calls (including 'booms', 'barks' and 'roars') are specific to adult ♂♂ (Gautier & Gautier-Hion 1977, Gautier 1988).

Reproduction and Population Structure In captivity the onset of puberty in ♂♂ occurs at about six years and is accompanied by an increase in body weight. Duration of oestrous cycles not known. No external signs indicate oestrous periods. The age of first parturition is 4–5 years (exceptionally 3.5 years). Gestation lasts 5.5 months (Gautier-Hion & Gautier 1976). The single offspring weighs ca. 350 g. In the wild (Gabon), births occur from Nov to Apr with a peak in Jan–Feb during the minor dry season when fruit availability is maximum ($n = 10$; Gautier-Hion 1968, Gautier-Hion & Gautier 1978). Similarly, in W Kenya, three births were observed in Jan–Feb dry season (Wahome *et al.* 1993). The adult ♂♂ : adult ♀♀ ratio varies from 1 : 1 to 1 : 3. De Brazza's Monkeys have lived to 31 years (♀) and 20 years (♂) in captivity (A. Gautier-Hion pers. obs.). This ♀ reproduced nine times between the age of five and 15 years, with a mean birth interval of 16 months (7–28 months). The two shortest intervals occurred after stillbirths.

Predators, Parasites and Diseases No predation event observed in the wild. Like other guenons, De Brazza's Monkeys react to African Crowned Eagles, large reptiles and humans.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

In the main forest block of central Africa, De Brazza's Monkey is probably not threatened. This species is not hunted systematically for bushmeat because it is so cryptic and, as such, is rarely seen for sale. The future of De Brazza's Monkey is more uncertain in East Africa where its habitat is under severe threat from human encroachment (cultivation, logging, firewood collection, cattle grazing) and the animals are victims of human harassment, including trapping and hunting by dogs (Mugambi *et al.* 1997, Chism & Cords 1998, Mwenja 2007). Said to be common in SW Ethiopia, near Godare (Brown & Urban 1969) but present status in Ethiopia not known (but likely that populations are now threatened by habitat loss). In Kenya, said to be plentiful on some slopes of Mt Elgon in 1954 (Hill 1966), but this is no longer the case. The population in the Mathews Range, estimated at 200–300 individuals, is probably the largest population in Kenya (Mwenja 2007). Brennan (1985) only found the species in a

few isolated small forest patches in W Kenya in Trans-Nzoia District (including Saiwa N. P., Mt Elgon, and Cherangani Hills). Since then the status of the species has deteriorated still further; recent deforestation was observed at 7 out of 15 sites visited; traps and snares were found on four sites and hunting with dogs was also recorded (Decker 1995). Small populations still present on Mt Elgon and in Cherangani Hills (Mugambi *et al.* 1997). Also present in Kisere Forest, 2 km north of Kakamega Forest with no evidence of its presence in the main block of Kakamega Forest (Chism & Cords 1998, M. Cords pers. comm.). Inhabits isolated forest patches in nearby Tororo District, E Uganda, where a 1984 census found 124 individuals at 13 small sites. De Brazza's Monkey now in danger of becoming locally extinct (Decker 1995) in E Uganda and W Kenya. Animals isolated amidst expanding farmlands (where populations number only 2–7) cannot successfully move to new sites, nor are these populations genetically viable (Brennan 1985, Decker 1995). Elsewhere in Uganda, De Brazza's Monkey is known from Semliki Forest, Sango Bay and Mt Kadam (Kingdon 1971), but current status at these sites is not known.

| <i>Cercopithecus (mona) pogonias</i> | Crowned Monkey | p. 335 |

We describe six species in the distinctive *Cercopithecus (mona)* Group. All are small, wholly arboreal, fast-moving monkeys: Mona Monkey *Cercopithecus (mona) mona*, Campbell's Monkey *Cercopithecus (mona) campbelli*, Lowe's Monkey *Cercopithecus (mona) lowei*, Dent's Monkey *Cercopithecus (mona) denti*, Wolf's Monkey *Cercopithecus (mona) wolfi* and Crowned Monkey *Cercopithecus (mona) pogonias*. All have grizzled dorsal pelage, crown with black temples between conspicuous ears, dark bluish masks around the eyes, pink muzzles and prominent brow-patches. Forelimbs black on their outer aspect. Forelimbs and hindlimbs white or orange on their inner sides. Hands and feet black. Outer surface of hindlimbs vary in colouring among species and races. Long tails have black tips but tend to be bicoloured in their middle section. Hands are compact with, relatively, the shortest digits among guenons. These proportions appear to be adapted for the capture of small, active invertebrates and rapid traverse over small branches. Chromosome number 2n = 66, 68 or 72 (Dutrillaux *et al.* 1988b).

Differing chromosome numbers and disparate affinities with other guenons demonstrate that this morphologically conservative

Tentative phylogenetic tree for the Mona Monkeys Group *Cercopithecus (mona)* (modified from Tosi *et al.* 2005).

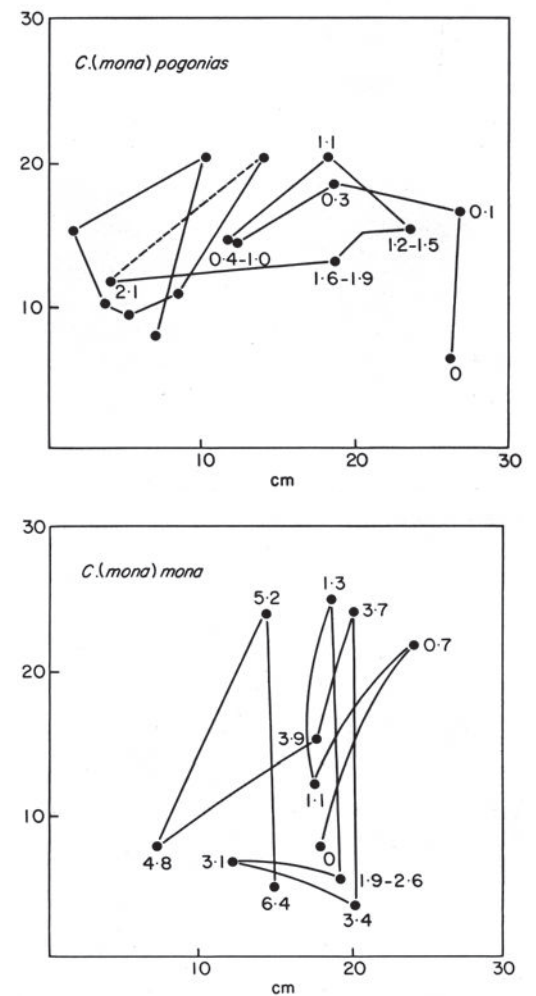

lineage has some poorly understood and puzzling relationships both within and outside the group. Nevertheless, we retain *C. (mona)* as a discrete group because it is an immediately recognizable entity.

Cercopithecus (m.) pogonias and *C. (m.) wolfi* are the most similar and derived in both morphology and chromosomes; *C. (m.) lowei*, *C. (m.) campbelli* and *C. (m.) denti* are the least derived. At the molecular level, *campbelli* differs most from other members of the *C. (mona)*

Analysis (from film) of Crowned Monkey *Cercopithecus pogonias* adult male threat behaviour sequences (top) compared with Mona Monkey *Cercopithecus mona* adult male (bottom). Both sequences (left to right) show: (1) 'cut-off' phase; (2) advertisement phase; (3) threat/vocalization phase; (4) 'cut-off' phase.

BELOW: Comparison of sonograms of adult male loud calls of Crowned Monkey *Cercopithecus pogonias* (left) and Wolf's Monkey *Cercopithecus wolfi* (right). Note species-specific modification of common sonic structure and pelage patterns.

ABOVE: Comparison of time and motion records from threat displays by (above) *C. (mona) pogonias* (below) *C. (mona) mona*. Note lateral signal design and greater lateral amplitude in the former.

The six species in the Mona Monkeys Group *Cercopithecus (mona)*.

Top, left to right: Campbell's Monkey *Cercopithecus campbelli*. Lowe's Monkey *Cercopithecus lowei*. Mona Monkey *Cercopithecus mona*. Bottom, left to right: Crowned Monkey *Cercopithecus pogonias*. Wolf's Monkey *Cercopithecus wolfi*. Dent's Monkey *Cercopithecus denti*.

Group that have been studied (Dutrillaux *et al.* 1988b, Moulin *et al.* 2008). The Dutrillaux and Moulin teams have determined that *C. (m.) pogonias* and *C. (m.) wolfi* have 72 chromosomes and a supposedly exclusive affinity with *C. hamlyni*, whereas *C. (m.) campbelli* has 66 chromosomes – the same as species in the Cephus Group *Cercopithecus (cephus)*. The chromosomes of *C. (m.) lowei* and *C. (m.) denti* have yet to be studied but *C. (m.) lowei* is likely to be the most conservative member of the *C. (mona)* Group. There are two interpretations for 66 chromosomes in *C. (m.) campbelli*. One is that hybridization has taken place, perhaps during a relatively recent period when the size of populations had greatly contracted. The other possibility is that *C. (m.) campbelli* has a much older basal position in the *C. (cephus)* radiation (and, by implication, also *C. (nictitans)*).

Using X-chromosome molecular analysis, Tosi *et al.* (2005) confirmed that *wolfi* and *pogonias* were the most recently evolved species while *mona* derived from an earlier branch. This study estimated that the *mona* radiation took place ca. 3.5 (2.9–4.1) mya (mid-Pliocene) subsequent to the emergence of the Diana Monkeys *Cercopithecus (diana)* and De Brazza's Monkey *Cercopithecus neglectus* lineages. This, and their restriction to well-developed equatorial forests, suggests that *C. (mona)* evolved within an established and diverse primate community to fill a relatively narrow niche, and were/are strongly constrained by the competition of other primates and, perhaps, birds.

The *C. (mona)* Group resembles the larger, semi-terrestrial *C. neglectus* in their longitudinally striped limbs, brow-patches, bright pattern contrasts and some aspects of their vocal repertoire (Gautier 1988).

Molecular studies also suggest that *C. neglectus* is their closest relative among guenons (Dutrillaux *et al.* 1988b, Disotell & Raam 2002, Tosi *et al.* 2004, Perelman *et al.* 2011). All members of this group are fast, omnivorous monkeys, living predominantly in the canopy. In response to predators they are adept at hiding and 'freezing' in patches of dense vegetation. Social structure consists of multifemale groups, usually with a single adult ♂. Group numbers average about 14 (8–25).

Jonathan Kingdon & Colin P. Groves

Dent's Monkey *Cercopithecus denti*.

Cercopithecus mona **MONA MONKEY**

Fr. Mone; Ger. Mona-Meerkatze

Cercopithecus mona (Schreber, 1774). Die Säugethiere 1: 103. 'Guinea'.Mona Monkey *Cercopithecus mona* adult male.*Cercopithecus mona*

Taxonomy Monotypic species. Formerly grouped as one species with other members of the *Cercopithecus (mona)* Group (or Superspecies). Now widely accepted as a distinct species (Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003, Oates 2011) due to differences in vocalizations with Campbell's Monkey *Cercopithecus campbelli* and Crowned Monkey *Cercopithecus pogonias* (Struhsaker 1970, 1981a) and sympatry with Lowe's Monkey *Cercopithecus lowei* and *C. pogonias*; however, some hybridization with both species occurs (Booth 1955, Struhsaker 1970). Common name 'Mona Monkey' often assigned to other members of the *C. (mona)* Group causing confusion. 'Mona Monkey' should refer only to *C. mona*. Synonyms: *monacha*, *monella*. Chromosome number: $2n = 68$ (Romagno 2001).

Description Medium-sized arboreal monkey with bright white underparts and bright white oval spot ('hip disc') on either side of base of tail. Sexes similar in colouration, but adult ♀ smaller, being ca. 60% as heavy as adult ♂. Skin above nostrils and around eyes dark greyish-blue. Head round. Muzzle short. Skin below nostrils light pink with sparse white hairs. Cheek pelage long, white to yellowish-white to light yellowish-grey. 'Mask' stripe black, extending from eyes to ears. Brow white or pale yellow. Crown flat, grizzled yellow and black. Ear tufts short and rounded. Dorsum reddish-brown agouti. Hands and outer forelimbs glossy black. Feet and outer hindlimbs glossy dark greyish-black. Throat, chest, belly, inside of limbs bright white. Sharp contrast between black and white surfaces of forelimbs and hindlimbs. Rump near base of either side of tail with bright white oval spots. Tail long (about 40% longer than HB), dark greyish-black, blackish towards tip. Young similar in colour to adults. Newborns blackish to black.

Geographic Variation None recorded.

Similar Species

Cercopithecus lowei. Just east of Cavally R., Côte d'Ivoire, to just east of Volta R., Ghana. Lacks white spot on either side of base of tail.
Cercopithecus pogonias. East of Cross R., Nigeria, to just north of Sanaga R., Cameroon. Lacks white spot on either side of base of tail; crown raised into a black crest.

Distribution Endemic to West Africa. Rainforest BZ. In forests from just west of Volta R., Ghana, eastwards through Togo, Bénin and Nigeria, to just south of Sanaga R., Cameroon (Booth 1955, 1956b, Struhsaker 1970, Oates 1988b). Introduced 150–500 years ago to Gulf of Guinea islands of São Tomé and Príncipe (Glenn *et al.* 1999b) and 150–300 years ago to Caribbean island of Grenada (Glenn 1998). Grenada population derived from São Tomé population (Horsburgh *et al.* 2002).

Habitat Secondary and primary moist forest, mangrove swamp, seasonal dry forest and riverine forest from sea level to 1700 m (Dunn 1993). In Cameroon occurs in mangrove swamp, secondary moist forest and forest edges more often than primary moist forest (Struhsaker 1969, Howard 1977, Whitesides 1981, Glenn *et al.* 1999a). Mean annual rainfall 800 mm to >8000 mm.

Abundance Populations locally reduced or eliminated in some areas in Nigeria and Cameroon due to overhunting by humans (M. E. Glenn & K. J. Bensen pers. obs.). Average of 0.04–0.09 groups

sighted/km and second most often sighted primate in Korup N. P., Cameroon (Linder & Oates 2011). Average of 0.22 groups sighted/km (4.5 groups/km^2) and most commonly sighted primate in Okomu N. P., SW Nigeria (Akinsorotan *et al.* 2011). Formerly common but now uncommon to rare in Ghana due to overhunting by humans (J. Mason pers. comm.). Common in Lama Forest Noyau Central, Bénin, despite hunting pressure (Matsuda Goodwin 2007). Average 15 ind/km^2 in the Douala Edea Reserve, Cameroon (Whitesides 1981), 49 ind/km^2 in E Nigeria (Dunn 1993) and $30\text{--}49 \text{ ind/km}^2$ in the Lama Forest Noyau Central (Matsuda Goodwin 2007). Common in introduced island range; estimated to be >6000 on São Tomé (19 ind/km^2), >1000 on Príncipe (21 ind/km^2) (Glenn *et al.* 1999b) and >2000 on Grenada (42 ind/km^2) (Glenn 1998).

Adaptations Diurnal and arboreal. Primarily arboreal but descends to ground for short periods. Spends 30% ($n = 1995$ scans) time on ground in seasonal dry forest (Matsuda Goodwin 2007). Regularly swims in rivers and mangrove estuaries (Howard 1977, Z. Tooze pers. comm.). Considered ecological generalists because of use of diverse forest types, varied diet and successful introduction to non-African forest habitats. Rapid quadrupedal locomotion facilitated by equal forelimb and hindlimb proportion. Extremely long tail used for balance.

Foraging and Food Omnivorous. Mona Monkeys forage in groups or in polyspecific associations. Home-range ca. 25–100 ha ($n = 4$) in SW Cameroon (Howard 1977). Often entire group forages in one fruiting tree where individuals rapidly pick ripe fruits, placing them into their cheek-pouches for consumption later. Unripe fruit dropped. Animals often investigate holes in trees and tree bark crevices, and scan leaves and twigs, for arthropods. They pounce upon arthropods moving in the open. They are most active during early morning and late afternoon, but forage at all times of the day (Howard 1977, Glenn 1996, Matsuda Goodwin 2007). The introduced population on Grenada uses primary forest more when fruit abundance there is high (Glenn 1996).

Mona Monkeys primarily eat fruit and arthropods, but also regularly eat other foods, including leaves, leaf piths, flowers, nectaries, lizards and birds' eggs and nestlings (Howard 1977, Glenn 1996). In mangrove swamp they also eat crabs, snails and perhaps fish (Gartlan & Struhsaker 1972, Glenn *et al.* 1999a, Z. Tooze pers. comm.). In seasonal dry forest in Bénin, Mona Monkeys eat fruits (42%), seeds (22%), leaves (13%), flowers (12%), insects (10%), others (1%) ($n = 566$ items); they eat more ripe fruits in the wet season and more unripe fruits, nectar, flowers and soft seeds in the dry season (Matsuda Goodwin 2007). Mona Monkeys regularly raid a wide variety of crops along the forest edge, such as banana *Musa* spp., Mango *Mangifera indica*, Cocoa *Theobroma cacao*, Breadfruit *Artocarpus altilis*, Oil Palm *Elaeis guineensis* and Maize *Zea mays* (Howard 1977, Glenn 1996, Glenn *et al.* 1999a, b.)

Social and Reproductive Behaviour Social. Two types of social groups occur. 'Bisexual groups' ranged in size from three to 40 individuals and comprised of one or more adult ♂♂, juveniles, subadults and several adult ♀♀ with their infants (Struhsaker 1969, Gartlan 1973, Glenn 1997, Matsuda Goodwin 2007). At Mungo Reserve, Cameroon, three groups averaged 20 animals,

Lateral view of skull of Mona Monkey *Cercopithecus mona* adult male.

with three adult ♂♂, 12 adult ♀♀ and the remaining animals subadults and juveniles (Howard 1977). In Bénin, groups averaged 13 animals (2–35, $n = 64$ groups), containing one or more adult ♂♂ (Matsuda Goodwin 2007). 'All-male groups' contain only adult and subadult ♂♂ and range in size from two to five individuals (Glenn 1997, Matsuda Goodwin 2007). On Grenada individually identifiable all-male groups averaged 2.4 animals (S.D. = 0.6, $n = 33$) with the same animals together for a few days to >2 years (Glenn *et al.* 2002). This is the only *Cercopithecus* species known to regularly form long-term all-male groups. Bisexual groups are territorial. Physical agonistic encounters between bisexual groups occur infrequently (Howard 1977). All-male groups appear to avoid agonistic encounters with bisexual groups but encounters occasionally occur. Males in all-male groups occasionally vocalize and/or visually threaten (head-bob) towards other all-male groups when in close proximity (M. E. Glenn, K. J. Bensen & R. Matsuda Goodwin pers. obs.).

Mona Monkeys observed in polyspecific associations during 95% ($n = 166$; Howard 1977) and 94% ($n = 173$; Struhsaker 1981a) of encounters. Observed in association with Crowned Monkeys, Putty-nosed Monkeys *Cercopithecus nictitans*, Red-eared Monkeys *Cercopithecus erythrotis*, Sclater's Monkeys *Cercopithecus sclateri* and White-throated Monkeys *Cercopithecus erythrogaster* (Gartlan & Struhsaker 1972, Howard 1977, Oates 1985). Polyspecific associations possibly provide anti-predator and/or foraging benefits (e.g. Gautier-Hion *et al.* 1983, Mitani 1991, Struhsaker 2000a).

In bisexual groups on Grenada usually only one adult ♂ gives the deep 'double boom' loud-call. This call is usually given twice in succession (range 1–5 times) followed by a long series of rapid 'hack' calls. These calls are given during alarm situations and/or as a territorial warning (Struhsaker 1970, Howard 1977, Glenn 1996). In seasonal dry forest in Bénin, 1–4 adult ♂♂ in the same bisexual group will give double booms and hacks, sometimes in succession. Some ♂♂ in these groups show affiliative behaviour (Matsuda Goodwin 2007). Other members of bisexual groups give 'high hack' calls when alarmed. Females occasionally give extremely high-pitched 'chirps' when alarmed. When foraging, a soft, high, one-note 'ooo' or 'squeak' contact call given by all group members. Infants 'scream' when abandoned (Struhsaker 1970, Glenn 1996). Members of all-male groups rarely vocalize except when giving contact calls or when encountering another all-male group (M. E. Glenn & K. J. Bensen pers. obs.). Possibly give predator-specific alarm calls (Howard 1977). Flee silently and give alarm vocalizations when encountering humans in areas where monkey hunting is

Mona Monkey *Cercopithecus mona* adult male.

common. Bisexual group members react to vocalizations of other primate species (Gartlan & Struhsaker 1972, Howard 1977). All individuals, both of bisexual and all-male groups, communicate threats by exaggerated head and upper body movements that alternately show and hide either white chest and belly or black eye-stripes (Struhsaker 1969, Howard 1977, Kingdon 1980, M. E. Glenn & K. J. Bensen pers. obs.). Agitated subadult and adult ♂♂ shake branches, and open mouths showing large canine teeth. Juveniles are the most curious and are often found on the periphery of the group. Juveniles are usually first to give alarm calls and last to depart from a perceived threat (M. E. Glenn & K. J. Bensen pers. obs.). On Grenada only ♂♂ in bisexual groups known to mate (Glenn 1996). In Cameroon multiple ♂♂ in same bisexual group mate (Howard 1977). The ♂ and ♀ emit unique 'rapid grunting' and 'warbling' vocalizations during copulation (Struhsaker 1970, Howard 1977, Glenn *et al.* 2002). Subadult ♂♂ in all-male groups and juveniles in bisexual groups in Grenada regularly mount each other without vocalizing (Glenn 1997). Only ♀♀ observed to carry young (M. E. Glenn, K.J. Bensen & R. Matsuda Goodwin pers. obs.). Young regularly play with each other and with young of other primate species (Howard 1977).

Reproduction and Population Structure Oestrous cycle, age at first reproduction, time to weaning and birth interval are unknown in the wild. Oestrous period occurs every six months in captive ♀♀ in Nigeria (Z. Tooze pers. comm.). Gestation length for one captive was between 128 and 187 days (median 158 days) (Takeshita 1962). Black newborns observed in Mar–Aug in Cameroon (Howard 1977). In Bénin one newborn observed in Mar (Matsuda Goodwin 2007). The introduced population on Grenada has no breeding seasonality (Glenn 1996). In Cameroon copulations observed throughout the year, but peaked in Sep–Oct (Howard 1997). Copulation calls heard most frequently from Sep–Mar during major dry season in seasonal dry forest in Bénin (Matsuda Goodwin 2007). Females give birth to one young; twins never observed in the wild. Age at first reproduction in captivity 3.2 years (Kappeler & Pereira 2003). Weight at birth in captivity ca. 284 g (Ross 1991).

Ratio of adult ♂♂ to adult ♀♀ in bisexual groups ranges from 1 : 5.5 to 1 : 8.8 (n = 3 groups). Ratio of adults to immatures ranges from 1.3 : 1 to 2.6 : 1 (n = 3 groups) (Howard 1977). Longevity, birth rates and mortality rates unknown for wild populations. Lives to 22 years in captivity (Ross 1991).

Predators, Parasites and Diseases Humans are the primary predator of the Mona Monkey throughout its range. The only observed wild predator is the African Crowned Eagle *Stephanoaetus coronatus* (Howard 1977, M. E. Glenn & K. J. Bensen pers. obs.). Other predators likely include Robust Chimpanzees *Pan troglodytes*, Leopards *Panthera pardus*, African Golden Cats *Profelis aurata* and large arboreal snakes. No details known about diseases. Nigerian populations tested positive for Yellow Fever neutralizing antibodies (Monath & Kemp 1973). The introduced Grenada population tested negative for simian immunodeficiency virus (S. Morse pers. comm.).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Populations are decreasing in parts of the range and the species has been extirpated from some sites due to habitat loss and over-hunting for the commercial bushmeat trade (M. E. Glenn & K. J. Bensen pers. obs.). Potentially more resilient to human hunting than most other monkeys (Linder & Oates 2011).

Cercopithecus lowei **LOWE'S MONKEY**

Fr. Mone de Lowe; Ger. Lowe-Meerkatze

Cercopithecus lowei Thomas, 1923. Ann. Mag. Nat. Hist., ser. 9, 11: 608. Bandama, Côte d'Ivoire.Lowe's Monkey *Cercopithecus lowei* adult male.*Cercopithecus lowei*

Taxonomy Monotypic species (Groves 2001, 2005c, Kingdon 2001). Often grouped with Campbell's Monkey *Cercopithecus campbelli* as one species (Booth 1955, Hill 1966, Dandelot 1974, Napier 1981, Lernould 1988, Grubb *et al.* 2003, Oates 2011). Intermediate forms with Campbell's Monkey near Guiglo, between the Cavally R. and Sassandra R., Côte d'Ivoire (Booth 1956b, Oates 1988b). Member of the *Cercopithecus (mona)* Group (or Superspecies) with *C. campbelli*, Mona Monkey *C. mona*, Dent's Monkey *C. denti*, Crowned Monkey *C. pogonias* and Wolf's Monkey *C. wolffi*. Synonyms: none. Chromosome number: not known.

Description Medium sized, arboreal monkey with yellow brow, rectangular cheek-ruffs and white ventrum. Adult ♀ approximately two-thirds the weight of adult ♂. Sexes similar in colour. Skin above nostrils and around eyes dark bluish-grey. Head round. Muzzle short. Skin below nostrils light pink with sparse white hairs. Cheeks light greyish-white to yellowish-white. Shape of cheek-ruffs long, broad, rectangular. 'Mask' (temporal) stripe broad, black, extending from eyes to ears. Brow yellow. Crown flat, grizzled dark yellow and black. Ear tufts grizzled light yellowish-white, short and rounded. Throat, chest, belly and inner limbs white. Dorsum reddish-brown agouti. Feet, hands and outer forelimbs black. Outer hindlimbs dark greyish-black. Sharp contrast between inner and outer limbs. Tail long, yellowish-grey to greyish-black near tip. Infant with pink face and pelage more greyish and less contrasted than adult; like adult at three months.

Geographic Variation No significant variation recorded.

Similar Species

Cercopithecus campbelli. Senegal to Cavally R. on Liberia–Côte d'Ivoire border. Sympatric between Sassandra R. and Nzo R. (G. Galat & A. Galat-Luong pers. obs.). Cheek-ruffs rounded. Brow white. Temporal stripe narrow. Belly and lower forelimbs brownish-tawny grizzle.

Distribution Endemic to West Africa. Rainforest BZ. Historically widespread in forest from Sassandra-Nzo R., Côte d'Ivoire, to Volta R., Ghana. Current distribution like historic distribution but more limited at ca. 300,000 km². Eastern-most record between Sassandra R. and Nzo R. at 06° 34' 30"N, 07° 07' 00"W in Forêt classée de Duékoué, Côte d'Ivoire (G. Galat & A. Galat-Luong pers. obs.). Distribution now more patchy than given by Lernould (1988) but less patchy than given by Oates (1988b) or Kingdon (2001). Distribution reduced due to hunting and habitat loss but still fairly widespread (McGraw 1998d).

Habitat Primary forest, secondary forest, forest outliers, gallery forests and mangrove swamps (Jones 1950). Marginal habitats include isolated forest blocks (e.g. Boabeng-Fiema Monkey Sanctuary, Ghana) that are considered sacred by some people (Fargey 1991). Present where mean annual rainfall is 1200–2500 mm.

Abundance One of the most common forest-dwelling monkeys in West Africa due to its ability to exploit degraded forest (McGraw 1998d). Relatively common near villages. Found in 13 of 19 protected forests surveyed in Ghana and Côte d'Ivoire (Oates *et al.* 2000a). Biomass was 363 kg/km² in a sacred protected forest in Ghana (Fargey 1991). One group of 5–6 individuals in degraded forest at Adiopodoume, Côte d'Ivoire, had a home-range of 14 ha (Galat-Luong & Galat 1979).

Adaptations Diurnal and arboreal. Does well in secondary forest and mangrove swamps. One of the arboreal monkeys best able to

survive outside primary forest. A. Galat-Luong (pers. obs.) found that at Adiopodoume, in degraded forest (without high emergent trees), Lowe's Monkeys are 68% of time in canopy, 30% in lower strata, 2% on ground ($n = 2811$), and spend 66% of time sitting and 30% in quadrupedal position ($n = 2793$). Spend 72% of time on branches, 25% on twigs, 2% on horizontal boughs, rarely on vertical trunks ($n = 2735$). Lowe's Monkeys sleep in tall trees with large spherical canopy (A. Galat-Luong pers. obs.). They frequently travel on the ground (W. S. McGraw pers. obs.).

Foraging and Food Primarily frugivorous. Home-ranges of two groups at Adiopodoume were 9 ha and 14 ha (A. Galat-Luong & G. Galat pers. obs.). At Boabeng-Fiema, home-range averaged 8.6 ha (S.D. = 3.6, $n = 13$ groups; Fargey 1991). In Ghana, Jeffrey (1974) noted that the fruit of *Musanga cercropiodes* was much favoured. At Adiopodoume, species eaten by Lowe's Monkeys include *Elaeis guineensis* and *Ficus exasperata* (fruit), *Ipomoea involucre* (flowers), grasshoppers and larvae in dead wood (Bourlière *et al.* 1969). They frequently feed on liana fruits. Feeding and locomotion (partially provisioned group in disturbed habitat) account for 6% and 15% of time, respectively ($n = 2841$) (A. Galat-Luong pers. obs.). Lowe's Monkeys obtain drinking water from deep tree-holes by dipping and then licking their hands (Bourlière *et al.* 1970, A. Galat-Luong pers. obs.). They also drink from freshwater springs flowing into salt water lagoons (A. Galat-Luong pers. obs.). Lowe's Monkeys can be a major pest of farms (Jeffrey 1974) and raid crops near villages (mangos, bananas, oil palm nuts; A. Galat-Luong pers. obs.).

Social and Reproductive Behaviour Social. At Adiopodoume, one group varied in size from 9 to 16 individuals (Bourlière *et al.* 1970), and declined to six individuals (Galat-Luong & Galat 1979). Average of 16.6 ind/group (S.D. = 3.8, $n = 13$) at Boabeng-Fiema (Fargey 1991). Groups at Boabeng-Fiema included one adult ♂, several adult ♀♀ and immatures. Non-sex-differentiated group structure averaged 4.9 (S.D. = 1.2) adults, 5.8 (S.D. = 1.5) subadults, 3.4 (S.D. = 1.0) juveniles and 2.5 (S.D. = 1.1) infants ($n = 13$; Fargey 1991). Subadult and young mature ♂♂ emigrate becoming solitary or forming new groups with emigrating ♀♀ (Bourlière *et al.* 1969, Hunkeler *et al.* 1972, A. Galat-Luong pers. obs.). Herding occurs (Galat-Luong & Galat 1979). Fission of groups occurs as subadult ♂♂ become 4–5 years old, following Dec–Feb births, significantly modifying group structure (Hunkeler *et al.* 1972). Galat-Luong & Galat (1979) observed the adult ♂ of one group take over leadership of a neighbouring group that comprised no adult ♂ but one subadult ♂. The adult ♀♀ of the neighbouring group, some carrying young, had severe conflicts with the new adult ♂. Four infants died during the conflicts, suggesting infanticides by the new adult ♂. The adult ♂ went back to his former group but returned to the neighbouring group during each of the following four years to copulate with the adult ♀♀ in the neighbouring group during the mating season.

Territorial behaviour is conspicuous: jumping, chest-thrusting, swaying side-to-side, penile display (Galat-Luong & Galat 1979). First inter-group distancing loud-calls made at five years of age, one year after testicles drop. At dusk the adult ♂ climbs an emergent tree and emits two 'booms', separated by ca. 4 sec. This low frequency sound (80 Hz) can be heard >1 km away. About 10 sec later he

Lateral, palatal and dorsal views of skull of Lowe's Monkey *Cercopithecus lowei* adult male.

emits a series of about ten noisy 'barks' (containing higher frequency sounds) that provide directional information. The intensity of barks is in a decrescendo, adding distance information. Neighbouring ♂♂ emit responses. Duets are performed with Lesser Spot-nosed Monkeys *Cercopithecus petaurista*. Similar barks are also emitted after a disturbance. Barks were once heard emitted in response to an ultra-light motorized airplane (the group then kept quiet for five hours) (A. Galat-Luong & G. Galat pers. obs.). All individuals emit a pure tone, non-quavered, cohesion-contact 'o-mii' call during which low and high pitches merge. As ♂♂ become four years old, and the testicles drop, this call becomes a low-pitched, still pure tone, 'mao' call (A. Galat-Luong & G. Galat pers. obs.). High-pitched warning calls (e.g. 'chirps') are not given. Adult ♀♀ give a protruded mouth, rhythmic, copulation request and copulation call (A. Galat-Luong & G. Galat pers. obs.). Other vocalizations include a loud sneeze alarm call and a nasal 'ooeeoo' contact call (Kingdon 2001).

Adult ♂ solicits mounting by putting his hand on the rump of the ♀. She puts her tail on her back permitting him to mount, or sits to refuse. Young ♀♀ accept courtship of extraneous ♂♂ more readily than do older ♀♀ (Galat-Luong & Galat 1979). Allocare of young infants by adult and immature ♀♀ is common (Bourlière *et al.* 1970), while rare by immature ♂♂ (one individual in five; Hunkeler *et al.* 1972, A. Galat-Luong pers. obs.).

Social and resting behaviours account for 8% and 70% of time, respectively (partially provisioned group) (A. Galat-Luong pers.

obs.). Cohesion of group important: mean distance of the nearest individual is 3 m at dawn (ca. 06:00h), increases gradually to 6 m at 09:00h, is 5 m until 14:00h, increases to 7 m at 16:00h, and decreases gradually to 4 m at dusk (ca. 18:45h) ($n = 2818$). The nearest neighbour is a ♀ 72% of the time ($n = 2499$); an adult 40% of the time and an infant 25% of the time ($n = 2862$) (A. Galat-Luong pers. obs.). Lowe's Monkeys display various play behaviours (Galat 1983), including chasing of ants (*Oecophylla longinidis*), frogs, Gambian Sun Squirrels *Heliosciurus gambianus*, doves, Black Kites *Milvus migrans* and African Pied Hornbill *Tockus fasciatus* (Bourlière *et al.* 1970, Hunkeler *et al.* 1972). Lowe's Monkeys associate with other monkey species, especially *C. petaurista*, and are frequently followed by White Crested Hornbills *Tropicranus albocristatus* (Bourlière *et al.* 1969, A. Galat-Luong pers. obs.).

Reproduction and Population Structure Oestrous cycle, birth-weight, time to weaning, and age at first reproduction unknown. After 25 weeks' gestation singletons are born ($n = 18$; Bourlière *et al.* 1969, A. Galat-Luong pers. obs.); twins are not reported. At Adiopodoume one adult ♀ gave birth to one infant per year for four years (i.e. birth interval ca. one year) from two different ♂♂ (A. Galat-Luong & G. Galat pers. obs.). Most matings occurred after the long rains and during the coolest part of the year (Jun–Sep). Birth peak in Dec–Jan at end of short rains and beginning of main dry season. Sex ratio ♂ : ♀ 1 : 2.0 to 1 : 1.5; adult to immature ratio 1 : 1.4 to 1 : 4.3 ($n = 1$ group; Bourlière *et al.* 1970). Longevity >28 years in the wild (A. Galat-Luong pers. obs.).

Predators, Parasites and Diseases Humans, and probably also Leopards *Panthera pardus*, African Crowned Eagles *Stephanoatus coronatus* and Robust Chimpanzees *Pan troglodytes* are the main predators. Harass mambas *Dendroaspis* sp. (as if they were potential predators) with sneezes, loud-calls (barks) and branch-shaking until the mambas fall (A. Galat-Luong & G. Galat pers. obs.). Lowe's Monkeys play a major role in the transmission of Yellow Fever to humans because they: (1) have a high proportion of immature animals in the population; (2) are adapted to second growth forest; (3) inhabit lower forest strata; and (4) readily live near villages (Galat-Luong & Galat 1979, Galat & Galat-Luong 1982, 1997).

Conservation IUCN Category (2012): Least Concern (as *C. campbelli lowei*). CITES (2012): Appendix II.

Lowe's Monkeys are threatened when forest patches are reduced and fragmented, but survive if they are sufficiently connected (Mühlenberg *et al.* 1990). Benefits from the protection of sacred forests (Galat & Galat-Luong 1997).

Measurements

Cercopithecus lowei

HB (♂♂): 480 (400–550) mm, $n = 3$

T (♂♂): 600 (510–770) mm, $n = 3$

HF (♂♂): 130, 150 mm, $n = 2$

E (♂♂): 28, 31 mm, $n = 2$

Cercopithecus campbelli CAMPBELL'S MONKEY

Fr. Mone de Campbell; Ger. Campbell-Meerkatze

Cercopithecus campbelli Waterhouse, 1838. Proc. Zool. Soc. Lond. 1838: 61. Sierra Leone.Campbell's Monkey *Cercopithecus campbelli* adult male.*Cercopithecus campbelli*

Taxonomy Monotypic species (Groves 2001, 2005c, Kingdon 2001). Often grouped with Lowe's Monkey *Cercopithecus lowei* as one species (Booth 1955, Hill 1966, Dandelot 1974, Napier 1981, Lernoould 1988, Oates 1988b, 2011, Grubb *et al.* 2003). Intermediate forms with Lowe's Monkey near Guiglo, between Cavally R. and Sassandra R., Côte d'Ivoire (Booth 1956b, Oates 1988b, 2011). Member of the *Cercopithecus (mona)* Group (or Superspecies) with Mona Monkey *C. mona*, Dent's Monkey *C. denti*, Crowned Monkey *C. pogonias* and Wolf's Monkey *C. wolffi*. Synonyms: *burnettii*, *monella*, *?temminckii*. Chromosome number: $2n = 66$ (Dutrillaux *et al.* 1988b).

Description Medium-sized, arboreal monkey with white brow, rounded cheek-ruffs, and brownish-tawny belly and lower limbs. Adult ♀ approximately two-thirds size of adult ♂. Sexes similar in colour. Skin below nostrils light pink with sparse white hairs. Skin above nostrils and around eyes dark bluish to greyish-black. Head round. Muzzle short. Cheeks pale greyish-white to yellowish-white, with long, broad, circular shape. 'Mask' (temporal) stripe narrow, black, extending from eyes to ears. Brow whitish. Crown flat, grizzled dark yellow and black. Ear tufts grizzled light yellowish-white, short and rounded. Dorsum reddish-brown agouti. Outer limbs and rump dark grey. Inner limbs and belly brownish-tawny grizzle. Tail long, grey in middle to greyish-black near tip. Infant with pink face and pelage more greyish and less contrasted than adult; like adult at three months.

Geographic Variation No significant variation recorded.

Similar Species

Cercopithecus lowei. Cavally R. (Groves 2001) or Sassandra-Nzo R. (Galat 1983), Côte d'Ivoire to Volta R., Ghana. Sympatric between Sassandra R. and Nzo R. (G. Galat & A. Galat-Luong pers. obs.). Cheeks rectangular. Brow yellow. Belly and lower inner forelimbs white.

Distribution Endemic to West Africa. Rainforest BZ. Gambia to Côte d'Ivoire, west of Sassandra–Nzo R. over an area of ca. 100,000 km². Distribution more patchy than drawn by Lernoould (1988) but less patchy than drawn by Oates (1988b) and Kingdon (2001). Historically, distributed throughout primary and secondary forest zone from Gambia to Sassandra–Nzo R.

Habitat Primary and secondary forests, forest outliers and gallery forests. Marginal habitats include isolated forests and gallery forests in wooded savanna, mangrove swamps and forests that people consider sacred (Jones 1950, Galat & Galat-Luong 1997). Annual rainfall 1200–2500 mm. Altitude ranges from 0 m (mangrove swamps) to 900 m at Mt Nimba, Guinea (Galat-Luong & Galat 1990), and to 1400 m at Fouta Djallon, Guinea (A. Galat-Luong pers. obs.).

Abundance The most common and widespread monkey in Sierra Leone (Jones 1950, Grubb *et al.* 1998). Represents 15% of the groups ($n = 427$ groups encountered) and 10% of the individuals

($n = 7455$ individuals encountered) in Tai Forest, Côte d'Ivoire. Based on these data and on the estimations of Bourlière (1985), Oates *et al.* (1990) calculated ca. 2.5–3.5 groups/km² and a biomass of 82–94 kg/km² for Tiwai, Sierra Leone. For 2006–08 in Tai N. P., 0.92 groups/km², 5.3 ind/km², and total population of 29,700 (N'Goran *et al.* 2012).

Adaptations Diurnal and arboreal. Adapts readily to young secondary forest and mangrove swamps. Particularly good swimmer in Sierra Leone (Grubb *et al.* 1998). One of the arboreal monkeys best able to survive near villages. In undisturbed forest (Tai) spends 15% of time on the ground, 79% in understorey and 5% in main canopy (Galat & Galat-Luong 1985, $n = 633$; McGraw 1998a). Fimbel (1994a) observed higher terrestriality (33%) in disturbed habitats, including abandoned farms. Frequently drops to the ground for long-distance travel in primary forest (McGraw 1998a). Predominantly quadrupedal (80%) with moderate amounts of climbing (14%) and leaping (5%) (McGraw 1996, 1998a, b, c, 2000); 71% of time sitting, 22% standing (McGraw 1998c). Uses large boughs (15–32%), branches (44–48%), twigs (20–28%) and other supports (<1–16%) (Galat & Galat-Luong 1985, McGraw 1998b, c). Sleeping sites include tall trees with large, spherical canopy (Galat 1983).

Foraging and Food Omnivorous. Campbell's Monkey is a slow, cautious forager. In Tai mean day range 1.2 km (1.0–1.5 km, $n = 85$ days; Buzzard 2006c) and home-range 40 ha ($n = 1$) (Galat & Galat-Luong 1985). Feeding (23–36%) and foraging (35–46%) are the principal maintenance activities, while resting and social activities take, respectively, 20–26% and 3–5% of time (Galat 1983, Galat & Galat-Luong 1997, McGraw 1998a, 2000). Diet comprises fruit 46–78%, invertebrates 15–33%, foliage 0–8%, flowers 0–1% and other 7–9% (data collected over 14 months; Galat & Galat-Luong 1985, Buzzard 2006b). Species eaten include *Ficus* spp., *Parinari excelsa*, *Dialium guineense*, *Mangifera indica*, *Parkia biglobosa* (Harding 1984a) and *Pseudospondias microcarpa* (D. Starin pers. comm.). Eat wild and cultivated fruits, seeds, cocoa, coffee, insects and grubs, small amphibians and lizards. In mangrove swamps eats mangrove leaves, germinating hanging seeds of *Rhizophora* sp., crabs, shrimps and mud skippers (Grubb *et al.* 1998).

Social and Reproductive Behaviour Social. Groups are one-adult male harems. Mean group size = 7.7 individuals (1–24, $n = 23$) at Kilimi, Sierra Leone (Harding 1984b), 11.4 (5–33, $n = 9$) at Tai (Galat & Galat-Luong 1985), 5–25 (Grubb *et al.* 1998) and 14 ($n = 1$) in Sierra Leone (Oates *et al.* 1990). Territorial behaviour is conspicuous. At dawn and dusk the adult ♂ climbs an emergent tree and emits two 'booms', separated by ca. 4 sec, the time necessary to inflate its vocal sac. This low frequency sound (80 Hz) can be heard for up to 1 km. After ca. 10 sec (the time necessary for other adult ♂♂ to also climb emergent trees), a series of up to ten noisy barks is emitted, including higher frequency vocalizations that give directional information. The intensity of these barks is in decrescendo, adding distance information. Speed of barks is related to context and caller identity (Lemasson *et al.* 2010). Concatenated sequences, affixations and ♀♀ alarm calls are linked to specific external events (Ouattara *et al.* 2009a, b, c). Pure tone, non-quavered, cohesion-contact calls are given; a low ('oo') and high-pitched whistle ('mii') merge ('o-mii').

No high-pitched warning calls (e.g. 'chirps') are emitted (G. Galat & A. Galat-Luong pers. obs.). Also see McGraw & Zuberbühler (2008).

The adult ♂ solicits mounting by putting his hand on the rump of the ♀. She puts her tail upon her back, permitting the mount.

In Sierra Leone, Campbell's Monkeys associated with one or more other monkey species in 37% of encounters ($n = 52$; Whitesides 1989, Oates & Whitesides 1990), and in 76% of encounters at Tai ($n = 63$; Galat & Galat-Luong 1985). At Tai they associate with Diana Monkeys *Cercopithecus diana* (44% of encounters during censuses), Putty-nosed Monkeys *Cercopithecus nictitans* (<1%), Lesser Spot-nosed Monkeys *Cercopithecus petaurista* (50%), Sooty Mangabeys *Cercocebus atys* (23%), Western Red Colobus *Procolobus badius* (31%), Olive Colobus *Procolobus verus* (28%) and King Colobus *Colobus polykomos* (12%). Campbell's Monkeys synchronize movements with *C. diana* and *C. petaurista* (Galat & Galat-Luong 1985) and engage in polyspecific territorial conflicts that are led by *C. diana*. During these conflicts, the species emit loud-calls in the following order: *C. diana*, Campbell's Monkey and *C. petaurista*, variously followed by *P. badius*, *P. verus* and *C. polykomos* (Galat 1983). Adult ♂♂ are the first to emit inter-group distancing loud-calls thus initiating the inter-location process of the other monkey species while choosing sleeping trees for the night. Long loud-call duets are performed with *C. petaurista*, with which home-range overlaps extensively (85%) (Galat & Galat-Luong 1985). One solitary subadult ♂ in Gambia associated with *P. badius* (Starin 1991). Blue Duikers *Philantomba monticola* follow below Campbell's Monkey groups (A. Galat-Luong pers. obs.). See also Buzzard (2010).

In Tai inter-specific interactions involving Campbell's Monkeys include displacement by *C. diana* and *P. badius*, play fighting with *P. badius*, grooming solicitation with *P. badius*, and grooming by *P. badius* and *P. verus* (Galat-Luong 1979, McGraw 2000, W. S. McGraw pers. obs.). D. Starin (pers. comm.) observed grooming by *P. badius* and a tentative mounting of an adult ♀♀ Green Monkey *Chlorocebus sabaeus*. Campbell's Monkey group members are often positioned closer to other cercopithecoid species than to conspecifics (A. Galat-Luong & G. Galat pers. obs.).

Reproduction and Population Structure Gestation is 25 weeks; singletons born; twins not reported. Birth peak Dec–Jan. At Tai ♂ : ♀ ratio ranges from 1 : 1.0 to 1 : 1.9 ($n = 7$ groups) and adult to immature ratio is 1 : 1 ($n = 11$). One solitary adult ♂ observed (Galat & Galat-Luong 1985). Maximum longevity in captivity 33 years (Jones 1982).

Predators, Parasites and Diseases Campbell's Monkeys are preyed upon by humans (McGraw 2007b), Leopards *Panthera pardus* (Hoppe-Dominik 1984, Zuberbühler & Jenny 2002, 2007), Robust Chimpanzees *Pan troglodytes* (Alp 1993, Alp & Kitchener 1993) and African Crowned Eagles *Stephanoaetus coronatus* (Schultz 2001, Schultz & Thomsett 2007). A young Campbell's Monkey survived a *S. coronatus* attack by fleeing on the ground and, just prior to the attack, crouching and hiding in the grass (Galat 1983). Campbell's Monkeys emit predator-specific alarm calls for *S. coronatus* and *P. pardus* (Zuberbühler 2000b, McGraw & Zuberbühler 2008).

Campbell's Monkey plays a major role in the transmission of Yellow Fever to humans because it is adapted to second growth forest, inhabits lower forest strata and readily lives near villages (Galat & Galat-Luong 1997).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The destruction of the rainforest and its replacement with farms, farm bush and secondary forest, with its congenial habitat and more abundant food supply, suits Campbell's Monkey and has led to its increase. Campbell's Monkey is now limited only by hunting, particularly in the south-east. They are a serious pest of crops, being particularly damaging to both swamp and upland rice, which is pulled up and the juicy ends of the central leaves eaten, and later also the grain. Also a pest of Cocoa *Theobroma cacao* (Grubb *et al.* 1998). The species is threatened or eliminated when forest patches are reduced or where it is over-hunted by humans, particularly in Gambia (Starin 1989). Probably extirpated from Gambia in the 1980s (E. D. Starin pers. comm. to T. Butynski). Campbell's Monkey is protected in sacred woods (Galat & Galat-Luong 1997) and survives in forest islands if they are sufficiently connected.

Measurements

Gérard Galat, Anh Galat-Luong, Mary E. Glenn & W. Scott McGraw

Cercopithecus denti DENT'S MONKEY

Fr. Mone de Dent; Ger. Dent-Meerkatze

Cercopithecus denti Thomas, 1907. Abstr. Proc. Zool. Soc. Lond. (1907) 38: 1. Ituri Forest between Mawambi and Avakubi, DR Congo.

Dent's Monkey *Cercopithecus denti* adult female.

Taxonomy Monotypic species. The most easterly distributed type of the *C. (mona)* Group or Superspecies (Schwarz 1928c, Booth 1955). This taxon is provisionally treated here as a monotypic species, although the taxonomic classification remains unresolved. While many have placed *denti* in its own species (Pocock 1907, Thomas 1907, Matschie 1912, Lonnberg 1919, Booth, 1955, Hill 1966, Thorington & Groves 1970, Napier 1981, Groves 2001, 2005c), others treated *denti* as a subspecies of Mona Monkey *Cercopithecus mona* (Schwarz 1928c, Allen 1939), Wolf's Monkey *Cercopithecus wolffi* (Colyn 1988, Lernoold 1988, Gautier-Hion *et al.* 1999), or more recently Crowned Monkey *Cercopithecus pogonias* (Thomas 1991, Grubb *et al.* 2003, Detwiler 2010). Because the range of *C. denti* must overlap or abut that of Gray's Crowned Monkey *Cercopithecus pogonias grayi* in forests north

of the Congo R., DR Congo, objective proof that *denti* is a species, as opposed to a subspecies, depends in part on what occurs at this contact zone. The specific status of *C. denti* would be further clarified by resolving the status of what some may argue is its closest relative, the Lomami River Wolf's Monkey *Cercopithecus wolffi elegans* (Lonnberg 1919, Schwarz 1928c, Booth 1955, Gautier-Hion *et al.* 1999, Grubb *et al.* 2003). In forests between the Lomami R. and Lualaba R. DR Congo, *C. elegans* may come into contact with *C. wolffi*, but nothing is known of this contact zone. Finding at this contact zone that *C. elegans* is specifically distinct from *C. wolffi* would suggest that *C. denti* (the closest relative of *C. elegans*) is also specifically distinct from *C. wolffi*. Nevertheless, there still would be the question as to whether *C. elegans* is more properly referred to as a subspecies of *C. denti* or belongs in its own species, *C. elegans*. If *C. denti* is recognized as specific, the various nested relationships and large number of types (11) within the *C. (mona)* Group (Schwarz 1928c, Booth 1955) indicate this group should be elevated to a generic rank, for which *Mona* (Reichenbach 1862) is available. Synonyms: *liebrechtsi*. Chromosome number: $2n = 68$ (Dutrillaux *et al.* 1988b).

Description Medium-sized, arboreal monkey with cream to white undersides that reach high up on flanks and are sharply demarcated from burnt-amber coloured back. Colouration same in both sexes. Average adult ♀ weight is about two-thirds that of average adult ♂. Bare facial skin around deeply sunk eyes is slate-blue. Frontal band off-white, indistinct, varies in presence and development (Lonnberg 1919, Allen 1925). Black hair tuft from outer corner of brow extends back to just above ear to form a high, variably fading, black temporal band. Upper and lower lips covered in short white hairs. Cheeks and jowls covered in buff hairs, some with

single black bands resulting variably in a light grey to grey tint. Ears with long, curved, off-white to straw-yellow hair tuft. Crown and nape olive-grey, speckled by hairs with off-white bands producing yellow highlights. Speckling continuous onto upper back, shoulders and arms. On back, from base of tail to shoulders, colour grades to burnt-umber. This colour is produced by grey-based hairs with three to four black and dark orange (sienna) alternating bands. Dorsum of forelimbs from elbow down to hand black. Outside of hindlimbs brown, lighter than back with speckling producing orange highlights. Foot dorsum black. Cream-white of undersides extends to chin and throughout inner-side of limbs where it is sharply demarcated from the colour of the outside limbs. Burnt-umber of back continues onto tail dorsum gradually grading into grizzled grey ca. 25% of the way down. Proximal ca. 25% of tail underside cream to light yellow, well demarcated from dorsal colour, but distally colour grades into light grey without clear demarcation from dorsum. Distal ca. 20–33% of tail gradually grades into black all around ending in a slight tuft. Scrotum pale greyish-blue. Palmar and plantar skin is black. As noted by Allen (1925), *C. denti* shows relatively little variation in coat colouration when compared to other guenon species. An infant with only an erupting first milk molar and first incisor had adult colour pattern. Hair, however, is much softer and shorter than in adult and undersides of body and inner-sides of limb are nearly bare, exposing golden skin (Allen 1925).

Geographic Variation There is no reported variation linked to geographic distribution that would relate to population or subspecific differences (Allen 1925, Napier 1981, Groves 2001, 2005c).

Similar Species

Cercopithecus wolffi elegans. Eastern Congo Basin between upper reaches of Lomami R. and Lualaba R. White brow-band extends back over temples to just above the ears, adpressed hair below temples, and sharp colour division between light grey thighs and dark greyish-brown of small of the back (Booth 1955, Napier 1981).

Cercopithecus pogonias grayi. West of 22° E between Congo R. and Ubangi R. Rump dark brown or black; tail black throughout dorsal extent; outer hindlimbs tan-grey to iron-grey; underparts light yellow to yellow grading into dark yellow flanks and chestnut-brown back without a sharp colour demarcation; sagittal crest of erect black hairs running back from the brow and flanked on either side by an oval patch of off-white hairs medial to wide black temporal bands.

Distribution Endemic to E DR Congo, Burundi, Rwanda and SW Uganda. Rainforest BZ. In forest block between Western (Albertine) Rift Highlands and right bank of Congo R. and Lualaba R. Distribution poorly known north of Congo R., but collected as far north at 03° 30' N (just south of Uele R.), and as far east as 30° 45' E (in headwaters of Kibali R. and Ituri R. in highlands west of L. Albert). Blancou's (1935) often cited (Malbrant 1952, Booth 1955, Napier, 1985, Lernoould 1988, Groves 2001, 2005c) claim of *C. denti* extending to forests north of the Ubangi R. (06° 40' N) near M'brés, Central African Republic, is based on a misidentification of *C. p. grayi* that was later corrected by Blancou (1958, cited in Lernoould 1988).

Along right bank of Congo R. the westward extent seems to be limited by the lower Itimbiri R. (Lernoould 1988), but, farther

Cercopithecus denti

north, collected on both sides of the Itimbiri R. Western extent past 24° E not known. Considering *C. p. grayi* has been collected just east of 22° E in forest between Ubangi R. and Congo R. (Schouteden 1944a, Booth 1955), and ranges as far east as 25° E to between Uele R. and Mbomu R. (E. E. Sarmiento pers. obs.), the intervening area is likely a zone of parapatry, sympatry or hybridization (Booth 1955). Records north of the Uele R., shown in Schouteden's (1944a), Booth's (1955) and Dandelot's (1965) maps, have not been verified on the basis of museum specimens, locality reports or field observations. Given that eastwards the Uele R. and its tributaries (Bomakandi R. and Kibale R.) are porous barriers, the north-eastern extent of *C. denti* is unknown. *Cercopithecus denti* may occur north of the Uele R. and its tributaries (Dandelot 1965), but has never been collected here, north of the Mbomu R. or in Sudan (Kock 1969), where forest fragmentation becomes extensive. Throughout most of its eastern extent *C. denti* is found west of the Western Rift lakes, only occurring east of the lakes along their interconnecting rivers (i.e. Semliki R. and Ruzizi R.); enters SW Uganda crossing the Semliki R. to reach Bwamba Forest at just over 30° E; enters W Rwanda north of L. Kivu to reach Kisenyi at 29° 15' E; and crosses the Ruzizi R. to enter S Rwanda (Nyungwe N. P.) and N Burundi (Ruzizi Plain) at ca. 29° 15' E. Southern limit for *C. denti* is Kabambare at roughly 04° 42' S. This is south of the Luama R. and coincides with the break-up of equatorial forest. No recent records for Virunga N. P., highlands west of L. Edward (Frechkop 1938, 1943, Hoier 1955, Curry-Lindhal 1956, Verschuren 1972) or region around L. Kivu (Rahm & Christiaensen 1963, E. E. Sarmiento pers. obs.), although there are early museum records for these localities.

Habitat Inhabits riverine, lowland and secondary forests and, less commonly, lower montane forest, at altitudes between 400 m and 1900 m (Haddow 1952, Rahm 1966, Thomas 1991, E. E. Sarmiento pers. obs. in DR Congo and SW Uganda). Report of an adult ♀ *C. denti* and its supposed hybrid offspring in a group of Doggett's Silver

Monkeys *Cercopithecus mitis doggetti* at 2500 m in Nyungwe N. P. (B. Kaplin pers. obs. in Detwiler *et al.* 2005) has not been verified. This report is 600 m higher than otherwise observed for *C. denti*.

In Semliki N. P., SW Uganda, and Ituri Forest, DR Congo, *C. denti* more often in secondary forest and forest interior than on periphery (Haddow 1952, Thomas 1991). In SW Uganda, marginally ranges into swamp forest and *Cynometra* forest (J. Kingdon pers. obs.). Usually found close to water or in forests where floods create sites with secondary growth. Mean annual rainfall is >1400 mm and may be >3000 mm in the highlands west of L. Albert where *C. denti* reaches maximum altitude. Mean annual temperature at the lowest (ca. 400 m) and highest (1900 m) altitudes is roughly 25 °C and 15 °C, respectively. Nowhere in the range do temperatures drop below freezing. Close to the Equator there are two dry seasons, each roughly two months in duration. One dry season progressively shortens and the other lengthens with distance from the Equator so that at those latitudes farthest from the Equator *C. denti* may endure a three-month dry period with little rain.

Abundance Common all along right banks of Congo R. and Lualaba R. from the Congo–Itimbiri confluence to 03°S (Colyn 1988). In Ituri Forest, common in the southern and central sectors, which have a wealth of rivers (Biena, Epulu, Ituri, Lindi, Nepoko and Semliki) creating gaps for secondary forest growth within mast-fruiting, monodominant (*Gilbertiodendron*) forests (Hart *et al.* 1986, Thomas 1991). Uncommon in northern Ituri with fewer rivers (Nepoko and Ituri) and mixed forests dominated by *Brachystegia laurentii* and *Cynometra alexandri* (Hart *et al.* 1986). In secondary forests within Ituri, *C. denti* most abundant in year-round fruiting stands of Umbrella Tree (African Corkwood) *Musanga cecropioides* (Thomas 1991). In central and northern Ituri, transect censusing estimated 23.1 ind/km² and group density of 2.4/km² (Thomas 1991). Common in forests between L. Kivu and Lualaba R. (Rahm 1966). Transect censusing within the Lowland Sector of Kahuzi-Biega N. P. yielded estimates of 12.6 ind/km² and 1.3 groups/km² in the KB1 Sector, and 17.3 ind/km² and 1.8 groups/km² in the KB2 Sector (Hall *et al.* 2003).

Adaptations Diurnal and arboreal. *Cercopithecus denti*'s ability to associate in groups with other monkeys, maximize food availability and minimize competition may be the most important adaptations, and all likely linked to its rich vocal repertoire. Unfortunately, the corresponding anatomy, physiology and behaviour underlying these adaptations is unknown. The relatively small body size enables *C. denti* to exploit food on peripheral branches and facilitates movement up trees and through the canopy.

Foraging and Food A frugivore–folivore supplementing diet with invertebrates. Diet of *C. denti* not studied in detail. Stomach of one animal collected in Bwamba Forest comprised almost entirely of leaves and shoots (Haddow *et al.* 1947). Stomachs from animals collected in lowland forests east of L. Kivu close to Irangi contained 'Mutakala' fruit and tree gum (Rahm 1966). Mbuti pygmies report that *C. denti* eats Maize *Zea mays*, Oil Palm fruits *Elaeis guineensis*, banana *Musa* sp., Papaya *Carica papaya* and pumpkin *Cucurbita* sp. (Carpaneto & Germi 1989). This species is likely to consume fruits, young leaves and shoots, seeds, insects and gum in order of decreasing proportion in the diet.

Nectar, mushrooms and vertebrates probably form a small part of the diet. As for other guenons, proportions of items in the diet are likely to change with season and availability, with seed consumption inversely related to insect and fruit consumption. Considering the diet of other *C. (mona)* Group members, the frequent association of *C. denti* with Schmidt's Red-tail Monkeys *Cercopithecus ascanius schmidtii*, and their similarities in body size, *C. denti* is likely to include less fruit and more leaves and seeds in their diet than *C. ascanius*. Haddow (1952) notes *C. denti* has two feeding periods during the day, one in early morning and a much longer one in afternoon to evening.

Cercopithecus denti usually occupies the higher levels of the understorey and lower levels of the canopy, but sometimes feeds in the highest part of the canopy. They occasionally move on the ground (Haddow *et al.* 1951), probably in search of food. Natives claim that *C. denti* never comes to ground to feed on salt or other minerals (Carpaneto & Germi 1989, E. E. Sarmiento pers. obs.) and they report that *C. denti* has the ability to swim (E. E. Sarmiento pers. obs.). Nothing is known of daily travel distance or of home-range. Given its body size and group size, a mean daily travel distance of 1.0–1.5 km is expected.

Social and Reproductive Behaviour Social. Group composition has yet to be studied in detail but *C. denti* groups appear to consist of a single adult ♂, with two or more ♀♀ and their offspring. All-male groups probably exist but have yet to be verified. Mean group size in Kahuzi-Biega N. P. was 9.8 individuals (Hall *et al.* 2003) and in Ituri Forest was 9.6 individuals (7–21, n = 52 groups; Thomas 1991). Kingdon (1971) observed a group of 12 individuals in Bwamba Forest and noted that *C. denti* groups disperse into subgroups of twos and threes when pursued by hunters.

Cercopithecus denti often feeds in company of *C. ascanius* and Grey-cheeked Mangabey *Lophocebus albigena* (Haddow 1952, Rahm 1966, E. E. Sarmiento pers. obs. in Semliki N. P.). In Semliki N.P. also seen with Guereza *Colobus guereza*. Mbuti pygmies in NE DR Congo report that *C. denti* also forms associations with Stuhlmann's Blue Monkeys *Cercopithecus mitis stuhlmanni*, Eastern Red Colobus *Procolobus rufomitratus* and *C. guereza* (Carpaneto & Germi 1989).

In Nyungwe N. P., *C. denti* reported to hybridize with *C. m. doggetti* and *C. a. schmidtii* (Detwiler *et al.* 2005, Detwiler & Gray 2006, Detwiler 2010). The hybrids resided with a *C. m. doggetti* group and an Angola Colobus *Colobus angolensis* group, respectively. Photographs of the alleged *C. denti* × *C. a. schmidtii* hybrid depict an animal that strongly resembles a *C. a. schmidtii* × *C. m. doggetti* hybrid. This, together with the absence of any obvious hybrids among hundreds of *C. denti* museum specimens (Allen 1925, E. E. Sarmiento pers. obs.), questions the existence of *C. denti* hybrids in Nyungwe N. P.

Cercopithecus denti has a large (but unstudied) vocal repertoire that includes 'chirps', 'screams', 'coos' and 'booms' (E. E. Sarmiento pers. obs. in Semliki N. P.). Boom calls, uttered only by adult ♂♂, probably serve to space-out neighbouring groups and rally group members, especially after disturbances (J. Kingdon pers. obs.).

Reproduction and Population Structure Nothing known of *C. denti* reproduction or population structure in the wild. Ovulatory cycle length and gestation length, as in most other guenons, are likely 30–32 days and 140–187 days, respectively (Hill 1966). Females show no external signs of ovulation. Museum records of infants of

the same dental age occur throughout the year (E. E. Sarmiento pers. obs.), indicating there is no exclusive breeding season. As for other guenons, an annual birth peak for *C. denti* is likely (Butynski 1988).

Predators, Parasites and Diseases Ugandan and Congolese natives do not commonly hunt *C. denti* (E. E. Sarmiento pers. obs.). Mbuti pygmies have taboos against adults of child-bearing age or participants in circumcision rites eating the flesh of *C. denti* (Carpaneto & Germe 1989). *Cercopithecus denti* not known to be used for utilitarian or ornamental purposes. As such, hunting by humans does not appear to pose a serious threat. *Cercopithecus denti* is a relatively rare prey of Leopards *Panthera pardus* (Hayward *et al.* 2006). Although its body size is probably within the optimal prey size for African Golden Cats *Profelis aurata*, Mbuti pygmies claim it climbs too fast to be this cat's prey (Carpaneto & Germe 1989). A propensity to feed high in trees makes *C. denti* a likely predator for African Crowned Eagles *Stephanoaetus coronatus*, but its constant association with other vigilant monkeys probably greatly reduces this threat. Its occasional forays into water may make it susceptible to attacks by Nile Crocodiles *Crocodilus niloticus*, especially in Semliki N. P. and Ituri Forest, where *C. niloticus* are numerous. Mbuti pygmies also claim *C. denti* is prey to pythons *Python* sp. (Carpaneto & Germe 1989).

Cercopithecus denti in SW Uganda carries Yellow Fever, Semliki Forest Virus and Bwamba Fever Virus (Haddow 1952). Early reports that *C. denti* carries simian immunodeficiency virus (SIV) were based on analyses of other *C. (mona)* Group members. More recent studies verify that *C. denti* carries a unique SIV strain (Dazza *et al.* 2005). This species harbours the liver parasite *Hepaticystes kochi* (Haddow 1952).

Conservation IUCN Category (2012): Least Concern (as *C. p. denti*). CITES (2012): Appendix II.

Cercopithecus denti has been extirpated from Kisenyi as a result of clearing of forests. Its survival on the Ruzizi Plain is far from certain and no doubt precarious. In Bwamba Forest numbers are said to be declining (Kingdon 1971). Dependent on forests within an area of occurrence of roughly 564,000 km² (correcting for hilly terrain). Rapidly growing human populations over much of the range of *C. denti* will continue to reduce the abundance and geographic range of this species.

Measurements

Cercopithecus denti

TL (♂ ♂): 1275 ± 95.7 (1050–1430) mm, n = 22

TL (♀ ♀): 1087 ± 84.4 (915–1215) mm, n = 14

Trunk length (♂ ♂): 467 ± 35.93 (380–515) mm, n = 22

Trunk length (♀ ♀): 414 ± 44.16 (320–475) mm, n = 14

T (♂ ♂): 808 ± 72.39 (650–960) mm, n = 22

T (♀ ♀): 673 ± 72.31 (530–770) mm, n = 14

HF (♂ ♂): 149 ± 9.79 (125–177) mm, n = 22

HF (♀ ♀): 142 ± 7.44 (115–142) mm, n = 14

E (♂ ♂): 36 ± 2.11 (32–39) mm, n = 12

E (♀ ♀): 35 ± 2.30 (31–38) mm, n = 14

WT (♂ ♂): 4.2 ± 0.572 (3.6–5.0) kg, n = 4

WT (♀ ♀): 2.8 ± 0.340 (2.0–3.7) kg, n = 36

Cercopithecus wolffi WOLF'S MONKEY

Fr. Mone de Wolf; Ger. Wolf-Meerkatze

Cercopithecus wolffi Meyer, 1891. Notes Leyden Museum 13: 63. 'Central West Africa'.

Congo Basin Wolf's Monkey *Cercopithecus wolffi wolffi* adult.

Taxonomy Polytypic species in the *Cercopithecus (mona)* Group (or Superspecies). Considered by some authorities as a subspecies of Crown Monkey *C. pogonias* or as conspecific with Dent's Monkey *C. denti* (Dorst & Dandelot 1970, Gautier-Hion *et al.* 1999, Grubb *et al.* 2003). Here we follow Groves (2001, 2005c) in recognizing three subspecies: Congo Basin Wolf's Monkey *C. w. wolffi*, Lomami River Wolf's Monkey *C. w. elegans*, and Fire-bellied Wolf's Monkey *C. w. pyrogaster*. Synonyms: *elegans*, *pyrogaster*. Chromosome number: 2n = 72 (Dutrillaux *et al.* 1988b).

Description A round-headed, short-muzzled, long-tailed, arboreal monkey with a black facial mask, long ear-tufts, and light dorsal stripe. Adult ♀ like adult ♂ in colouration but smaller, weighing ca. 75% as much as adult ♂. There is considerable variation in pelage colour among the three subspecies (see Geographic Variation). Facial skin above nostrils dark blue. Eyelids flesh-coloured. Muzzle below nostrils flesh-coloured with sparse white hairs. Pelage of nasal region and around eyes black, fine and short, forming a facial 'mask'. Black pelage of upper cheeks shorter and

Congo Basin Wolf's Monkey *Cercopithecus wolfi wolfi* adult.

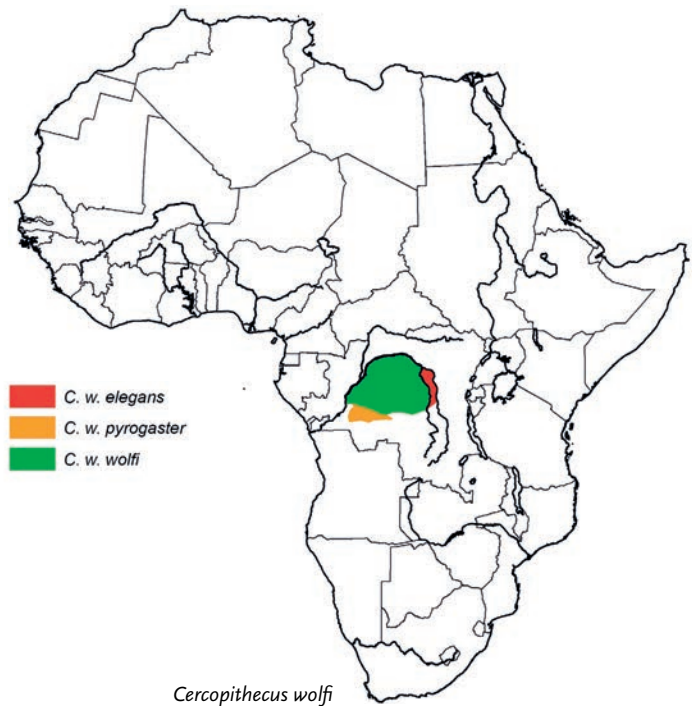

thinner than pelage on lower cheeks, which is pale agouti. Brow diadem extends to ears. Ears with long (up to 35 mm) tufts tapering to a point. Crown flat, not raised into a crest or bouffant. Upper body pelage dense, agouti grizzled, with paler, broad, dorsal midline stripe. Underside and inner limbs white or pale. Outer forearms black. Hindlimbs sharply differentiated in colour. Hands (relative to other guenons) slight, short and broad with stubby third and fourth fingers of similar length. First digit (thumb) relatively long. Feet relatively small and short with long, strong first digits ('big toes'). Feet and outer surfaces of forearms and hands blackish or black, glossy. Tail dorsum blackish or black. Tail ventrum off-white to grey near base, more uniform and paler in mid-section, and blackish or black distally with black terminal tuft. Young similar in colour to adults (Gautier-Hion *et al.* 1999).

Geographic Variation

- C. w. wolfi* Congo Basin Wolf's Monkey. Central Congo Basin between Congo R. and Kasai R. Diadem broad, off-white; facial 'mask' narrow; lower cheeks yellow speckled with black; ear-tufts orange to red; back slate-grey; dorsal midline stripe olive; lateral stripes broad, orange; ventral and inner limb surfaces white or yellow; thighs and lower hindlimbs tawny orange or reddish.
- C. w. elegans* Lomami River Wolf's Monkey. Eastern Congo Basin between upper reaches of Lomani R. and Lualaba R. Diadem of medium width, white; facial 'mask' broad; ear-tufts grey or white; lower cheeks whitish; back dark greyish-brown; dorsal midline stripe greyish-ochre; no lateral stripes; ventral and inner limb surfaces white; thighs and lower hindlimbs light grey with greenish freckle. Morphology somewhat intermediate between *C. wolfi* and *C. denti*.
- C. w. pyrogaster* Fire-bellied Wolf's Monkey. Southern Congo Basin south of Kasai R. to ca. 07° S and west to Kwango R. Diadem narrow, buff; ear-tufts reddish; facial 'mask' broad; lower cheeks orange; back dark greyish-brown to black; dorsal midline stripe chestnut; lateral stripes narrow, reddish; ventral and inner limb surfaces yellowish-orange to red; thighs and lower hindlimbs orangish-red to rusty red.

Similar Species

Cercopithecus ascanius. Throughout range of *C. wolfi*. Tail mostly reddish. Nose-spot white, black or russet.

Distribution Endemic to Congo Basin, DR Congo. Rainforest BZ. In most forests on the left bank of the Lualaba/Congo R. south to about 07° S. Present at Lokutu (01° 09' N, 23° 37' E) on the Congo R., which must be close to, or at, the northern extreme of the range (Butynski & Sanderson 2007). Kwango R. is probably western limit (Colyn 1988, Gautier-Hion *et al.* 1999).

Habitat Lowland rainforests. Rainforest BZ. Details available only for *C. w. wolfi* (McGraw 1994 at Lomako; F. Maisels & A. Gautier-Hion pers. obs. at Salonga). Occurs both in terra firma and in flooded areas. More common in primary forest than in swamp forests. Rarely observed in secondary forests. At Lomako most often in the mid-canopy of primary forest (usually 20–40 m above ground); in swamp forests tends to frequent lower levels. In flooded forests in Salonga mostly in upper and middle canopy; also in emergent trees. Altitude range ca. 100–400 m. Mean annual rainfall 1700–2100 mm.

Abundance Mean of 44 ind/km² and biomass of 168 kg/km² at Lomako (McGraw 1994). At Salonga the population studied within an area of ca. 2.5 km² included five groups that totalled about 75 individuals. This yields a population density of ca. 30 ind/km² (A. Gautier-Hion pers. obs.).

Adaptations Diurnal and arboreal. Never observed on the ground. Like other species of the *C. (mona)* Group, adult ♂ *C. wolfi* gives loud 'boom' calls that help maintain intra-group cohesion and spacing among neighbouring units (Gautier 1988). The 'boom' can be heard by the human ear to ca. 300 m. The typical ♂ display is a stiff-legged raised-rump posture. Ritualized head-flagging resembles that found in some other guenons (Kingdon 1997).

Foraging and Food Omnivorous. Diet of fruit, leaves, flowers and invertebrates. At Salonga the annual plant diet in a flooded forest dominated by Caesalpiniaceae (ca. 40% of trees) was composed

of ca. 30% arils, 20–25% seeds, 30% leaves, 11–15% flowers and only 5% fleshy fruit. Nectar of *Daniellia* flowers (Caesalpiniaceae) constituted a major resource during the period of fruit scarcity. Leaves and flowers mostly taken from Caesalpiniaceae. Seeds mainly came from Caesalpiniaceae, Mimosaceae and Olacaceae, and arils from Myristicaceae and Annonaceae (F. Maisels & A. Gautier-Hion pers. obs.). Mean size of five group home-ranges was ca. 60 ha (50–70). Home-ranges did not overlap.

Social and Reproductive Behaviour Social. Groups contain only one adult ♂ that gives loud ‘booms’; other adult ♂♂ can be present. Solitary individuals not observed. At Lomako mean group size is 10.1 individuals (n = 37 groups). At Salonga mean group size is 16 individuals (13–25, n = 5). Both at Lomako and Salonga *C. wolffi* observed in polyspecific groups in >80% of encounters. Mixed groups include either one species (57% of encounters), two species (37%) or three species (6%; McGraw 1994). At both sites, such associations include Grey-cheeked Mangabey *Lophocebus aterrimus* in >80% of encounters. This pattern is similar to *C. pogonias*, which most frequently associates with *L. albigena*. *Cercopithecus wolffi* also often associates with *C. ascanius* (50% of encounters). Less often, mixed groups include Angola Colobus *Colobus angolensis* (Lomako and Salonga) and/or Tshuapa Red Colobus *Procolobus rufomitatus tholloni* (Salonga).

Reproduction and Population Structure No field data available. It is likely that life history characteristics are similar to those of *C. pogonias*. Two captive-born ♀♀ gave birth for the first time when five years old. Then they reproduced at one to three year intervals with a mean of about two years (n = 11 births; T. Petit pers. comm.).

Predators, Parasites and Diseases Little is known about predation or disease in *C. wolffi*. African Crowned Eagle *Stephanoaetus coronatus*, Central African Rock Python *Python sebae*, African Golden Cat *Profelis aurata* are likely predators.

Conservation IUCN Category (2012): Least concern as *C. p. wolffi*. CITES (2012): Appendix II.

Habitat loss and hunting for the bushmeat trade are the two primary threats. *Cercopithecus wolffi* is an alert and fast-moving species, characteristics that make it relatively difficult to hunt. This, together with a small body size, probably makes *C. wolffi* one of the least attractive targets in the diurnal primate community (Butynski & Sanderson 2007).

Measurements

Cercopithecus wolffi

Cercopithecus pogonias CROWNED MONKEY

Fr. Cercopithèque couronné; Ger. Kronenmeerkatze

Cercopithecus pogonias Bennett, 1833. Proc. Zool. Soc. Lond. 1833: 67. Fernando Po (=Bioko I.), Equatorial Guinea.

Taxonomy Polytypic species in the *Cercopithecus (mona)* Group (or Superspecies). Some authorities include *wolffi* as a subspecies within *C. pogonias* (e.g. Grubb *et al.* 2003). Based on analyses of chromosomes (Dutrillaux *et al.* 1988b), proteins (Ruvolo 1988) and vocalizations (Gautier 1988) the two species are, indeed, phylogenetically close together. This profile follows Groves (2001, 2005c) in recognizing the subspecies: Golden-bellied Crowned Monkey *C. p. pogonias*, Black-footed Crowned Monkey *C. p. nigripes* and Gray's Crowned Monkey *C. p. grayi*. A fourth subspecies, Schwarz's Crowned Monkey *C. p. schwarzianus* from Mayumbe, DR Congo, was put in synonymy by Napier (1981) but is recognized by Groves (2001, 2005c). This profile follows Grubb *et al.* (2003) in leaving poorly-known *C. p. schwarzianus* in synonymy. Synonyms: *erxlebeni*, *grayi*, *nigripes*, *pallidus*, *petronellae*, *schwarzi*, *schwarzianus*. Chromosome number: 2n = 72 (Dutrillaux *et al.* 1988b).

Crowned Monkey *Cercopithecus pogonias* adult male.

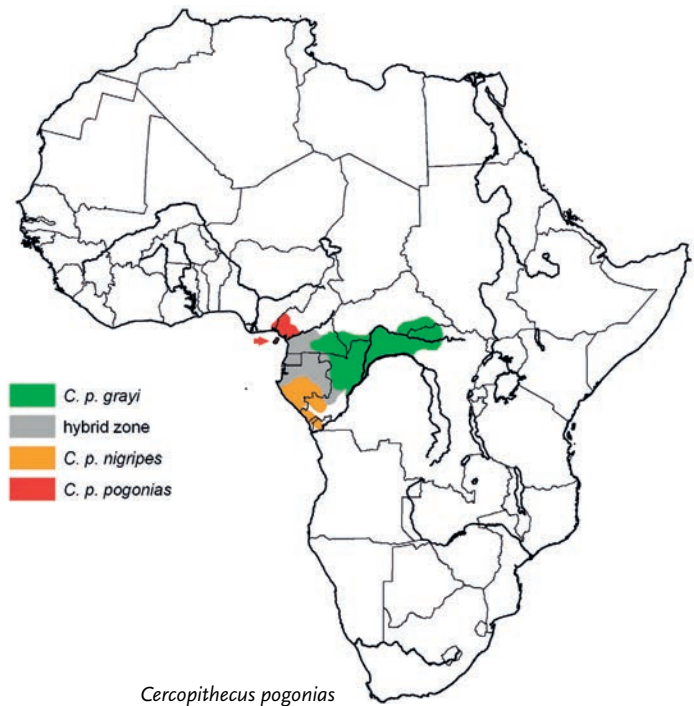

Gray's Crowned Monkey *Cercopithecus pogonias grayi* adult male.

Description Arboreal, long-tailed, medium-sized monkey with three broad black stripes on crown and prominent ear-tufts. Sexes similar in colour but adult ♀ smaller, weighing ca. 65–75% as much as adult ♂. Facial skin bluish or grey with pinkish eyelids and muzzle. Broad black central crest on crown and broad black stripes on temples separated by white or yellow patches. Ear-tufts prominent and pointed, orange-yellow or whitish. Black or grey ridge down middle of back. 'Saddle' on lower back black or dark red. Sides grizzled khaki to grey-olive. Outer arms black or blackish. Outer parts of lower hindlimbs yellowish or buffy-grey. Underside and inner sides of limbs whitish, yellow or orange. Toes black. Tail dorsum black, at least distally; tail ventrum pale yellowish-grey to orange.

Geographic Variation

C. p. pogonias Golden-bellied Crowned Monkey. Bioko I. (former Fernando Po), Equatorial Guinea, and the adjacent mainland between Cross R., Nigeria and Sanaga R., Cameroon. On Bioko I., limited to the southern ca. 25% of the island and to the lower southern slope of Pico Basilé (Butynski & Koster 1994, Hearn *et al.* 2006). Gautier-Hion *et al.* (1999) believe it possible that the Cameroon form may be an undescribed subspecies. Crown and nape dark grey with yellowish speckling; has least brightly coloured crest. Cheeks yellowish, lightly speckled with agouti near ear. Ear-tufts orange to red. Saddle black, sharply defined with variably tinted agouti on flanks. Underside and inner sides of limbs yellow to orange. On Bioko, underside of adult ♂♂ is darker orange than in adult ♀♀ (T. Butynski pers. comm.). Outer lower hindlimbs yellowish-agouti. Hands and feet black. Black on outer surfaces of forelimbs extends up to elbow or higher. Tail as above.

C. p. nigripes Black-footed Crowned Monkey. Endemic to Gabon from south of Ogooué R. southwards to perhaps the Kouilou R. (Gautier-Hion *et al.* 1999). Crown and nape dark grey with yellowish speckling; has strongly contrasting crest but frontal part of crest pale with central crown dark only on distal part. Cheeks

yellowish, lightly speckled with agouti. Ear-tufts yellow or orange. Saddle black, sharply defined with variably tinted agouti on flanks. Underside and inner sides of limbs orange. Outer lower hindlimbs buffy-grey agouti. Hands and feet black. Tail dorsum orange.

C. p. grayi Gray's Crowned Monkey. Sangha Basin of SE Cameroon, S Central African Republic and Congo, eastward to north of Itimbiri R., NC DR Congo, southwards to north bank of Congo R. to Cabinda (Gautier-Hion *et al.* 1999). Crown and nape dark chestnut-red with yellowish speckling; well-defined crest with dark central stripe extending onto brow. Cheeks yellowish, lightly and partially speckled with agouti. Ear-tufts whitish or pale yellow. Saddle dark red blending with orange-tinted agouti on flanks. Underside and inner sides of limbs orange to yellow. Outer lower hindlimbs and feet buffy-grey agouti. Only toes of feet black. Tail dorsum yellowish-grey.

A large zone of hybridization between the three subspecies may exist in the Atlantic coastal basin between Sanaga R. and Ivindo R., along the upstream tributaries of the Congo R. (see map p. 37 in Gautier-Hion *et al.* 1999).

Similar Species No sympatric monkeys are likely to be confused with this species.

Distribution Rainforest BZ. Endemic to western central Africa from Cross R. south to Congo R. On Bioko I., otherwise limited by the Atlantic Ocean on the west and extending eastwards to north bank of Itimbiri R. (Gautier-Hion *et al.* 1999). See details of distribution in Geographic Variation.

Habitat Preferentially inhabits mature lowland rainforests with tall trees and clear understorey. Also in inundated forests and old secondary forests. Avoids young secondary forests with dense understorey (Gautier-Hion *et al.* 1983, Butynski & Koster 1994).

Lateral view of skull of Crowned Monkey *Cercopithecus pogonias* adult male.

Rarely encountered in gallery forests and never seen in small forest fragments that extend into savanna (Tutin *et al.* 1997b). Not reported to be crop-raider. Altitude range is from sea level to 1200 m (south Bioko I.; Butynski & Koster 1994). Mean annual rainfall ranges from 1500 mm on the mainland to 10,000 mm on south Bioko I.

Abundance Biomass is 9–11 kg/km² in C Gabon (Forêt des Abeilles and Lopé Reserve; White 1994, Brugière *et al.* 2002), 60 kg/km² in NE Gabon, and 115 kg/km² in Ngotto Forest, Central African Republic (Gautier-Hion & Gautier 1974, Gautier-Hion 1996). Density is 4–48 ind/km². Minimal density occurs at the forest-savanna ecotone (Tutin *et al.* 1997b). In Ngotto Forest *C. pogonias* has the lowest density and biomass of the arboreal guenons. Encounter rates of 0.04 groups/km of transect on Bioko I. during an island-wide survey in 1986 (373 km of census; Butynski & Koster 1994). Encounter rate of 0.34 groups/km in 2008 along 44 km of transect in the Gran Caldera de Luba, and 0.56 groups/km in 2009 along 48 km of transect and 0.52 groups/km in 2010 along 50 km of transect at Badja North, south-west Bioko (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. comm.). The Gran Caldera de Luba and Badja North are remote sites where hunting is relatively uncommon and where there are no other anthropogenic impacts. As such, the encounter rates at these two sites are likely close to what is expected for an undisturbed population of *C. pogonias*.

Of 108 groups of monkeys encountered on Bioko during the island-wide survey in 1986, 15 (14%) were *C. pogonias* (Butynski & Koster 1994). During a 2008 survey in the Gran Caldera de Luba, south-west Bioko, *C. pogonias* accounted for 24% of the 62 groups of monkeys (six species) encountered. At Badja North, south-west Bioko, 26% of 105 groups encountered in 2009, and 29% of 91 groups encountered in 2010 were *C. pogonias* (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. comm.).

Adaptations Diurnal and arboreal. Agile and highly vocal monkey with a wide repertoire of graded calls. Like many African cercopithecines, adult ♂♂ and ♀♀ possess laryngeal sacs. Male sacs are twice as large as those of ♀♀ and among the most developed of the arboreal guenons. When inflated, they act as resonators and amplifiers, especially for the adult ♂ 'boom' call (Gautier 1971). The boom can be heard to a distance of >200 m (T. Butynski pers. comm.). An 'arched' posture, accompanied by 'pouting', is common in receptive ♀♀. Tail-twining postures are common in resting groups (Gautier & Gautier-Hion 1977). They also perform a ritualized head display (Kingdon 1997).

Foraging and Food Omnivorous. Fruit and seeds dominate the diet (60–87% depending on the site). Relative amount of seeds, taken from immature fleshy fruit, dry pods or fruit with wind dispersed seeds, varies from 3% (NE Gabon; Gautier-Hion 1980) to 50% in a forest dominated by Leguminosae (Forêt des Abeilles; Brugière *et al.* 2002). At both sites, arils may account for up to 50% of fleshy pulp ingested. Leaves and flowers make up about 15–17% of diets. In NE Gabon, 67 fruit species in the diet; mostly from tall trees and lianas belonging to three families: Annonaceae, Apocynaceae and Euphorbiaceae. Throughout the year, fruit of the liana *Cissus dinklagei* (Vitaceae) was the most consumed item. During the period of fruit scarcity, arils of Myristicaceae (*Coelocaryon* and *Pycnanthus*) are the staple plant food (the same was observed at Lopé Reserve; Tutin *et al.* 1997a). At Forêt des Abeilles, seeds and leaves of Caesalpiniaceae contribute 52% to the annual plant diet and Burseraceae contribute 12%. During the period of fruit scarcity, pulp and seeds of drupes of several species of *Dialium* may account for 75% of monthly feeding scores. However, the fruiting of these species is irregular from year to year, so they cannot be considered a true keystone resource. Animal prey makes up 6–16% of the diet of *C. pogonias* and includes mainly orthoptera and caterpillars, and to a lesser extent ants, cocoons, spiders, insect larvae, moths and butterflies. Compared to sympatric Putty-nosed Monkey *Cercopithecus nictitans* and Moustached Monkey *Cercopithecus cephus*, *C. pogonias* has the least seasonal variation in diet and the least dietary difference between ♀♀ and ♂♂ (Gautier-Hion 1980).

Cercopithecus pogonias forage in groups or in polyspecific associations. Home-range size varies from 55 to 148 ha depending partly on whether alone or in a polyspecific association. Monospecific *C. pogonias* groups rarely occur and they have the smallest home-ranges. One group of 18 individuals (followed for 900 h) associated all the time with a *C. nictitans* group of 20 individuals and ranged over 148 ha. When both groups associated with a *C. cephus* group of 15 individuals (42% of the time), home-range declined to 119 ha; home-range size appears to depend on which species are involved, not on the size of the association. Mean day range of *C. pogonias* monospecific groups estimated at 1600 m. Mean day range of *C. pogonias* when associated with *C. nictitans* was 1825 m and increased to 1980 m when *C. cephus* was present (Gautier-Hion & Gautier 1974, Gautier-Hion *et al.* 1983). *Cercopithecus pogonias* strongly favour upper strata (20–25 m with >50% of observations over 20 m); descending occasionally to <10 m (10% of observations). Never observed on the ground (Gautier-Hion & Gautier 1974).

Social and Reproductive Behaviour Social. Mean group size varies from 8 to 20 with a mean of 12.6 individuals at Lopé Reserve (White 1994), 14 at Makandé, Gabon (Brugière 1998) and 16 at Ngotto Forest and Odzala N. P. (Gautier-Hion 1996). Groups only contain one adult ♂ capable of giving the 'boom' calls. This call serves to rallying group members and in spacing groups (Gautier & Gautier-Hion 1977, T. Butynski pers. comm.). This suggests that *C. pogonias* live in one-male groups. Additional adult ♂♂ may, however, be present in some groups as indicated by their loud 'barks' that accompany the boom sequences of the group adult ♂ (A. Gautier-Hion pers. obs.).

On Bioko I. the group adult ♂ typically gives 'booms' in series of twos (43% of the time) or threes (51%), but sometimes once

(4%) or four times (2%) ($n = 51$ series). The interval between booms given in a series is usually 5–7 sec (range 4–9). When a series of three booms is given, the time interval between the first and second booms is ca. 1–2 sec shorter than between the second and third booms. Adult ♀♀, subadults, and probably juveniles, give soft ‘honk’ and (louder) ‘myaow’ contact calls. Myaows can be heard to >200 m. Adult ♀♀, by giving a chorus of ‘strained honks’, are able to elicit booms from the group’s adult ♂♂. This is reminiscent of when adult ♀♀ Gentle Monkeys *Cercopithecus mitis* give a chorus of ‘strained grunts’ that elicits a single boom from the adult ♂♂. On Bioko, adult ♂♂ frequently give loud, sharp two or three syllable hacks (‘padunk’ and ‘padunkaka’). These calls vary greatly in volume and often grade into ‘hack-trains’ (similar to the ‘ka-trains’ of adult ♂♂ *C. mitis*). Hacks can be heard to >200 m and are given in the context of alarm/warning. Adult ♂♂ Red-eared Monkey *Cercopithecus erythrotis* sometimes give ‘hacks’ (which are shorter than those of *C. pogonias*) in response to the hack call of *C. pogonias*. Calls similar to the ‘trill’, ‘grunt’ and ‘chirp’ of the sympatric *C. erythrotis* and other species in the *C. (cephus)* Group are not given by *C. pogonias* (T. Butynski pers. comm.).

No all-male groups observed. Solitary adult ♂♂ are less frequent than in other arboreal guenons, partly because they associate easily with groups of other species. Group cohesion is maintained by the modulated ‘myaow’ exchanged among adult ♀♀ and immature animals. Territorial conflicts occur. When two groups come in contact, adult ♂♂ exchange aggressive ‘hacks’ until they space out again after which one ♂ in each group gives boom calls. No overlap between home-ranges described. Infants carried only by the mother (Gautier-Hion & Gautier 1976).

Cercopithecus pogonias is rarely in monospecific groups: 0–15% of encounters in Central African Republic (Fay 1988, Gautier-Hion 1996), less than 5% both at Lopé Reserve (Ham 1994) and Forêt des Abeilles (A. Gautier-Hion pers. obs.) and 20% in NE Gabon. Occurs most often in bi-specific groups with *C. nictitans* or Grey-cheeked Mangabey *Lophocebus albigena*, and in tri-specific groups with *C. nictitans* and/or *C. cephus*, and/or *L. albigena*. Bi-specific groups with *C. cephus* are rare, the latter species being found with *C. pogonias* in the presence of at least a third species. Both at Lopé Reserve and Forêt des Abeilles, the association between *C. pogonias* and *L. albigena* accounted for at least 55% of all observed associations. Some groups may include up to six species (Gautier & Gautier-Hion 1969). Contrary to bi- or tri-specific groups, which may be stable over years (Gautier-Hion *et al.* 1983), associations including more than four species are temporary. Lone *C. pogonias* adult ♂♂ may associate with *L. albigena* groups (Ham 1994) or with Black Colobus *Colobus satanas* groups (Fleury & Gautier-Hion 1997). A lone *C. pogonias* was regularly observed within a group of *C. satanas* for three years. *Cercopithecus pogonias* is particularly adept at catching the more mobile of insects that have been flushed by other species, one benefit that they apparently obtain by associating with other primates. This species, which is often high in the canopy, is more alert to aerial predators than other monkeys, and the first to give alarm calls (Gautier & Gautier-Hion 1983). Male *C. pogonias* are the first to give loud-calls, thereby providing a vocal control in the formation and disbanding of mixed groups. This also serves to coordinate movements and spacing among groups, suggesting a supraspecific organization in which *C. pogonias* plays a leading role.

When the association includes *L. albigena*, this species may lead the mixed group (Ham 1994). On Bioko I., *C. pogonias* forms associations with *C. nictitans*, *C. erythrotis* and Pennant’s Red Colobus *Procolobus pennantii* (Butynski & Koster 1994, T. Butynski pers. comm.).

Cercopithecus pogonias has a graded vocal repertoire that is comprised of at least nine calls (see above in this section). Low-pitched cohesion calls and high-pitched contact calls are both non-quavered. These two call types may be associated or even merged. High-pitched warning calls are given by ♀♀ and immatures (Gautier 1988).

Reproduction and Population Structure Like the majority of guenons, *C. pogonias* has a mating season centred on the main dry season (Jul–Aug) and a birth season centred on the short dry season (Dec–Feb; Butynski 1988). Gestation ca. 5.5 months. The single newborn weighs ca. 300 g. In captive animals the onset of ♂ puberty occurs at about six years following a large increase in body weight. However, social maturity and especially a male’s ability to give boom calls depend not only on age but both may be inhibited by the presence of a calling leader ♂ within the captive group. In ♀♀ sexual maturity is reached around four years (Gautier-Hion & Gautier 1976). Ratio of ♂♂ to ♀♀ is 1 : 2.8, and adults to immatures 1 : 1.5 ($n = 11$; Maisels 1995).

Predators, Parasites and Diseases Crowned Monkeys are highly vigilant towards the African Crowned Eagle *Stephanoaetus coronatus* (observed to kill a juvenile ♀ in Ngotto Forest; A. Gautier-Hion pers. obs.). Upon sensing a predator, adult ♂♂ often stay in the tree canopy and bark. Warning calls by ♀♀ follow. Then ♀♀ and immatures may plunge into the understorey. Other likely predators are Leopards *Panthera pardus* (Henschel *et al.* 2005) and large snakes. Humans are the primary predator throughout the range.

Conservation IUCN Category (2012): Least Concern as a species, but *C. p. pogonias* is Vulnerable. CITES (2012): Appendix II. Like other arboreal monkeys, *C. pogonias* is vulnerable to hunting by humans for the commercial bushmeat trade over much of its range. Despite their vigilance, *C. pogonias* constituted ca. 15% of 397 arboreal guenons and mangabeys killed for bushmeat in Cameroon (P. Auzel pers. comm.). On Bioko I. (2017 km²), during 2005, about 320 *C. p. pogonias* carcasses were brought to the main bushmeat market in Malabo. Hunting with shotguns is the only threat to *C. p. pogonias* on Bioko, but this activity may extirpate this species from the island. The total number of *C. p. pogonias* killed on Bioko I. during 2005 for the bushmeat trade was ca. 720. The price paid per carcass in 2005 was ca. US\$27. It is unlikely that there were >5000 *C. p. pogonias* on Bioko I. in 2005 (Hearn *et al.* 2006). Forest clearance also threatens this species, which prefers tall primary forest. Protection of the population in the Gran Caldera & Southern Highlands Scientific Reserve (510 km²) on south Bioko is critical to the long-term conservation of this monkey on Bioko (Hearn *et al.* 2006).

Measurements

Cercopithecus pogonias

Cercopithecus pogonias (subsp. ?)

HB (♂♂): 540 (520–550) mm, $n = 5$

HB (♀♀): 440 (440–480) mm, $n = 5$

T (♂♂): 820 (750–870) mm, $n = 5$

T (♀ ♀): 724 (710–740) mm, n = 5

Localities not given (Napier 1981)

Cercopithecus p. nigripes

WT (♂ ♂): 4.4 (3.3–4.5) kg, n = 6

WT (♀ ♀): 2.9 (2.4–3.2) kg, n = 10

Makokou area, NE Gabon (Gautier-Hion *et al.* 1999)

Cercopithecus p. pogonias

HB (♂ ♂): 407 (370–480) mm, n = 46

HB (♀ ♀): 372 (340–410) mm, n = 40

T (♂ ♂): 624 (560–730) mm, n = 47

T (♀ ♀): 557 (480–610) mm, n = 42

HF (♂ ♂): 124 (118–140) mm, n = 47

HF (♀ ♀): 114 (110–120) mm, n = 41

E (♂ ♂): 27 (22–30) mm, n = 47

E (♀ ♀): 26 (22–30) mm, n = 41

WT (♂ ♂): 3.7 (3.0–5.1) kg, n = 45

WT (♀ ♀): 2.8 (2.2–3.8) kg, n = 39

Upper canine (♂ ♂): 14 (10–20) mm, n = 48

Upper canine (♀ ♀): 10 (7–14) mm, n = 32

Lower canine (♂ ♂): 10 (6–13) mm, n = 48

Lower canine (♀ ♀): 7 (4–12) mm, n = 33

Bioko I., Equatorial Guinea (Butynski *et al.* 2009)

***Cercopithecus hamlyni* OWL-FACED MONKEY (HAMLYN'S MONKEY)**

Fr. Cercopithèque à tête de hibou; Ger. Eulenkopfmeerkatze

Cercopithecus hamlyni Pocock, 1907. Ann. Mag. Nat. Hist. ser. 7, 20: 521. Ituri Forest, DR Congo.

Owl-faced Monkey *Cercopithecus hamlyni* adult male.

Taxonomy Polytypic species. Two subspecies recognized by Colyn & Rahm (1987), Kingdon (1997), Gautier-Hion *et al.* (1999), Groves (2001, 2005c) and Grubb *et al.* (2003): the nominate lowland form *C. h. hamlyni* and a montane subspecies *C. h. kahuziensis* (Colyn & Rahm 1987). *Cercopithecus h. kahuziensis* described from one juvenile and two subadult specimens collected in 1959, and reputedly restricted to a small area of bamboo forest in the Kahuzi-Biega N. P., DR Congo. Field studies over the past two decades in Kahuzi-Biega N. P., however, cast doubt on the validity of *C. h. kahuziensis*. All *C. hamlyni* observed on primate surveys in the Kahuzi-Biega N. P., in areas within the reported range of *C. h. kahuziensis* (Colyn & Rahm 1987), had prominent white nose-stripes, the primary diagnostic character for *C. h. hamlyni*; no individuals without white nose-stripes were observed (J. Hall, J. Hart, P. Kaleme & B. Finch pers. obs.). Similarly, during eight encounters with three groups at 2100–2400 m in Kahuzi-Biega N. P., Maruhashi *et al.* (1989) found that all adults had white nose-stripes,

while in some of the younger individuals the white nose-stripe was not clear. On the other hand, the white nose-stripe is variably present and often reduced in lowland populations of *C. hamlyni* in the Ituri Forest and South Kivu (Itebero and Shabunda regions, DR Congo; J. Hart, J. Mwanga & P. Kaleme pers. obs.). Described on the basis of three immature animals, and on characters that are variably present in immature *C. h. hamlyni*, it is not clear that *C. h. kahuziensis* is a valid subspecies. While we are doubtful of the validity of *C. h. kahuziensis*, we provisionally accept this subspecies – pending further study.

Rahm (1970) speculated that highland forms have longer tails than lowland forms, and may be separated on this basis, but makes no mention of the nose-stripe or other features. In addition to the lack of a white nasal stripe, *C. h. kahuziensis* may have a darker face and a reduced diadem (photo in Rahm & Christiaensen 1963: 24). Concerning relative tail length and variation in the colour of the dorsum, Colyn (1988: 115) says:

Rahm (1970) emphasizes the difference in relative length of head-body and tail existing between the mountain forest (Kivu Ridge) and the lowland forest populations. This character, however, has no taxonomic importance, as similar differences were found in a single population around Kisangani, DR Congo; the same applies to the differences in mantle colour, which range from greenish to dull yellow-buff, some times tinged with orange.

Cercopithecus hamlyni is most closely related to the recently discovered Lesula *C. lomamiensis* (Hart *et al.* 2012; see this volume p. 17). Otherwise, not closely related to any other species, as borne out by the unique structure of the skull (Raven & Hill 1942, Hill 1966). Blood protein analyses (Ruvolo 1988) place *C. hamlyni* close to L'Hoest's Monkey *Allochrocebus lhoesti*, as do similarities in palatine bone shape, coat colour and texture, external nose hair distribution, molar cusp relief, and genital colour and morphology (Schwarz 1928b, Groves 2000a, E. E. Sarmiento pers. obs.), but their karyotypes differ (2n = 64 for *C. hamlyni* and 2n = 60 for *A. lhoesti*; Romagno

2001) and molecular data do not support a close relationship (Hart *et al.* 2012). Similarities between De Brazza's Monkey *Cercopithecus neglectus* and *C. hamlyni* in most of their (relatively few) vocalizations (Gautier 1988), ritualized scent-marking behaviours (Loireau & Gautier-Hion 1988), and natal coat colour and age-related changes in coat colour (Hill 1966), suggest that *C. neglectus* is relatively close to *C. hamlyni*. These similarities, however, are probably all characteristic of the primitive Cercopithecini condition and do not reflect a uniquely shared relationship between the two. They more likely reflect conservative evolution in these two lineages since their divergence from the ancestral Cercopithecini stock. Synonyms: *aurora*, *kahuziensis*. Chromosome number: $2n = 64$ (Romagno 2001, Moulin *et al.* 2008).

Description Medium-sized, semi-terrestrial, stocky, large-headed, grizzled olive-grey monkey, with conspicuous white nose-stripe in nominate race. Sexes alike in colour but adult ♀ ca. 64% as heavy as adult ♂. Muzzle relatively heavy and prolonged with contrasting white stripe running along midline from crown, down nose to upper lip. De-pigmented pink skin underlying white hair stripe continues onto glabrous portions of upper and lower lip midline giving the appearance that the stripe crosses mouth. White-stripe absent in *C. h. kahuziensis* and variably absent in juveniles and adult *C. h. hamlyni*. Face skin dark brown in *C. h. hamlyni*, covered with tiny dark brown hairs interspersed with white hairs on upper and lower lip. Face entirely black in *C. h. kahuziensis*, except for interspersed white hairs in orbits around eyes and on chin. Neck, throat, chin and cheeks of *C. h. hamlyni* with black tipped, tan hairs banded pale yellow. This results in an olive hue that progressively lightens from crown to throat. Wider white or pale yellow bands on the hairs of the crown result in a pale yellow or white diadem that, together with the nose-stripe, forms a characteristic 'T' that demarcates the face. Brow of *C. h. kahuziensis* indistinct (no diadem), not demarcated from cheeks or crown. Wide white or pale yellow bands on hair surrounding face result in a lighter olive hue than is typical of *C. h. hamlyni*. Iris brown or brick red. Crown hairs long, soft and continuous with bushy cheek whiskers extending to ears to form a smooth, compact, 'hood' over crown, cheeks and throat, completely hiding the ears. Hood gives animals a distinctive, large-headed, 'owl-like' appearance. Ears largely bare with no tuft. Nape and upper back greyer than crown; hairs silver at base usually with three alternating pale yellow and black bands ending in a white tip ($n = 19$; E. E. Sarmiento pers. obs.). Lower back, flanks and rump hairs may have as many as four to five alternating bands (Hill 1966, Groves 2001, E. E. Sarmiento pers. obs.). Dorsum and flanks yellowish-grey or olive-grey, becoming paler towards base of tail. Variably darker yellow or orange banding on hairs of dorsum may produce a yellow or orange tinged mantle. Dorsum of *C. h. kahuziensis* with a more olive-green hue than typical of *C. h. hamlyni*. Outer thigh has white tipped grey/brown hairs with a single wide black band and narrow yellow band, producing a darker grey hue than on dorsum. Upper limbs, hands, inner thighs, legs and feet black or dark brown. Proximal two-thirds of tail with silver-green hue produced by white-tipped black or dark grey hairs with no banding. Distal third of tail black with slight tuft at tip. Tail slightly longer than HB. Ventrums, black or dark brown. Pelage of ventrum not as thick as on dorsum. Callosities blackish-brown. Scrotum, perineum and lower abdomen of ♂ a striking aquamarine or malachite green.

Lateral view of skull of Owl-faced Monkey *Cercopithecus hamlyni* adult male.

Newborn lacks facial pattern and is uniformly light yellowish-brown with a paler (fawn) face (photo in Hill 1966: 513). Young juvenile (four months of age) differs both from infant and adult by having brighter colours and more golden-yellow on the face, throat, sides of neck and upper chest; medium yellow over the lower back, limbs, hands and feet. Tail mostly greenish-yellow proximally and greyish-black distally (Hill 1966). Juveniles that are half adult size, and that are still carried by mothers, have adult markings and pelage colour (see photos in Schouteden 1944a: 50–51). M1 erupts when juvenile about half adult size.

Geographic Variation

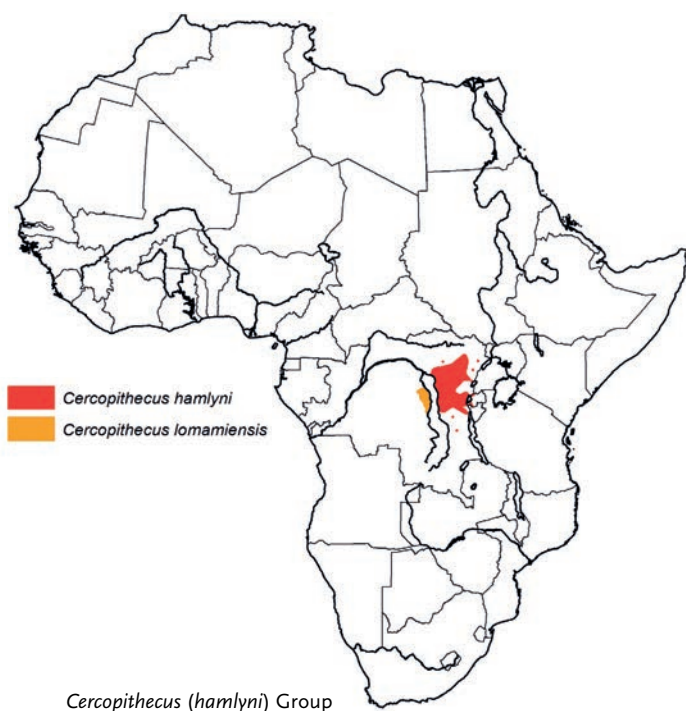

C. h. hamlyni Nose-stripe Owl-faced Monkey. Found over entire range of *C. hamlyni*, including the Bamboo *Sinarundinaria alpina* zone (2000–3000 m) of Mt Kahuzi (Maruhashi *et al.* 1989). Nose with white stripe from between eyes to mouth. Diadem white.

C. h. kahuziensis Mt Kahuzi Owl-faced Monkey. Only known from the bamboo zone and the marshy zone below the bamboo zone (2000–3000 m) on Mt Kahuzi, DR Congo. Type from the vicinity of Musisi Swamp (02° 18' S, 28° 42' E) between Mt Kahuzi and Mt Biega (Colyn & Rahm 1987). The montane portion of Kahuzi-Biega N. P. is at 02° 04'–02° 37' S, 28° 36'–28° 46' E; 2000–3308 m). No white vertical stripe on face.

Similar Species None that is parapatric or sympatric. Similar *C. lomamiensis* is separated from *C. hamlyni* by two major rivers, the Lualaba R. and the Lomami R. (Hart *et al.* 2012). See map on p. 341 and illustration on p. 344.

Distribution Endemic to CE DR Congo and W Rwanda. Rainforest BZ. Geographic range not well known, but range east of Congo R. similar to that of *A. lhoesti*. Present in the Lindi River Basin in the north-west, Nepoko R. in the Okapi Faunal Reserve in the north (J. Hart pers. obs.), southward through Ituri Forest and along right bank of Lualaba R. to at least 50 km south of confluence with the Elila R. (A. Vosper & J. Hart pers. obs.). Eastward to the Albertine (Western) Rift Valley to within ca. 70 km south of L. Albert in the north and to the north end of L. Tanganyika in the south. Several isolated, outlying populations in extreme E DR Congo and in W Rwanda. Extent of occurrence roughly 193,000 km², but area of occupancy much less than this (Y. de Jong & T. Butynski pers. obs.).

The following are the known range limits for *C. hamlyni* (Schouteden 1944a, Rahm 1965, 1970, Colyn 1988, Dowsett & Dowsett-Lemaire 1990, J. Hart pers. obs.). All sites are in DR Congo unless otherwise indicated. *Western limit*: ca. 25° 10' E to north of Congo R. near

Kisangani, and to ca. 24° 14' E to south along Lualaba R. *Northern limit*: ca. 02° 24' N, just south of Nepoko R. *North-eastern and eastern limit*: ca. 01° 57' N, 30° 01' E at Mongbwalu (Kilo Mines). Limit of contiguous moist forest and great lakes of Albertine Rift Valley are the apparent barriers to the north-east and east. Recently recorded for Semliki Forest in the Virunga N. P. (Nixon & Lusenge 2008). *Southern limit*: ca. 05° 20' S at Butondo (ca. 80 km north of Nyunzu). Limit of moist forest and/or the Lukuga R. the apparent barriers. Butondo (05° 20' S, 27° 52' E) and Nyombe (03° 53' S, 27° 25' E) are both isolated forests far south of the main distribution for *C. hamlyni*. At least one specimen collected at each of these two sites. *South-western limit*: ca. 03° 05' S, 25° 58' E, about 16 km south of Kindu. *South-eastern limit*: ca. 02° 47' S, 29° 27' E in Nyungwe N. P., SW Rwanda.

Important, but isolated, populations present in upland sector of Kahuzi-Biega N. P. (Hall *et al.* 2003), Mt Tshiaberimu in the Virunga N. P. (Sarmiento & Butynski 1997), and Nyungwe N. P. (ca. 02° 36'–02° 48' S, 29° 12'–29° 29' E; Dowsett & Dowsett-Lemaire 1990, Ntare *et al.* 2006, Easton *et al.* 2011, N. Barakabuye, A. Vedder & A. Plumptre pers. comm.). The south-eastern limit is in Nyungwe N. P. at 02° 47' S, 29° 29' E. Although there are no reports of *C. hamlyni* in Burundi, this species may well occur there in the bamboo zone of the Kibira N. P., which is contiguous with the bamboo zone at Nchili in Nyungwe N. P. where *C. hamlyni* is present (A. Vedder, N. Barakabuye & B. Kaplin pers. comm.).

Rahm (1970) says *C. hamlyni* present in 'bamboo forest near Kabale (Uganda)'. His locality map indicates that what he is referring to is the Echuya F. R., a now isolated bamboo forest centred on 01° 17' S, 29° 49' E. This is apparently the only reference for *C. hamlyni* in Uganda. Rahm (1970) does not indicate the basis for this locality record. There is no museum specimen from any site in Uganda (E. Sarmiento & T. Butynski pers. obs.). While Echuya F. R. (34 km², 2270–2570 m) appears to be suitable habitat for *C. hamlyni* (as was once much of extreme SW Uganda), *C. hamlyni* is almost certainly not present there today (T. Butynski

& E. E. Sarmiento pers. obs.). If this is a valid record, *C. hamlyni* has been extirpated from Uganda.

Locations where museum specimens were collected, but where the species is now apparently extirpated, include the Virunga Mts and several sites in NW Rwanda (e.g. Gishwati Forest and Gisenyi Bamboo Forest; A. Plumptre pers. comm.). All sites were greatly reduced in size during the twentieth century. The most recent record for *C. hamlyni* in this region is for Gishwati Forest in 1989 (J. Ray pers. comm.).

Habitat In lowland, montane and bamboo forest (J. Hart, J. Hall & P. Kaleme pers. obs.). The lowest altitude record is 450 m (east of Kisangani). The nominate race occurs in various types of evergreen forest, from ca. 450 m (Yamagiwa *et al.* 1989, Hall *et al.* 2003) in lowland forest and older secondary forest through submontane, montane and bamboo forest to ca. 3000 m. The highest sites are Nyungwe Forest N. P., Kahuzi-Biega N. P. and Mt Tshiaberimu (Rahm & Christeaensen, 1963, Rahm 1965, 1966, Dowsett & Dowsett-Lemaire 1990, Sarmiento & Butynski 1997). In Nyungwe N. P. (970 km²) *C. hamlyni* restricted to 2260–2570 m within bamboo forest (Dowsett & Dowsett-Lemaire 1990, A. Vedder pers. comm., N. Ntare pers. comm.), even though there is a large area of montane forest here. There is an extraordinary record of a mummified head found in 1927 at ca. 4500 m on Mt Karisimbi, Virunga Mts, Rwanda–DR Congo border (Raven & Hill 1942). This is the only record for the Virunga Mts. Whether this animal was a 'wanderer' that reached this altitude on its own accord, or whether the head was carried there by another species (e.g. White-necked Raven *Corvus albicollis*) is a matter for speculation. In Ituri Forest (ca. 740–1100 m) and in relatively low altitude forests in Kivu District (down to 600 m), *C. hamlyni* is present in the extensive monodominant stands of *Gilbertiodendron dewevrei*, as well as in mixed canopy moist forests (Hart & Bengana 1996, Hall *et al.* 2003). *Cercopithecus hamlyni* appears to be restricted to terra firma forests. Except for the museum specimen that represents the southernmost location (at Butondo), there is no evidence that *C. hamlyni* ranges into the forest savanna mosaic. *Cercopithecus h. kahuziensis* reported only from the bamboo zone and marshy zone below the bamboo zone (2000–3000 m) on Mt Kahuzi. Mean annual rainfall over the geographic range of *C. hamlyni* ca. 1200–2500 mm (perhaps 3000 mm at 3000 m asl at Kahuzi-Biega N. P.; Inogwabini *et al.* 2000). Night-time temperature sometimes <0°C at the highest altitudes where *C. hamlyni* occurs.

Abundance A shy, cryptic, quiet species and, therefore, difficult to detect or observe. Absent or rare over large areas of its geographic range, while locally abundant in other areas, in particular, Kahuzi-Biega N. P., Irangi, Masisi and Kasese, DR Congo (Yamagiwa *et al.* 1989, Hall *et al.* 2003), and in central Ituri Forest (Hart & Bengana 1996). J. P. Chapin & H. Lang, who collected >400 primate specimens from Kisangani through the Ituri Forest from 1909–1915, never encountered a live *C. hamlyni*, although they did purchase dead specimens (Allen 1925). Density in central Ituri Forest estimated at 0.1 ind/km² (Thomas 1991). Based on frequency of dawn call, *C. hamlyni* is widespread and common in the Okapi Faunal Reserve, where the dawn call was heard at least once during 40% of 115, 30-minute 'dawn call point counts'. *Cercopithecus hamlyni* especially prevalent in monodominant *Gilbertiodendron* forests in the Epulu area, central Ituri Forest (J. Hart pers. obs.).

Widely distributed and common in Kahuzi-Biega N. P. and the adjoining Kasese region between the Lowa R. and Oku R. Hall *et al.* (2003) provide the following estimates for *C. hamlyni* in the KB1 Lowland Sector (700–800 m) of Kahuzi-Biega N. P.: 2.5 groups/km², 6.7 ind/km², 18.4 kg/km² and the following estimates for the KB2 Lowland Sector: 2.0 groups/km², 5.3 ind/km² and 14.7 kg/km². In the Mountain Sector (2000–3308 m) of Kahuzi-Biega N. P., *C. hamlyni* is also widespread and common, with the ‘boom’ call being heard by primate survey teams on about half of the days, a rate similar to that heard in the lowland sectors (Inogwabini *et al.* 2000). Encountered rate 0.08 groups/km in Nyungwe N. P. (Easton *et al.* 2011).

Adaptations Semi-terrestrial and diurnal. The impression is that *C. hamlyni* spends more time on the ground than any other forest guenon (J. Hart pers. obs.). Although *C. hamlyni* uses all forest strata, a preliminary study in Nyungwe N. P. found that, during the daytime, *C. hamlyni* spends ca. 61% of time on the ground; ca. 81% of play, 68% of feeding, 64% of travel, 43% of grooming and 47% of resting occurs on ground. About 18% of time spent both at 0–2 m and 2–12 m above ground, with only 3% of time >12 m above ground (N. Ntare pers. comm.). When threatened, *C. hamlyni* often flees quietly on the ground rather than climbs. Initial reports (e.g. Allen 1925) that *C. hamlyni* is nocturnal are not supported by field observations (Rahm 1970, J. Hart & J. Hall pers. obs.). The brilliant aquamarine scrotum and perineum of the adult ♂♂ is typical of other semi-terrestrial guenons (i.e. *C. neglectus*, the Mountain Monkeys Group *Allochrocebus (preussi)*, the Savanna Monkeys Group *Chlorocebus (aethiops)* and Patas Monkey *Erythrocebus patas*).

Cercopithecus hamlyni has a distinctive odour, readily detected when the animals are nearby. Male and ♀ captives mark their surroundings by rubbing with their chests (Kingdon 1997, D. Messenger pers. comm.), on which there are scent-producing sternal (apocrine) glands. The only other guenons for which ritualized olfactory marking has been observed are *C. neglectus*, Green Monkey *Chlorocebus sabaenus*, Vervet *Chlorocebus pygerythrus*, Allen’s Swamp Monkey *Allenopithecus nigroviridis*, and a free-living *C. pygerythrus* × Sykes’s Monkey *Cercopithecus mitis* hybrid (De Jong & Butynski 2010b). All four of these species (and the hybrid) are semi-terrestrial. The ritualized olfactory marking in *C. neglectus* is believed to be related to that species’ low development of visual and vocal signalling, small group size, cryptic behaviour and small home-range size (Gartlan & Brain 1968, Gautier & Gautier-Hion 1977, Gautier-Hion & Gautier 1978, Loireau & Gautier-Hion 1988). Like *C. neglectus*, *C. hamlyni* is a highly cryptic species with a relatively limited vocal repertoire (Gautier 1988) and small group size. This suggests that *C. hamlyni* will also be found to have a small visual signal repertoire and small home-ranges relative to other *Cercopithecus* spp. as well as to *Allochrocebus* spp.

With more colobine-like molars than any other guenon (Hill 1966), *C. hamlyni* is probably less dependent on fruits than other guenons. As such, *C. hamlyni* is expected to do well in monodominant forests (e.g. bamboo forest and *Gilbertiodendron* forests) where the year-round availability of fruit is relatively low and where, concomitantly, competing species (e.g. Stuhlmann’s Blue Monkey *Cercopithecus mitis stuhlmanni* and *A. lhoesti*) are absent or at low densities.

Kingdon (1997: 78) notes that: ‘The hands of owl-faced monkeys are unique among guenons in the elongation of the phalanges. This is the opposite of a terrestrial trait and, combined with a relatively

Visual suppression of facial expression in the Owl-faced Monkey *Cercopithecus hamlyni*.

strong thumb, suggest a powerful grip (as would be needed for climbing slippery bamboo stalks).’

Foraging and Food Poorly known. Probably omnivorous. Forages mainly on the ground, often in dense bamboo and herbaceous vegetation (Dowsett & Dowsett-Lemaire 1990, J. Hart & J. Hall pers. obs.). Bamboo *Sinarundinaria alpina* shoots (leaves) and fruits of *Syzygium guineense* in stomach of an individual from Mt Kahuzi (Rahm & Christiaensen 1963). Local people at Mt Tshiaberimu state that *C. hamlyni* feeds largely on fungi and bamboo, and cleanly breaks off young bamboo shoots from the stem base to feed on them. In contrast *C. m. stuhlmanni* tease apart shoots with hands separating individual leaves from the shoots (E. E. Sarmiento pers. obs.). Removal of individual blades from bamboo shoots also observed for Doggett’s Blue Monkey *Cercopithecus mitis doggetti* in Nyungwe N. P. (N. Ntare pers. comm.). Main foods during one brief study in Kahuzi-Biega N. P. were the fruits of *Macaranga kilimandscharica* and *Maesa lanceolata* (Maruhashi *et al.* 1989). Eats fruits of Maranthaceae (Rahm 1966). Raids crops (e.g. Maize), but this is not common (Mwanza *et al.* 1989).

In Nyungwe N. P., at least 17 species of plants eaten (Ntare *et al.* 2006). Items eaten include, piths, stems, leaves, shoots, sheaths, flowers, roots, insects, mushrooms and lichens. During the dry season, *Triumfetta cordifolia* and *Anisoparum humberti* consumed. In October, diet dominated by young bamboo shoots; a highly seasonal food only available during the wet season. Diet comprised 36% stems, 36% pith, 10% leaves, and 7% bamboo shoots – which is yet another source of leaves (Ntare *et al.* 2006). This is a unique diet for an African monkey, with fruit comprising a minor part of the diet. Fruits of *M. kilimandscharica*, *S. guineense* and *Rubus pinatus* eaten (N. Ntare pers. comm.). Fruits are relatively uncommon in bamboo forest. *Cercopithecus hamlyni* living in mid-altitude and montane forest probably eat much more fruit than those living in bamboo forest. In the lowland and mid-altitude monodominant primary forests, however, periods of low fruit availability are prevalent and fruit availability at these times may not be that different from the situation in bamboo forests.

In the Epulu area *C. hamlyni* feeds on the ground on fallen seeds of *Erythroleum suaveolens* and on the sprouting seeds of *G. dewevrei*.

Stomach contents of two animals in the Ituri Forest during a period of low fruit availability only contained fungi. Mbuti pygmies here report that *C. hamlyni* joins Blue Duikers *Phlantomba monticola* and other duikers *Cephalophus* spp. in foraging on the ground under feeding groups of arboreal primates. Observed accompanying Olive Baboons *Papio anubis* and Robust Chimpanzees *Pan troglodytes* in south Ituri Forest (J. Hart pers. obs.). An adult *C. hamlyni* ♂ seen chasing a *C. m. doggetti* ♀ out of a fruiting *Maesa* tree (Maruhashi *et al.* 1989).

Social and Reproductive Behaviour Social. Groups described as small (Dowsett & Dowsett-Lemaire 1990), not exceeding ten individuals (Rahm 1970, Gautier-Hion *et al.* 1999). Usually encountered in groups of 2–4 individuals, but larger groups also occur (J. Hart & J. Hall pers. obs.). Fourteen observations on the Terrain Scientifique de Lenda (an area of no hunting, 10 km south-east of Epulu), where group size was determined with certainty, included three single animals (twice adult ♂♂, once sex not determined), five groups of two animals (♂ and ♀, or sex unknown), two groups of three, two groups of four, one group of six (including two adult ♂♂ and two ♀♀ with young), and one exceptional group of 30–35, including multiple adult ♂♂, which was accompanied by one White-bellied Duiker *Cephalophus leucogaster* (J. Hart pers. obs.).

Mean minimum group size for three groups encountered during censuses in the lowland sector of Kahuzi-Biega N. P. was 2.7 individuals (Hall *et al.* 2003). During eight encounters with three groups at 2100–2400 m in Kahuzi Biega N. P., Maruhashi *et al.* (1989) judged all three groups to be comprised of at least five individuals, including one adult ♂. *Cercopithecus hamlyni* was in association with *C. m. doggetti* during three of seven group encounters. Solitary adult *C. hamlyni* ♂♂ present here.

One study group in Nyungwe N.P. comprised 24 individuals, including two adult ♂♂. The two adult ♂♂ fought when they met, suggesting that the study occurred during a period when a satellite ♂ was attempting to usurp the harem ♂. *C. hamlyni* and *C. m. doggetti* form polyspecific associations in Nyungwe N. P. (N. Ntare pers. comm.). Ranger-Based Monitoring Patrols in Nyungwe N. P. recorded an average of 5.3 individuals/encounter ($n = 78$ groups), but this method is likely to underestimate group size (Easton *et al.* 2011).

Vocalizations include the ‘boom’ loud-call and ‘uh-uh-uh’ or ‘tyo-tyo-tyo’ alarm call of the adult ♂. The boom may be given once, or more than once, with a brief pause in between. Other calls include the ‘pitiak’ alarm call, and the ‘moan’ or ‘oooh-oooh’ contact call (Gautier 1988, Gautier-Hion *et al.* 1999, N. Ntare pers. comm.). A distinctive ‘barking’ call (‘krot, krot, kro-krot ...’) described from Nyungwe Forest N. P. (Dowsett & Dowsett-Lemaire 1990). The loud, high-pitched warning ‘chirps’ of most guenons is given by infant *C. hamlyni* but is not part of the vocal repertoire of older animals (Kingdon 1997).

In the Ituri Forest and Kahuzi–Biega lowlands, the distinctive descending boom call is usually uttered for a brief period before dawn. Hall *et al.* (2003) and Hart & Bengana (1996) used the boom call to determine the presence and relative abundance of *C. hamlyni* on wide-ranging surveys. However, if the boom call is not known, the presence of this species can easily be overlooked.

Diverse modelling of hair on the crowns of Owl-faced Monkeys *Cercopithecus hamlyni*.

Cercopithecus hamlyni is often described as being a discrete and quiet monkey that is relatively difficult to detect and observe. When encountered by humans it usually remains quiet, retreating on the ground without giving warning calls (N. Ntare pers. comm., J. Hart & J. Hall pers. obs.).

Reproduction and Population Structure Females carrying infants recorded in Ituri Forest in Feb, May and Aug. Birth season in western portion of range (i.e. Kisangani and Kindu) is Jul–Nov based on the size of embryos in 13 collected specimens. As such, births occur during the single annual dry season (Jun–Aug) and well into the subsequent wettest period of the year (Gevaerts 1992). Records from Singapore Zoo show a gestation of 5–6 months. Twins not reported. No birth weights available, but one 3-day-old ♂ infant at Edinburgh Zoo weighed 320 g (G. Catlow pers. comm.). The European Endangered Species Breeding Program (EEP) Studbook indicates the following for *C. hamlyni* in captivity: gestation = 180 days; youngest ♀ at first birth = 2.25 years; oldest ♀ to give birth = 24 years. Captive ♂ lived to >23 years and captive ♀ lived to >28 years.

Predators, Parasites and Diseases Four *C. hamlyni* captured in net drives on the Terrain Scientifique de Lenda were equipped with radio collars. Within 45 days all had been killed: one by an African Crowned Eagle *Stephanoaetus coronatus*, and three by Leopards *Panthera pardus*. The four animals were caught over three

days during a food shortage and unusual drought. They were readily detected as they moved through dry forest litter, and appeared to be in weakened condition, making them relatively easy to capture. Hairs of *C. hamlyni* found in two (0.9%) of 222 Leopard scats in Ituri Forest (Hart, J. A. *et al.* 1996). Although no *C. hamlyni* hairs were found in 60 African Golden Cat *Profelis aurata* scats examined during this study, *P. aurata* is a likely predator of *C. hamlyni*. Robust Chimpanzees and African Rock Pythons *Python sebae* are probable predators. The most important predator for *C. hamlyni* is almost certain humans. The semi-terrestrial habit of *C. hamlyni* makes this species especially susceptible to snares and hunters with dogs. They are more frequently caught in snares set for duikers than any other primate species in the Ituri Forest (J. Hart pers. obs.). No information on diseases and parasites.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Category II.

Probably extirpated from Uganda (depending on validity of Rahm's (1970) record), and restricted in Rwanda to the bamboo zone in Nyungwe N. P. (Easton *et al.* 2011, R. Dowsett, A. Vedder & A. Plumptre pers. comm.). The population on Mt Tshiaberimu must be very small and, as such, may not be viable. Most important threats are habitat degradation (including the harvesting of bamboo), loss and fragmentation of forest as a result of agricultural expansion, as well as hunting for bushmeat (Mwanza *et al.* 1989, Inogwabini *et al.* 2000, Easton *et al.* 2011). Protected areas important for the long-term survival of *C. hamlyni* include Okapi Faunal Reserve, Maiko N. P., Kahuzi-Biega N. P. and Nyungwe N. P.

Cercopithecus hamlyni is a survivor of a unique primate lineage. None the less, it remains one of Africa's least studied species of primate. A long-term, detailed, study of the ecology, behaviour and habitat requirements of *C. hamlyni* would not only be exceedingly interesting and help fill a major gap in African primatology, it would also contribute valuable information towards the conservation of this species.

Measurements

Cercopithecus hamlyni

HB (♂ ♂): 540 (510–550) mm, n = 3

HB (♀ ♀): 460 (430–480) mm, n = 3

T (♂ ♂): 570 (500–630) mm, n = 3

T (♀ ♀): 530 (490–560) mm, n = 3

HF (♂): 148 mm, n = 1

HF (♀ ♀): 133 (120–145) mm, n = 3

E (♂): 44 mm, n = 1

E (♀ ♀): 29 (28–30) mm, n = 3

WT (♂ ♂): 5.5 (4.4–7.3) kg, n = 14

WT (♀ ♀): 3.6 (2.6–4.5) kg, n = 18

GWS (♂ ♂): 110, 112 mm, n = 2

GWS (♂ ♂): 74, 74 mm, n = 2

Various localities (Hill 1966, Rahm 1966, Gevaerts 1992, Gautier-Hion *et al.* 1999, P. Kaleme pers. comm., E. Gilissen & W. Wendelen pers. comm., J. Hart pers. obs.)

Cercopithecus (nictitans) GROUP

Nictitans Monkeys Group

Cercopithecus nictitans (Linnaeus, 1766). Systema Naturae, 12th edn, 1: 40. Benito R., Rio Muni, Equatorial Guinea.

The name *Cercopithecus nictitans* has two different taxonomic expressions. One restricts the name to a single species, the Putty-nosed Monkey. The other, much more complex expression, *Cercopithecus (nictitans)*, refers to a more inclusive taxon, a species-group (or superspecies) that ranges from West Africa to Zanzibar I., and from SW Ethiopia to the southern tip of South Africa. In this appellation, the *C. (nictitans)* Group, described in 1766, includes both the Putty-nosed Monkey *Cercopithecus (nictitans)* Subgroup and the Gentle Monkey *Cercopithecus (mitis/albogularis)* Subgroup (first described in 1822 and 1831, respectively) (Grubb *et al.* 2003).

While 52 forms have been named within the *C. (nictitans)* Group, we provisionally recognize 21 forms here. It has been a matter of convention and convenience that the western *C. nictitans* has been profiled separately from the rest of the *C. (nictitans)* Group in this and many other works. Three species are frequently recognized: *C. (n.) nictitans*, Blue Monkey *C. (n.) mitis* and Sykes's Monkey *C. (n.) albogularis*. The boundaries between taxonomic subgroups and sections of all monkeys of the *C. (nictitans)* Group remain poorly understood (Grubb *et al.* 2003). There is the strong likelihood that at least a third/fourth species, *C. (n.) opisthostictus*, should be distinguished as it, like *C. (n.) nictitans*, has a chromosome count of $2n = 70$, whereas all of the other forms

Schematic distribution of populations in the *Cercopithecus (nictitans)* Group.

in the *C. (nictitans)* Group that have so far been assayed have $2n = 72$ chromosomes (Dutrillaux *et al.* 1980). In addition, *opisthostictus* may be sympatric with *moloneyi* (Ansell 1958, O. Burnham pers. comm., T. Davenport pers. comm.).

Some outlying and geographically separate forms in the *C. (nictitans)* Group appear to share certain conservative traits. This implies a complex history of population expansions and contractions out of and back into climatically determined enclaves. Recent molecular studies hint at just such complications, reinforcing the recognition that *nictitans* and *albogularis* belong to the same complex and are closely related in spite of coming from opposite sides of Africa (Tosi *et al.* 2005). The latter authors' use of X chromosomes as an indicator of affinity has also confirmed the relationship of *albogularis* with *mitis*. The phylogenetic tree offered here attempts to sketch out one possible sequence of events whereby seven regional clusters might have evolved, but until detailed genetic profiles become available, any phylogenetic tree must be regarded as tentative and provisional. Taking Tosi *et al.*'s (2005) study of X chromosomes and their associated molecular clock as a guide, this tree supposes the initial spread of a large, relatively unspecialized ancestor across those parts of Africa that were webbed at that time by a network of riverine forests. Molecular clocks are consistent in positioning this spread during a warm spell that preceded the cold, arid period of 3.2–2.8 mya (mid-Pliocene). This prolonged dry period would have fragmented forests and with them early *C. (nictitans)* populations. The main fracture-lines between forest blocks would have fragmented this lineage, much as they did many other forest lineages (see map of biogeographical sub-regions in Volume I, Chapter 6). Regional subpopulations would have emerged in far Upper Guinea, on both sides of the northern Congo Basin and, divided by the Congo R., on both sides of the southern Congo Basin. Forests watered by moist Indian Ocean winds would have sustained a separate population along the eastern African littoral but these too would have fragmented. Climate has fluctuated many times over the

past 2.8 million years and it is currently impossible to correlate the emergence of specific contemporary populations with particular past climatic events. However, differences among contemporary members of the *C. (nictitans)* Group encourage the identification of seven 'deep' lineages. These are consistent with geography and with the forest refugia listed above.

On the eastern side of the south Congo Basin *opisthostictus* is the most likely candidate for direct descent from the founding lineage. It may be that *opisthostictus* still lives in the vicinity of, or in a part of, the region in which the ancestors of the *C. (nictitans)* Group emerged. It has already been pointed out that, with the exception of *C. (n.) nictitans*, *opisthostictus* has a smaller number of chromosomes than other members of the *C. (nictitans)* Group ($2n = 70$ instead of $2n = 72$; Dutrillaux *et al.* 1982a). (*Cercopithecus (n.) heymansii*, which most resembles *C. (n.) opisthostictus*, possibly shares the same count.) *Cercopithecus (n.) heymansii* occupies what looks like a relict range, sandwiched between two major rivers, with the implication that it belongs to a group that was formerly more widespread. When more is known about primate populations in the Congo Basin the two forms may actually be shown to represent a clinal continuum.

Assuming that their primary spread reached the farthestmost parts of their present range it seems significant that geographically isolated populations from the extreme west, north-east and south of the range of the *C. (nictitans)* Group should show striking similarities. Thus *C. (n.) n. stamflii*, from West Africa, *C. (n.) albogularis labiatus* from South Africa, *C. (n.) albogularis zammaranoi* from the Juba R., Somalia, and *C. (n.) m. boutourlinii* from SW Ethiopia all have white throats and upper chests, dark olive backs, intensely black arms graduating to dark agouti grey on upper shoulders, and dark grey agouti legs. Some further resemblances between these four populations and *opisthostictus* and *heymansii* are best explained by retention of conservative genotypes shared by the most isolated populations in their common ancestor's once extensive range. In spite of their likely genetic heritage, these outliers are commonly assigned to three different species. The isolation of *C. (n.) n. stamflii* in the west is enough to explain its differentiation from the Eastern Putty-nosed Monkey *C. (n.) n. nictitans*. On the face of it, the latter should descend from the same *nictitans* ancestor, yet its close resemblance to *C. (n.) m. stuhlmanni* suggests many complications, including the possibility that the latter genotype has mixed with that of *nictitans* long after their parental stocks diverged. Should this turn out to be so, *C. (n.) n. nictitans* would represent a stabilized hybrid, or even, in places, a hybrid swarm.

Late genetic crossing might also help explain mixed characteristics in *boutourlinii*, which combine many *opisthostictus*-like features with some of those of its nearest neighbour, *stuhlmanni*. Should *boutourlinii* be allied with *stuhlmanni* (as it now is) or are there any ways in which its likely links to an older heritage could find expression? Some of the ancestors of *boutourlinii* were probably shared with those of *zammaranoi* at the time of their first entry into north-east Africa. Yet today there are decisive differences in body size, habitat and geographic range. Both forms have continued to evolve adaptations to their localities. Their current taxonomic allocations are certainly artificial and are likely to be changed in the future.

The penetration of geographic extremities includes an altitudinal dimension and it is possible that descent from an earlier *nictitans* may be exemplified in the mountains of the Western Rift Valley by *doggetti*,

Some monkeys in the Nictitans Monkeys Group *Cercopithecus (nictitans)* radiation.

Top row, left to right: Eastern Putty-nosed Monkey *Cercopithecus nictitans nictitans*. Angola Pluto Monkey *Cercopithecus mitis mitis*. Moloney's Monkey *Cercopithecus mitis moloneyi*. Stuhlmann's Blue Monkey *Cercopithecus mitis stuhlmanni*. Kolb's Monkey *Cercopithecus mitis kolbi*.

Bottom row, left to right: Martin's Putty-nosed Monkey *Cercopithecus nictitans martini*. Lomami River Monkey *Cercopithecus mitis heymsi*. Rump-spotted Monkey *Cercopithecus mitis opisthictus*. Doggett's Silver Monkey *Cercopithecus mitis doggetti*. Tanzania Sykes's Monkey *Cercopithecus mitis monoides*.

kandti and, farther south, by *moloneyi*. The isolation of such distinctive types on cool upland suggests that past global glacials encouraged the spread of an appropriately adapted morpho-type and that subsequent climatic changes led to regional differentiation. Thus, *doggetti*, *kandti*, *moloneyi* and possibly another outlying and isolated population, *C. (n.) m. mitis* (which occurs south of the Congo R. mouth both in upland and low-lying areas of N Angola), might all have a common ancestry and have been connected across the temperate southern African highlands. The exceptionally successful *stuhlmanni* is predominantly a lowland form but probably represents a late derivative from the same stock as *doggetti*. Thus there appear to be multiple temporal levels in a slow-growing evolutionary radiation that may well have been strung out over some 3 million years.

These are but a few of the phylogenetic questions. As such, it is not surprising that current taxonomic allocations are confused, contradictory, and sometimes arbitrary. Since the *C. (nictitans)* Group represents one of the most promising exemplars of 'evolution in action', these monkeys beg much more study. In the interests of provoking further study of these ecologically and evolutionarily significant monkeys, we list and map the ranges of identifiable regional populations and allocate them, provisionally, to seven regional 'clusters' (Kingdon 1997) that have also been called 'sub-groups' and 'sections' (Grubb 2001, Grubb *et al.* 2003). We have used established names to tentatively rank each of these clusters and while these imply that each could be regarded as a species in its own right we regard formal recognition at the species level as premature, pending deeper molecular studies. We believe our restraint might help move the study of these interesting monkeys towards a less superficial and more eco-biogeographic and evolutionarily based treatment. The 22 forms listed here are generally recognized as morphologically and geographically distinct. All of the seven proposed clusters embrace more than one subspecies.

Cluster I: *Cercopithecus opisthictus* Cluster

C. (n.) opisthictus. A highly distinctive form with a different chromosome count from all others in the *C. (nictitans)* Group

except for *C. (n.) nictitans* ($2n = 70$ instead of $2n = 72$, Dutrillaux *et al.* 1982a). Appears to be sympatric without interbreeding in a narrow region of overlap with *C. (n.) moloneyi* (see below). The dense, light olive to steel-grey agouti pelage of the dorsum is exceptionally soft, resembling that of Owl-faced Monkey *Cercopithecus hamlyni* and De Brazza's Monkey *Cercopithecus neglectus* in colour and texture. Cheek-fur particularly long, hiding the ears and drooping down towards the shoulders. Muzzle, chin and throat off-white. Diadem upwardly arched, 'sculpted' and poorly defined in colour, but paler than rest of the crown (which matches colour of dorsum). Arms and underside black. Hindlimbs a darker shade of agouti than dorsum. Muzzle longish in adult ♂.

C. (n.) o. opisthictus Rump-spotted Monkey. Crown relatively monochromatic agouti. Throat off-white. Face pale. Inhabits forest mosaics, especially ground-water swamp forests, within the moister miombo woodlands of the south-eastern Congo Basin and upper Zambezi Basin to western littoral of L. Tanganyika. In low-lying forests along the southern eastern littoral of L. Tanganyika (T. Davenport pers. comm.). Kasai R. possibly forming western boundary with L. Tanganyika and Muchinga Uplands defining much of eastern limit.

C. (n.) o. heymsi Lomami River Monkey. Similar to *C. (n.) o. opisthictus* but black band across temples and nape and diadem near-white, narrow. Face black. White on throat less extensive. Crown, neck and shoulders blue-grey. Ventrums lighter than back. Between Lualaba R. and Lomami R., E DR Congo. Some authors allocate *heymsi* to other clusters (Colyn & Verheyen 1987b, Lawes *et al.* this volume).

Colyn & Verheyen (1987) suggest that *heymsi* and *opisthictus* hybridize near Lusambo, DR Congo, but it is also plausible that there is (or has recently been) a more or less continuous cline between the two forms.

The singular distribution pattern of the *opisthictus* Cluster implies a formerly more extensive range. If so, displacement to the east could have been due to expansion by *C. m. stuhlmanni*. To the

Martin's Putty-nosed Monkey *Cercopithecus nictitans martini* adult male.

west, competition from what are now rare forms of the *C. (nictitans)* Group seems unlikely. However, species that are rare today need not have been rare in the past. Furthermore, if the *opisthictus* Cluster represents an early form of (*nictitans*), then displacement by subsequent descendant populations is plausible. With regard to understanding the dynamics of speciation/sub-speciation in the *C. (nictitans)* Group, it is important to document details of the relationships of *C. (n.) opisthictus* with *C. (n.) m. stuhlmanni* and *C. (n.) m. doggetti* to the north-east and with some form of *C. (n.) mitis* (possibly *C. (n.) m. maesi*) to the west.

Cluster II: *Cercopithecus nictitans* Cluster

- C. (n.) nictitans*. Most strikingly distinguished by its white 'putty nose'. Back pelage greyish-olive or kaki-olive agouti and relatively coarse (compared with *opisthictus*). Arrangement of cheek-fur differs between subspecies. Arms black. Hindlimbs a darker shade of agouti than dorsum. Muzzle medium length in adult ♂. *Cercopithecus (n.) nictitans* has a lower number of chromosomes ($2n = 70$) than all other members of the *C. (nictitans)* Group ($2n = 72$) with the exception of *opisthictus* ($2n = 70$). Based on protein analyses, the *C. nictitans* Cluster, the four *C. (n.) mitis*-like clusters (i.e. *mitis*, *doggetti*, *moloneyi* and *stuhlmanni* Clusters) and the *C. (n.) albobularis* Cluster are phylogenetically extremely close. In the eastern parts of the range of *C. (n.) nictitans* the possibility of long-term hybridization, even replacement of earlier *stuhlmanni* populations, should be borne in mind.
- C. (n.) n. nictitans* Eastern Putty-nosed Monkey. Back, head and underside warm, greyish-olive. Laterally bunched fur on cheeks. Chest black. Some features of this form may have been influenced by hybridization, possibly on a broad scale, with *stuhlmanni*. Sanaga R. and Cameroon Highlands eastwards to Congo R. and Itimbiri R. (DR Congo), and southwards to Congo R.
- C. (n.) n. martini* Martin's Putty-nosed Monkey. Khaki-olive back and head. Throat off-white. Chest and abdomen dusky grey. Restricted to Bioko I., Equatorial Guinea.
- C. (n.) n. stampflii* Stampfli's Putty-nosed Monkey. Khaki-olive back and head. Cheek-fur downwardly deflected giving face a narrower appearance. Throat, chest, inner surfaces of upper arms and underside with variable amounts of white, cream or light grey.

Sanaga R. and Cameroon Highlands, disjointedly, westwards to far western Upper Guinea. Probably the most conservative form within this cluster. Synonyms: *insolitus*, *ludio*.

Cluster III: *Cercopithecus mitis* Cluster

- C. (n.) mitis*. Back dark grizzled agouti. Crown with paler diadem. Chin pale. Cheek-whiskers broad. Muzzle longish in adult ♂. Populations appear to be relictual.
- C. (n.) m. mitis* Angola Pluto Monkey. Diadem very pale. Muzzle with short, white hairs. Crown, neck and limbs black. Dorsal and ventral pelage dark grey to black. Synonyms: *diadematus*, *dilophus*, *leucampyx*, *pluto*, *nigrigenis*. W Angola.
- C. (n.) m. maesi* Kutu Pluto Monkey. The validity of this apparently rare form has been challenged and the provenance (Kutu, near the centre of the Congo Basin) of the holotype questioned (Colyn & Verheyen 1987, Groves 2001), but Schouteden (1947) allocated several specimens from west of Lomami R. and south of Congo R. to this subspecies. Whatever taxonomic designation is eventually arrived at, it is clear that *C. (n.) mitis* is of sporadic occurrence through the Congo Basin south of the Congo R. and west of the Lomami R. The occurrence of the *C. (n.) mitis* form in this region needs further study. It should be noted that this heavily forested region is well separated from both *C. (n.) mitis* and *C. (n.) stuhlmanni* (the two forms *maesi* has been commonly allied with). Schouteden's descriptions imply most resemblance with *C. (n.) m. mitis* but with a narrower brow-band, a black temporal streak and fine agouti cheek-fur tones that graduate from paler near the face to darker on the margins.

Cluster IV: *Cercopithecus doggetti* Cluster

- C. (n.) doggetti*. Back grizzled grey or golden. Crown black with sharply defined diadems. Cheek-whiskers high, well-developed. Muzzle of adult ♂ long. Isolated populations associated with Western Rift Valley of DR Congo, Uganda, Rwanda, Burundi and Tanzania.
- C. (n.) d. doggetti* Doggett's Silver Monkey. Back grizzled varying from ash-grey to tawny-grey. Arms, hands and feet intense shiny black. Legs dark grey with some agouti on upper thighs. Occurs in both upland and lower-lying forests from western shore of L. Victoria westwards to Bwindi Impenetrable N. P. southwards to northern shore of L. Tanganyika. Synonym: *sibatoi*.
- C. (n.) d. kandti* Golden Monkey. Cape and base of tail red or orange. Cheeks and diadem with 'golden' tints. Crown, arms and tail black. The amount of red varies individually with some individuals scarcely distinguishable from *doggetti*. Inhabits montane and bamboo forests on Virunga Mts (where Uganda, Rwanda and DR Congo meet). Synonym: *insignis*.
- C. (n.) d. schoutedeni* Schouteden's Silver Monkey. An island isolate possibly deriving from hybridization between *doggetti* and *kandti* or an example of founder-effect. Idjwi and Shushu Is. in L. Kivu and western Virunga Mts, DR Congo. Diadem very pale agouti. Crown, neck and forelimbs black. Back pale olive-grey. Underside lighter.

Cluster V: *Cercopithecus moloneyi* Cluster

- C. (n.) moloneyi*. Until the ambiguous affinities of these monkeys have been clarified we treat them, provisionally, as a distinct cluster.

ABOVE: Pousargues's Monkey *Cercopithecus mitis albatorquatus* adult male.
 ABOVE LEFT: Moloney's Monkey *Cercopithecus mitis moloneyi* adult female.
 BELOW LEFT: Stuhlmann's Blue Monkey *Cercopithecus mitis stuhlmanni* adult male.

distinguished by red ear-tufts and by red and white hairs under tail. Restricted to Vipya/Nyika plateau and Mt Waller, Malawi.

Cluster VI: *Cercopithecus stuhlmanni* Cluster

C. (n.) stuhlmanni Cheek-whiskers broad. Cheek-whiskers, back, sides and base of tail deep slate-blue agouti. Diadem paler. Crown and arms black. Legs dark blueish-grey agouti. Muzzle relatively short in adult ♂. Expansive range in E and NE DR Congo and East Africa. Possibly into Ethiopia.

C. (n.) s. stuhlmanni Stuhlmann's Blue Monkey. As above. From east of Itimbiri R. and north of Congo/Lualaba R., DR Congo to Eastern Rift Valley, north of L. Victoria, SW Kenya. Also isolated massifs in N and W Uganda and SE Sudan. Includes *neumanni*, *carruthersi*, *mauae*, *elgonis* (*elgonis* is a particularly dark form from the montane forests of Mt Elgon).

C. (n.) s. boutourlinii Boutourlini's Blue Monkey. Crown grizzled (not black). Diadem undifferentiated from crown. Dorsum with greenish or yellowish tinge. Dandelot & Prévost (1972) emphasize similarity with *opisthostictus*. Genetically, might be allied to a hypothetical class of 'relictual populations on the extremities', so the possibility of *stuhlmanni* and an earlier relict type meeting and hybridizing in Ethiopia should be borne in mind. SW Ethiopia from L. Turkana northwards to L. Tana, along west side of Eastern Rift Valley. Synonym: *omensis*.

Cluster VII: *Cercopithecus albogularis* Cluster

C. (n.) albogularis. Back grizzled and mostly relatively light in colour. Cap and diadem grizzled, not clearly differentiated from one another. Diadem peaked, long and pointed in centre. Boundary between white or off-white chin/chest fur and grizzled cheek-fur highly variable. Tail mainly black. Muzzle medium length in adult ♂.

This cluster is distributed from S Somalia to Eastern Cape Province, South Africa, along the littoral and up most (perhaps all) Indian Ocean major river basins. It could be argued that the dark, apparently conservative populations at the northern (*C. (n.) a. zammaranoi*) and southern (*C. (n.) a. labiatus*) extremities of this range should be excised from this cluster. Were these two populations to be excluded, a more

This cluster has been variously associated with *doggetti* (Kingdon 1971), *albogularis* (Groves 2001) and *mitis* (Kingdon 1997). A flat 'cap' and light diadem are conspicuous features and, for all higher-altitude populations, a dark mahogany 'saddle'. Muzzle of adult ♂ medium length. Restricted to montane areas to north and west of L. Malawi. On the extreme western edges of range may be sympatric with *C. (n.) opisthostictus* without interbreeding (Ansell 1958, O. Burnham pers. comm., T. Davenport pers. comm.). This separation appears to be facilitated by *opisthostictus* inhabiting swamp or lower-altitude forests while *moloneyi* occupies montane forests or narrow riverine strips descending from higher altitudes. May form a phenotypic cline with *C. (n.) albogularis monoides* in the Udzungwa Mts, SC Tanzania (T. Butynski pers. comm.).

C. (n.) m. moloneyi Moloney's Monkey. Cheek-fur broad, grizzled. Throat pale grey. Dorsum with mahogany saddle. Sides and thighs light grey. Individuals from lower altitudes may have olive dorsum: whether this is due to admixture with *C. (n.) albogularis monoides* is not known. Arms, hands and feet black. Ventrums of tail sometimes reddish. Widely distributed in the Southern Highlands of Tanzania, from the north shore of L. Malawi westwards along riverine forests draining the Lavusi/Muchinga Highlands and the Luangwa R., Zambia.

C. (n.) m. francescae Red-eared White-collared Monkey. Often subsumed as a synonym of *moloneyi* but regarded as a distinct montane isolate by Ansell (1960). Resembles *moloneyi* but darker overall and

Pousargues's Monkey *Cercopithecus mitis albоторquatus*.

restricted *albogularis* Cluster might turn out to represent a self-contained radiation centred on the tropical Indian Ocean littoral, but embracing most of the major river basins between the Zambezi R. and the Tana R.

- C. (n.) a. albogularis* Zanzibar Sykes's Monkey. Ear-tufts small, white. Neck collar narrow, white. Back pale khaki agouti graduating to darker reddish-yellow on rump. Head and shoulders agouti grey. Distributed along the Indian Ocean coast and inland between the Galana/Sabaki River Basin and the Ruvu River Basin. Also Mt Kilimanjaro, Mt Meru, Taita Hills and Zanzibar (Nguja) I. After observing monkeys in the field at many sites within and at the extremes of the range of *C. (n.) a. albogularis*, De Jong & Butynski (2009) conclude that there is gradual but considerable phenotypic variation along north–south and west–east clines. For example, monkeys at the extremes of the range (e.g. at Gedi, EC Kenya, and west of Mt Kilimanjaro, NCTanzania) differ greatly in appearance from those on Zanzibar I., the type locality for *C. (n.) a. albogularis*. Multiple photographs of several of these subspecies are available at: www.wildsolutions.nl Synonym: *kibonotensis*.
- C. (n.) a. kolbi* Kolb's Monkey. Neck collar broad, nearly encircles the neck, and pure white, contrasting strongly with narrow brown agouti cheeks and jet black arms. Crown brown agouti, sometimes nearly black. Ear-tufts long, prominent, white. Back varies from khaki to deep brown or mahogany-red. Legs variable shades of grey. *Cercopithecus (n.) a. kolbi* forms a west–east cline with *C. (n.) a. albоторquatus* down the east side of the Kenya Highlands then down the Tana R. to the Indian Ocean (De Jong & Butynski 2009). Found in forests in the Kenya Highlands east of the Rift Valley (mainly Aberdares Range and Mt Kenya). *Cercopithecus (n.) a. kolbi* may also be the form in the Chuyulu Hills, SC Kenya. Synonyms: *hindei*, *nubilus*.
- C. (n.) a. albоторquatus* Pousargues's Monkey. Back and sides pale agouti yellow ochre. Upper cheek-patches narrow. Legs and shoulders dove-grey. Arms black. Conspicuous and extensive white ear-tufts and collar. Found on the lower Tana R., Tana Delta and north along the coast, perhaps as far as the Caanoole R., SE Somalia. Also Pate I. It is presumably *albоторquatus* that is on Lamu I. and Manda I., Kenya (De Jong & Butynski 2009). Along the course of the Tana R., *albоторquatus* graduates with *kolbi* on

the Aberdares Range and Mt Kenya. In contrast, there are sharp differences between *albоторquatus* and *C. (n.) a. zammaranoi*, the two being separated by ca. 100 km of unsuitable habitat along the dry littoral of S Somalia. Synonyms: *phylax*, *rufotinctus*.

- C. (n.) a. monoides* Tanzania Sykes's Monkey. Crown, cheeks, neck and shoulders yellowish-olive. Rump reddish-brown. Underside grey. Otherwise similar to *albogularis* (and only marginally separable taxonomically). Occurs on coastal littoral from Rufiji Basin southwards to the Rovuma Basin. Also Mafia I. Synonym: *rufilatus*.
- C. (n.) a. erythrarchus* Stairs's Monkey. Similar to *monoides* but with variable infusions of yellow (non-agouti) colouring on back, crown, cheeks, ear-tufts and root of tail (where red fur may surround ischial callosities). Underside off-white to grey. Inhabits Indian Ocean littoral (including Bazaruto I.) and Mozambique interior from Mualo Basin south to Limpopo Basin and Manica Highlands. Synonyms: *mossambicus*, *nyasae*, *schwarzi*, *stairsi*, *stevensoni*.
- C. (n.) a. zammaranoi* Zammarano's Monkey. The smallest of all forms in the *C. (nictitans)* Group. Once given the Italian vernacular name of *scimmia nera* (black monkey) (Funaioli 1957, 1971), this is a dark form (in spite of coming from the arid S Somali coastal/riverine region) (de Beaux 1923, 1937, Zammarano 1930, Patrizi 1935). Resembles *C. (n.) a. labiatus* and *C. (n.) n. martini* in white throat and chest, dark olive back, intensely black arms graduating to dark agouti grey on upper shoulders, and dark grey agouti legs. *Cercopithecus (n.) a. zammaranoi* differs in lacking black on head, the crown being grizzled dark olive graduating at the temples to dark grey on the cheeks. Diadem not differentiated in colour from the crown but is prominently peaked. Nape paler grey. Ears protrude only slightly and are without tufts (unlike its nearest neighbour, the pale, white bibbed, white ear-tufted *C. (n.) a. albоторquatus*, to which it is not closely related) (Funaioli & Simonetta 1966, Varty 1988, Gippoliti 2003).
- C. (n.) a. labiatus* Samango Monkey. Like *C. (n.) a. zammaranoi* this is a dark form but significantly larger. *Cercopithecus (n.) a. labiatus* shows some resemblances with *C. (n.) o. heymansi*. The similarities might be superficial or convergent but are more likely to signify the retention of a conservative genotype at the extremities of the range of the *C. (nictitans)* Group. Cheek-whiskers dark olive agouti, long and downwardly deflected. Diadem prominent, strongly peaked and sometimes contrasts strongly with black crown. Back dark grey agouti tinged with yellow. Arms black. Legs grey. Found from Eastern Cape Province to the Pongola R. Valley. Synonym: *samango*. Like *zammaranoi* and *boutourlinii*, this form may require re-allocation once its genotype has been examined and compared with those of other members of the *C. (nictitans)* Group.

Of all the true forest guenons, *C. (nictitans)* spp. and ssp. are the only ones with sufficient ecological plasticity to sustain a wide distribution in southern and eastern Africa. Showing a striking adaptability to both altitude and latitude, they range up into cool montane habitats and south into temperate South African forests. The secret of their success in peripheral forests appears to derive from a physiological ability to fall back on leaves as a staple during periods when fruit and invertebrates are lacking or in short supply. These relatively large, mainly arboreal monkeys are therefore relatively generalized compared to other arboreal forest guenons (which specialize in fruit and/or invertebrates, leaving leaf-eating

Tentative phylogenetic tree for the Nictitans Monkeys Group *Cercopithecus (nictitans)* (J. Kingdon reconstruction).

to appropriately adapted colobines). Within the crowded primate communities of the equatorial forests *C. (nictitans)* are frequently rare, even absent, and it would seem to be competition from other guenons (and perhaps colobines) that constrains, or excludes them from some areas. Outside the main forest block this susceptibility to competition may not include the mangabeys (*Cercocebus* and *Lophocebus*), with which they co-exist over parts of their range. Indeed, under conditions of food stress it is the mangabeys that may be too specialized to compete with *C. (nictitans)*. The relatively large body-size of *C. (nictitans)* must operate as a constraint under some climatic and ecological states, as well as in some competitive contexts. Thus it may be significant that one population, *zammaranoi*, isolated in botanically impoverished gallery forests in Somalia in the absence of other forest monkeys, is relatively small. The same trend was probably followed in far western Africa, resulting in the emergence of a dwarfed lineage ancestral to the *Cercopithecus (cephus)* lineage. For this initially restricted population small size opened new opportunities that are discussed in the *C. (cephus)* Group profile. With regard to their conservation, although the *C. (nictitans)* Group, taken as a whole, is common and widespread, several forms, notably *mitis*, *zammaranoi*, *stampflii*, *francescae*, *kandti* and *labiatus*, are rare and localized. All forms deserve to be studied and conserved as representatives of one of the most complex and interesting of all pan-tropical primate radiations.

Jonathan Kingdon

Cercopithecus nictitans PUTTY-NOSED MONKEY (GREATER SPOT-NOSED MONKEY)

Fr. Pain à cacheter; Ger. Große Weißnasemeerkatze

Cercopithecus nictitans (Linnaeus, 1766). Systema Naturae, 12th edn, 1: 40. Benito R., Rio Muni, Equatorial Guinea.

Taxonomy Polytypic species that is treated here as a species within the *Cercopithecus (nictitans)* Group or Superspecies (see previous profile). This profile follows Dandelot (1971), Groves (2001, 2005c)

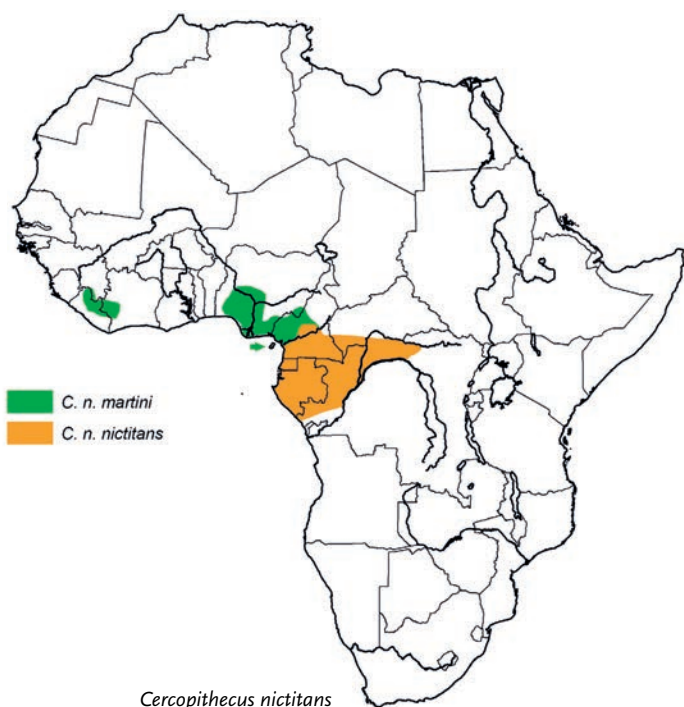

Eastern Putty-nosed Monkey *Cercopithecus nictitans nictitans*.

and Grubb *et al.* (2003) in recognizing two subspecies, Eastern Putty-nosed Monkey *C. n. nictitans* and Martin's Putty-nosed Monkey *C. n. martini*. While the validity of *C. n. stampflii* is in question, this subspecies is recognized by several authorities, as well as in the *C. (nictitans)* Group profile presented above. Oates (1988b, 2011) and Grubb *et al.* (2000) recognize an additional two subspecies; *C. n. ludio* and *C. n. insolitus*.

Cercopithecus nictitans has fewer chromosomes ($2n = 70$) than most members of the *C. (nictitans)* Group ($2n = 72$), although the Rump-spotted Monkey *Cercopithecus mitis opisthostictus* also has $2n = 70$ chromosomes (Moulin *et al.* 2008). Based on protein analyses, *C. nictitans* and forms in the *Cercopithecus mitis/albugularis* Subgroup are phylogenetically extremely close (Dutrillaux *et al.* 1988b, Ruvolo 1988). They also possess similar vocal repertoires (Gautier 1988). Thorington & Groves (1970) suggested they should be considered as conspecific, a conclusion that was later retracted (Groves 2001, 2005c). Synonyms: *insolitus*, *laglaizei*, *ludio*, *martini*, *stampflii*, *sticticeps*. Chromosome number: $2n = 70$ (Dutrillaux *et al.* 1988b, Ruvolo 1988, Moulin *et al.* 2008).

Description A moderately large, long-tailed monkey with a white nose spot on a grizzled greyish-olive or khaki-olive face. Sexes alike in colour but adult ♀ smaller, weighing ca. 60% as much as adult ♂ in the nominant subspecies and ca. 80% as much as adult

♂ in *C. (n.) n. martini* on Bioko I. (Butynski *et al.* 2009). Nose with white oval spot. Whiskers, diadem, crown, shoulders, back, legs and basal part of tail dark greyish-olive or khaki-olive due to ringed (grizzled) hairs. Arms, hands, feet, belly and distal part of tail black. Young similar in colour to adults but white nose spot not present at birth.

Geographic Variation

C. n. nictitans Eastern Putty-nosed Monkey. Occurs mainly south of Sanaga R., Cameroon, southwards through Equatorial Guinea (Rio Muni), Gabon and Cabinda (Angola) to Congo R. and eastwards across Central African Republic and Congo into DR Congo to north of Congo R. and west of Itimbiri R. (Oates 1988b, Gautier-Hion *et al.* 1999, Grubb *et al.* 2000). The Sanaga R. is not, however, a clear-cut barrier as at least one population occurs north of Sanaga R. Overall dark greyish-olive with broad, largely blackish crown and rounded face. Underside as dark as upperside. Chest black.

C. n. martini (including *stampflii*) Martin's Putty-nosed Monkey. Disjunct distribution; N Liberia and SW Côte d'Ivoire and then in S Nigeria and SW Cameroon to Sanaga R. (Oates 1988b, 2011, Grubb *et al.* 2000). Also Bioko I., Equatorial Guinea, where it appears to be limited to the lower southern slope of Pico Basilé and to the remote and extremely wet southern ca. 25% of the island (Butynski & Koster 1994). Overall, khaki-olive (lighter than *C. n. nictitans*). Crown with black, narrow sides. Whiskers downward deflected giving face a narrower appearance. Throat and inner surfaces of upper arms white or off-white. Underside dusky grey.

Similar Species

Cercopithecus mitis stuhlmanni. Mainly allopatric. Bluer and lacks distinctive white nose spot. Kingdon (1980), however, points out that spot-nosed individuals resembling *C. m. stuhlmanni* are described from places as far apart as Gabon (Pocock 1907) and Ubangi, DR Congo (Elliot 1909a). He suggests that relict

populations of *stuhlmanni* might be in a late process of being absorbed genetically by *C. n. nictitans*.

Cercopithecus petaurista. Sympatric with *C. n. stampflii*. Body smaller and coat lighter. Ventrums white. White stripe on lateral sides of face.

Distribution Endemic to West Africa and western central Africa. Rainforest BZ. See details for distribution in Geographic Variation. Northern limit in central Africa is at ca. 08° 20' N in Central African Republic to ca. 05° S in Congo. Absent from the left (south) bank of Congo R. (Schouteden 1947, Colyn 1988, Oates 1988b, 2011, Gautier-Hion *et al.* 1999).

Habitat Lowland and medium-altitude forests. Typically lives in primary forest with tall trees, but also in riverine and old secondary forests. In relict patches of high forests within forest-savanna mosaics (Oates 1988b for West Africa). In gallery forests and patches of forest in Central African Republic (Fay 1988) and Gabon (Tutin *et al.* 1997b). Prefers middle and upper strata of the canopy, at similar height to Crowned Monkey *Cercopithecus pogonias*. Spends 56% of time above 20 m and only 3% below 10 m. Rarely observed on the ground (Gautier-Hion & Gautier 1974) except to cross savanna between forest patches/forest galleries and continuous forest (C. Tutin pers. comm.). On Bioko I. observed only in pristine forest and in slightly degraded primary forest, not in secondary forest (T. Butynski pers. comm.). From sea level to >1000 m on the mainland. From 0–900 m on Bioko I. where it appears to have the most limited altitude range of any of the seven species of primates (Butynski & Koster 1994). Annual rainfall from ca. 1500 mm to ca. >4000 mm on the mainland and from ca. 4000–10,000 mm on Bioko I.

Abundance Biomass for *C. n. nictitans* in primary forests ranges from ca. 40 kg/km² in the Forêt des Abeilles, C Gabon (Brugière 1988), to ca. 480 kg/km² at Odzala N. P., Congo (Bermejo 1999). At most sites the greatest biomass is in mature forest. At Odzala N. P., biomass varies from 41 kg/km² in forest patches, 60 kg/km² in riverine forests, 90 kg/km² in secondary forests to 480 kg/km² in mature forest (adapted from Bermejo 1999). In Lopé Reserve, C Gabon, biomass is lower in the continuous forests (Marantaceae forests with dense undergrowth) than in gallery forests and forest patches of the neighbouring savanna (81 kg/km² vs. 135 kg/km²; Tutin *et al.* 1997a, b). In gallery forests of St Floris N. P., Central African Republic, the biomass is less than 10 kg/km² (Fay 1988). At most sites, in both mainland mature forest and riverine forest, *C. n. nictitans* is more abundant than its congeners *C. pogonias* and Moustached Monkey *Cercopithecus cephus*. In secondary forest its density is generally lower than that of *C. cephus*. On the mainland, in northern Korup N. P., W. Cameroon, the density of *C. n. martini* ca. 1.1–1.5 groups/km² and biomass at 51 kg/km² (A. Edwards quoted by J. Oates pers. comm.). Another study in Korup N. P., conducted in 2004–05, found 0.08–0.37 groups/km² (Linder & Oates 2011). Uncommon in Okomu N. P., SW Nigeria, where Akinsorotan *et al.* (2011) sighted only 0.02 groups/km. In Liberia and Côte d'Ivoire, *C. n. nictitans* is usually rare and occurs only in the drier, more deciduous forest north of the main evergreen forest (H.-J. Kuhn quoted by J. Oates pers. comm.). This might be influenced by competition with Diana Monkey *Cercopithecus diana* (Oates 1988b).

Lateral view of skull of Eastern Putty-nosed Monkey *Cercopithecus nictitans* adult male.

Perhaps the rarest primate on Bioko I. Encounter rate of 0.01 groups/km of transect during an island-wide survey in 1986 (373 km of census; Butynski & Koster 1994). Encounter rate of 0.02 groups/km in 2008 along 49 km of transect the south slope of Pico Basilé, and 0.06 groups/km in 2009 along 48 km of transect and no groups encountered in 2010 along 50 km of transect at Badja North, SW Bioko (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. comm.). The south slope of Pico Basilé and Badja North are remote sites where hunting is relatively uncommon and where there are no other anthropogenic impacts. As such, the encounter rates at these two sites are likely close to what is expected for an undisturbed population of *C. nictitans* living near the upper altitude range for the species (i.e. 500–900 m). In contrast, at Arihá, SE Bioko, an area in which there is a moderate level of hunting for primates but that is at the lower altitude range for *C. nictitans*, Maté & Colell (1995) encountered 0.10 groups/km in 1992 along 100 km of transect. They estimated 0.05 groups/km² and ca. 0.3 ind/km² at Arihá.

Adaptations Diurnal and arboreal. As a species, *C. nictitans* is a successful monkey, able to colonize different habitats and to come to the ground occasionally to cross open areas. This generalist species has two adaptive advantages: highly developed arboreal skills and the ability to eat leaves and insects during periods when fruit is scarce. The large white spot on the nose provides a distinctive cue for species recognition. The main function of the white nose spot seems to be to serve as a visual distraction from the eyes. The nose-spot becomes especially conspicuous during 'head flagging', which Kingdon (1988b, 2007) considers part of 'cut-off' behaviour. This behaviour has resulted in the French name of 'hocheur' (i.e. 'head shaker') for this species. However, this name is confusing because the behaviour also occurs in other guenons and, in DR Congo, the Red-tailed Monkey *Cercopithecus ascanius* is also named 'hocheur'. Like other cercopithecines, *C. nictitans* possesses large cheek-pouches. These are used to store large amounts of fruit before moving to ingest the fruit in a place more sheltered from predators and while foraging for more nutritious insects. Adult ♂♂ have large air sacs used for producing loud-calls that are highly specific to the *C. nictitans* Group (Gautier 1971).

Foraging and Food Omnivorous. In Makokou area, NE Gabon, annual diet of *C. nictitans* dominated by fruit and seeds (70%), followed by leaves (17%) and animal matter (10%; Gautier-Hion 1980). Great seasonal variations in diet occur with an inverse relationship between

fruit and leaf intake. Adult ♂♂ are more frugivorous than adult ♀♀, especially when fruit is abundant, while the ingestion of leaves by adult ♀♀ is twice that of adult ♂♂. Seventy-one plant species identified in the diet, mainly taken from Annonaceae, Apocynaceae, Burseraceae and Euphorbiaceae. Females eat more animal matter. Sedentary prey forms the great majority of captures (>90%), caterpillars and ants being the most common prey. In Forêt des Abeilles, the annual plant diet comprised 36% fruit (including 11% arils), 57% seeds and 11% leaves. Seeds and leaves of Caesalpiniaceae comprised 46% of the diet (Brugière *et al.* 2002). At Lopé Reserve, diet of *C. nictitans* in a continuous forest differed from that in neighbouring forest fragments by more fruit eating (59% vs. 44%) and seed eating (11% vs. 4%) and by less insect eating (3% vs. 24%; Tutin *et al.* 1997a, b). Forages in groups or in polyspecific associations. Most active in early morning and late afternoon. Home-range size ca. 55–100 ha; daily range ca. 1500 m (Gautier-Hion 1988).

Social and Reproductive Behaviour Social. Bisexual groups contain only one adult ♂ who gives 'pyow' calls, especially at dawn and dusk (Gautier & Gautier-Hion 1977). These loud-calls help to maintain space between groups and rally group members. When two groups are close to each other, 'pyow' calls are accompanied by loud aggressive 'barks'. Territorial conflicts occur. Mean group size varies from 11 individuals at Forêt des Abeilles (8–19, $n = 35$; Brugière *et al.* 2002), to 14.6 individuals at Odzala N. P. (5–27, $n = 61$; Maisels 1995), to 18 individuals at Ngotto Forest, Central African Republic (15–20, $n = 6$; Gautier-Hion 1996). In large groups the number of adult ♀♀ may reach 11. Solitary adult ♂♂ are frequent (up to 28% of encounters during a census).

Cercopithecus n. nictitans is in polyspecific associations with one or more arboreal monkey species 50% of the time on average (30–87% of the time, depending on site). The lowest incidence is at Odzala N. P., which harbours the highest density of *C. n. nictitans*; suggesting that not all groups can find partners with which to associate. The species that associate most frequently with *C. n. nictitans* are *C. cephus* (45% of cases), *C. cephus* + *C. pogonias* (32%), and *C. pogonias* (16%). On Bioko I., *C. n. martini* in association with *C. pogonias*, Red-eared Monkey *Cercopithecus erythrotis*, Black Colobus *Colobus satanas* and Pennant's Red Colobus *Procolobus pennantii* (Butynski & Koster 1994, T. Butynski pers. comm.).

In tri-specific associations that include *C. pogonias* + *C. cephus*, the adult ♂ *C. n. nictitans* generally gives his 'pyow' calls after the 'boom' calls of the adult ♂ *C. pogonias*. This is true for the call sequences given ritually at dawn, during which the adult ♂ *nictitans* called after the adult ♂ *pogonias* in 77% of cases, as well as when the mixed group faced an avian predator (adult ♂ *nictitans* called first in 11% of cases) or a climbing predator (adult ♂ *nictitans* called first in 8% of cases). These figures suggest reduced vigilance by the adult ♂ *nictitans*. The adult ♂ *nictitans* called first mostly after violent, loud, perturbations such as a tree fall or a rumble of thunder (Gautier & Gautier-Hion 1983, Gautier-Hion *et al.* 1983). When in polyspecific association, the adult ♂ *nictitans* may actively pursue African Crowned Eagles *Stephanoaetus coronatus* even when the eagles' attack was on a monkey of another species (Gautier-Hion & Tutin 1988).

Cercopithecus n. nictitans in Gabon gives the boom call. The boom of *C. nictitans* is weaker and lower-pitched (112 Hz) than the boom of De Brazza's Monkey *Cercopithecus neglectus* or Crowned Monkey

Cercopithecus pogonias (150 Hz). In this regard, the boom of *C. n. nictitans* is similar to that of the Gentle Monkey *Cercopithecus mitis* (Gautier 1973, J.-P. Gautier pers. comm.). A particularly interesting question is, does *C. nictitans* give the boom over its entire geographic range? The opinion of T. Butynski (pers. comm.) is that *C. n. martini* on Bioko does not give the boom, or else gives this call so infrequently that it has not, as yet, been detected by researchers. *Cercopithecus n. martini* is a common monkey in Korup N. P., but J. Linder has not heard this species give the boom there, nor has J. Oates heard this call from *C. n. martini* in the Cross R. forests of Nigeria. Struhsaker (1970) makes no mention of the boom call for *C. n. martini* in Cameroon. In Gashaka Gumti N. P., NE Nigeria, *C. n. martini* does give the boom, but much less frequently relative to Campbell's Monkey *Cercopithecus campbelli* (K. Arnold pers. comm.).

Reproduction and Population Structure *Cercopithecus nictitans* reproduces seasonally in synchrony with other cercopithecines (Gautier-Hion 1968, Butynski 1988). Mating takes place in the main dry season (most often Jul–Aug) and births peak around the short dry season (Dec–Feb). Sexual maturity is reached around six years for ♂♂ and four years for ♀♀. Gestation length is about 5.5 months (Gautier-Hion & Gautier 1976). The single infant weighs about 350 g (Gautier-Hion 1968). Structure of 36 groups in Odzala N. P. averaged 8% adult ♂♂, 35% adult ♀♀, 20% subadults, 24% juveniles and 14% infants (Maisels 1995). Solitaries account for about 9% of a population in C Gabon (Brugière *et al.* 2002).

Predators, Parasites and Diseases Leopard *Panthera pardus* is a predator of *C. nictitans* (Henschel *et al.* 2005, 2011). Humans are the most frequent predators of *C. nictitans* on Bioko I. where *S. coronatus*, Leopards and Golden Cats *Profelus aurata* are absent (Struhsaker 2000a, T. Butynski pers. comm.). No information on diseases and parasites.

Conservation IUCN Category (2012): *C. nictitans* is Least Concern, whereas *C. n. martini* is Vulnerable. CITES (2012): Appendix II.

Among arboreal monkeys, *C. nictitans* may be the most tolerant of heavy hunting pressure, but near villages, this species is often decimated by hunting (Linder & Oates 2011). There remain large, dense populations in several places. There is particular concern for *C. n. martini* (including *stampflii*) as this subspecies has a relatively small, highly fragmented range and is heavily hunted both on the mainland (Oates *et al.* 2004) and on Bioko I. (Hearn *et al.* 2006). On Bioko I.

(2017 km²), hunting with shotguns is the only threat to *C. n. martini*. The price paid per carcass in 2005 was ca. US\$31. This is possibly the least common monkey on Bioko I. and is unlikely to number >1000 individuals (Hearn *et al.* 2006). Forest clearance also threatens this species, which prefers primary lowland forest. Protection of the population in the Gran Caldera & Southern Highlands Scientific Reserve (510 km²) is critical to the long-term conservation of this monkey on Bioko (Hearn *et al.* 2006).

Measurements

Cercopithecus nictitans

Cercopithecus n. nictitans

HB (♂♂): 550 mm, n = 9

HB (♀♀): 435 mm, n = 3

T (♂♂): 910 mm, n = 9

T (♀♀): 765 mm, n = 3

HF: n. d.

E: n. d.

WT (♂♂): 6.7 (3.5–9.8) kg, n = 56

WT (♀♀): 4.1 (2.7–6.1) kg, n = 48

Makokou area, NE Gabon (Gautier-Hion *et al.* 1999); ranges not available for linear measurements

Cercopithecus n. martini

HB (♂♂): 485 (420–570) mm, n = 14

HB (♀♀): 439 (400–500) mm, n = 20

T (♂♂): 740 (700–790) mm, n = 13

T (♀♀): 648 (558–700) mm, n = 19

HF (♂♂): 139 (130–150) mm, n = 14

HF (♀♀): 125 (112–132) mm, n = 18

E (♂♂): 30 (28–35) mm, n = 15

E (♀♀): 29 (26–32) mm, n = 20

WT (♂♂): 5.1 (4.0–6.0) kg, n = 14

WT (♀♀): 4.1 (3.0–5.6) kg, n = 20

Upper canine (♂♂): 16 (12–20) mm, n = 13

Upper canine (♀♀): 9 (6–12) mm, n = 16

Lower canine (♂♂): 11 (10–12) mm, n = 13

Lower canine (♀♀): 6 (4–10) mm, n = 18

Cercopithecus mitis Wolf, 1822. Abbild. Beschreib. Merkw. Naturgesch. Gegenstandes 2: 145. Angola (holotype a menagerie animal and not in existence).

Golden Monkey *Cercopithecus mitis kandti* adult male.

Taxonomy Polytypic species. Several classifications place *Cercopithecus mitis* and *Cercopithecus nictitans* in the *Cercopithecus* (*nictitans*) Group or Superspecies (Hill 1966, Dandelot 1974, Lernould 1988, Kingdon 1997, Grubb *et al.* 2003). See *Cercopithecus* (*nictitans*) Group profile. This classification is supported by DNA analysis (Van der Kuyl *et al.* 1995, Tosi *et al.* 2005), vocalizations (Gautier 1989a), facial pattern (Kingdon 1980, 1988b, 1997), proteins (Ruvolo 1988), chromosomes (Sineo 1990), and external morphology and distribution patterns (Hill 1966). A recent molecular study recognizes *C. nictitans*, *C. mitis* and *C. albogularis* as a single genetic entity (Tosi *et al.* 2005). This profile deals with the Gentle Monkeys *C. mitis/albogularis* Subgroup of the *C. (nictitans)* Group.

Highly polytypic species (Kuhn 1967, Rahm 1970, Groves 1993) within which Grubb *et al.* (2003) recognize 16 subspecies. Two species, Blue Monkey *C. mitis* and Sykes's Monkey *C. albogularis*, have been widely recognized (Hill 1966, Dandelot 1974, Napier 1981, Lernould 1988). Groves (2001) recognizes four species in the *C. mitis/albogularis* Subgroup; *C. mitis*, *C. albogularis*, Silver Monkey *C. doggetti* and Golden Monkey *C. kandti*. The great variability in this taxon and its disputed taxonomy is indicated by the use of non-traditional nomenclature in previous classifications including

'subspecies-groups' (Napier 1981), 'clusters' (Kingdon 1997), 'sections' (Grubb 2001, Grubb *et al.* 2003), 'species-groups' and 'species-subgroups' (Grubb *et al.* 2003).

In the *C. (nictitans)* Group profile presented above, Kingdon presents a taxonomy that recognizes 18 forms of Gentle Monkeys in six 'clusters'. Here we recognize 17 subspecies in five sections in two clusters. The difference is that Kingdon recognizes *maesi*. Both of these taxonomies are similar to Grubb *et al.* (2003) except that Grubb *et al.* (2003) do not recognize *maesi* or *zammarnoi*. The five sections put forth here follow Grubb *et al.* (2003).

Hybridization between Red-tailed Monkey *Cercopithecus ascanius* and *C. mitis* occurs in East Africa at several sites (Aldrich-Blake 1968, Struhsaker *et al.* 1988, Detwiler 2002, Detwiler *et al.* 2005). There are also three instances of a inter-generic hybridization between *C. mitis* and Vervet *Chlorocebus pygerythrus* in Kenya (De Jong & Butynski 2010b). Several authors report intra-specific hybridization in *C. mitis*. Individuals showing intermediate pelage patterns reported by Rahm (1970), Colyn (1988, 1991) and Twinomugisha *et al.* (2003) – *C. m. doggetti* × *C. m. kandti*, *C. m. stuhlmanni* × *C. m. schoutedeni*, *C. m. opisthostictus* × *C. m. stuhlmanni*, *C. m. heymansi* × *C. m. opisthostictus*, *C. m. stuhlmanni* × *C. m. kandti* and *C. m. doggetti* × *C. m. stuhlmanni*. Booth (1968) noted a hybrid swarm (*C. m. stuhlmanni* × *C. m. albogularis*) in the Ngorongoro–L. Manyara area of N Tanzania.

Synonyms: *albogularis*, *albotorquatus*, *beirensis*, *boutourlinii*, *carruthersi*, *chimango*, *diadematus*, *dilophos*, *doggetti*, *elgonis*, *erythrarchus*, *francescae*, *heymansi*, *hindei*, *insignis*, *kanti*, *kibonotensis*, *kima*, *kolbi*, *labiatus*, *leucampyx*, *maesi*, *maritima*, *mauae*, *moloneyi*, *monoides*, *mossambicus*, *neumanni*, *nigrigenis*, *nubilis*, *nyasae*, *omensis*, *opisthostictus*, *otoleucus*, *phylax*, *pluto*, *princeps*, *rufilatus*, *rufotinctus*, *samango*, *schoutedeni*, *schubotzi*, *schwarzi*, *sibatoi*, *stairsi*, *stevensoni*, *stuhlmanni*, *zammarnoi* (Groves 2001, 2005c, Grubb *et al.* 2003).

Chromosome number in *C. mitis* (including *C. albogularis*): 2n = 72 (Chiarelli 1962b, 1968a, b, Bender & Chu 1963, Sineo 1990, Hirai *et al.* 2000, Moulin *et al.* 2008). Dutrillaux *et al.* (1980) report 2n = 70 for a captive hybrid *C. m. opisthostictus* × *C. m. stuhlmanni* and a *C. m. opisthostictus* ♀.

Description A moderately large, long-tailed arboreal monkey. Face dark with backward- and downward-directed whiskers and often with oval-shaped cheeks giving face a round appearance. Lacks a beard. Forelimbs, hands, feet and distal half of tail black or blackish. Saddle and shoulders variously coloured from dark grey to grey suffused with green, yellow or orange. Shoulder/saddle hair can be long, giving appearance of a mantle. Ventrums black or grey to white. Sexes alike in colouration but adult ♀ smaller than adult ♂, weighing ca. 60% as much. Adult ♂ has a more prognathous jaw and larger canines than adult ♀. Newborns black/brown, without grizzled pelage; sometimes with faint diadem.

General descriptions of this species are here divided into two clusters: one of eight subspecies found north and west of the Eastern

Rift Valley, and one of nine subspecies found east and south of the Eastern Rift Valley.

Northern and Western Cluster: West of the Eastern Rift Valley in SW Ethiopia, S Sudan, Uganda, W Kenya, DR Congo, Zambia and Angola, includes subspecies *boutourlinii*, *doggetti*, *heymansi*, *kandti*, *mitis*, *opisthostictus*, *schoutedeni* and *stuhlmanni*. Pale brow-band (diadem) contrasting in colour with dark crown, except in *opisthostictus*; cheeks rounded, speckled; chin pale; ear-tufts white. Crown and neck dark grey or black. Back dark, usually grey or greenish, except in *kandti*; black band across shoulders.

Southern and Eastern Cluster: East of the Eastern Rift Valley from SE Somalia to the Eastern Cape Province in South Africa, includes subspecies *albogularis*, *albotorquatus*, *erythrarchus*, *francescae*, *kolbi*, *labiatus*, *moloneyi*, *monoides* and *zammaranoi*. Diadem not distinct; ear-tufts white, buff, or red; brow hairs long, speckled, stiff and projecting forward; chin and cheeks white; throat-patch pale and forms partial neck collar in northern forms. Back grey, yellowish-grey, or dark olive, in some shows gradual increase in yellow or red from the shoulders to back of rump; shoulders same colour as crown and without black band. Ventrums light. Undersurface of tail base with orange, red or brown hairs, except in *labiatus*. Photographs of several of these subspecies are available at: www.wildsolutions.nl

Geographic Variation

South and East

Cercopithecus mitis albogularis Section:

- C. m. zammaranoi* Zammarano's Monkey. S Somalia, along course of Jubba R. and Shabeelle R. Small size; back, shoulders and rump olive-green; ventrum ashy-grey; no rufous tint on inner thighs or lumbar region; limbs dark, almost black; white collar reduced compared with nearby *albotorquatus*.
- C. m. albotorquatus* Pousargues's Monkey. Extreme S Somalia, Pate I., and middle and lower course of Tana R., Kenya. Diadem and crown dark olive; throat and (near complete) neck collar white. Back and shoulders dark olive; rump olive, yellowish, or reddish-brown; inner thighs may also be reddish-brown. Ventrums ashy-grey or cream. See De Jong & Butynski (2011) for details. Synonyms: *phylax*, *rufotinctus*.
- C. m. kolbi* Kolb's Monkey. Kenya Highlands east of the Rift Valley. Ear-tufts long, white; collar broad, white, and nearly complete. Back russet, slightly darker than *albogularis*. Ventrums dark. Synonyms: *hindei*, *nubilus*.
- C. m. albogularis* Zanzibar Sykes's Monkey. SE Kenya, Zanzibar I., Mt Kilimanjaro, Mt Meru, NE Tanzania. Head and shoulders grey; ear-tufts small and white; throat white; collar narrow. Rump reddish-yellow. Synonym: *kibonotensis*.
- C. m. monoides* Tanzania Sykes's Monkey. Coastal Tanzania, Mafia I., NE Mozambique. Throat-patch variable in size; crown, cheeks, neck and shoulders yellowish-olive. Back reddish-brown. Ventrums dark slate-grey. Synonym: *rufilatus*.
- C. m. francescae* Red-eared White-collared Monkey. West of L. Malawi, Malawi. Collar short and grey; ear-tufts red. Shoulders dark grey. Back brownish-grey. Ventrums dark grey.
- C. m. moloneyi* Moloney's Monkey. SW Tanzania to northern shore of L. Malawi, Zambia east of Luangwa R., N Malawi. Throat-patch cream. Back with dark red saddle. Sides and thighs light grey. Ventral surface of tail reddish.

C. m. erythrarchus Stairs's Monkey or Samango Monkey. N South Africa (Limpopo Province, N KwaZulu–Natal Province), Mozambique (incl. Bazaruto I.), NE Zimbabwe. Ear-tufts yellowish-white. Back light grey to olive-green, especially on saddle, grizzled. Ventrums whitish or pale grey. Ischial callosities with yellow, orange or red hairs. Tail black. Synonyms: *beirensis*, *mossambicus*, *nyasae*, *schwarzi*, *stairsi*, *stevensoni*.

C. m. labiatus Samango Monkey. Eastern Cape Province to KwaZulu–Natal midlands and southern Mpumalanga Province, South Africa. Crown almost black. Back dark-grey, darkest of all subspecies in the *albogularis* Section. Ventrums pale ashy grey. Tail with dark dorsal band, buff laterally and ventrally; base of tail with no red. Synonym: *samango*.

North and West

Cercopithecus mitis heymansi Section:

- C. m. heymansi* Lomami River Monkey. Between Lualaba R. and Lomami R., DR Congo. Face black; diadem white and narrow; crown, neck and shoulders blue-grey. Ventrums lighter than dorsum.

Cercopithecus mitis mitis Section:

- C. m. opisthostictus* Rump-spotted Monkey. S DR Congo, N Zambia, N Zimbabwe, E Angola. Lips, chin, throat white; diadem grey, speckled; crown like back. Back uniformly olive to light grey; shoulders, neck and ventrum black. Hindlimbs dark but not black.
- C. m. mitis* Angola Pluto Monkey. Coastal Angola. Diadem whitish and conspicuous; nose, lips, chin with short, white hairs; crown, neck, shoulders and hindlimbs black. Back and ventrum dark grey to black. Synonyms: *diadematus*, *dilophos*, *leucampyx*, *nigrigenis*, *pluto*.

Cercopithecus mitis boutourlinii Section:

- C. m. boutourlinii* Boutourlini's Blue Monkey. SW Ethiopia. Diadem not differentiated from crown; lips, chin and throat white. Back dark green or yellowish-grey. Shoulders black with grey speckling. Hindlimbs and ventrum black. Synonym: *omensis*.

Cercopithecus mitis stuhlmanni Section:

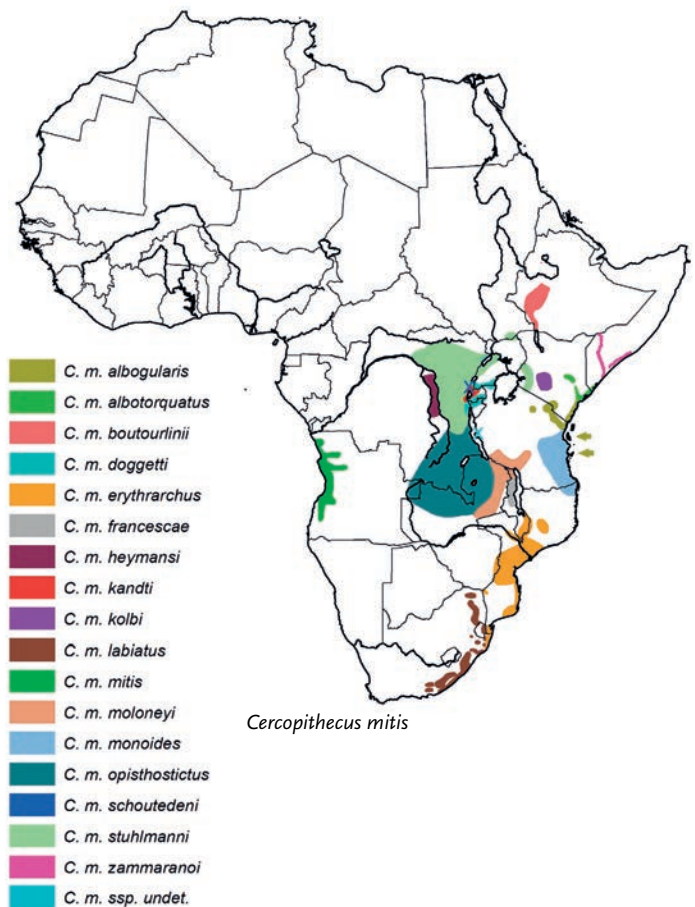

- C. m. stuhlmanni* Stuhlmann's Blue Monkey. NE DR Congo, Uganda, W Kenya, SE Sudan. Chin and throat white; diadem grey; crown and neck black. Back steel blue-grey, but sometimes faintly greenish. Ventrums lighter than dorsum. Synonyms: *carruthersi*, *elgonis*, *maesi*, *mauae*, *neumanni*, *otoleucus*, *princeps*.
- C. m. schoutedeni* Schouteden's Silver Monkey. Idjwi I. in L. Kivu and western Virunga Mts, E DR Congo. Diadem white and speckled; crown and neck black. Back pale olive-grey. Ventrums lighter than dorsum.
- C. m. doggetti* Doggett's Silver Monkey. Burundi, Rwanda, SW Uganda, NW Tanzania, E DR Congo. Crown and neck black, contrasting sharply with diadem. Back light grey-brown. Hindlimbs blackish-grey. Synonym: *sibatoi*.
- C. m. kandti* Golden Monkey. E DR Congo near L. Kivu, Virunga Mts and Nyungwe N. P., SW Rwanda. Diadem dark yellowish-grey; crown and nape black. Back large amount of red or orange, amount of red individually variable; shoulder band narrow. Ventrums rust or orange. Synonym: *insignis*.

Similar Species

Cercopithecus nictitans. Western central Africa and West Africa. Parapatric and, perhaps, narrowly sympatric at eastern edge of geographic range. Nose with large white spot.

Distribution Endemic to Africa south of the Sahara. Rainforest, Afromontane–Afroalpine, Somalia–Masai Bushland, Zambezian Woodland, and Coastal Forest Mosaic BZs. Widespread in all forest types in central, East and southern Africa. Nominal subspecies in extra-limital populations in W Angola. Occurs south of ca. 11°N on the Ethiopian Plateau (*C. m. boutourlinii*; Napier 1981), in SE Sudan (*C. m. stuhlmanni*; Butler 1966), SE Somalia (*C. m. zammaranoi*; Gippoliti 2003), S Somalia and NE Kenya, including Pate I. (*C. m. albotoxatus*; Lernould 1988). *Cercopithecus m. stuhlmanni* east of Congo R. and to west of Eastern Rift Valley in Kenya. *Cercopithecus m. stuhlmanni* common on right bank of Congo/Lualaba River, from Itimbiri R. confluence to ca. 05°S (Colyn 1991). Range of *C. m. heymsi* is known with certainty only from northern part of forest between Lualaba R. and Lomami R. (E DR Congo; Colyn 1988). *Cercopithecus m. opisthostictus* in E Angola along the High Zambezi (Machado & Crawford-Cabral 1999). *Cercopithecus m. stuhlmanni* and *C. m. opisthostictus* in contact and may hybridize north of Lukuga R., E DR Congo (Colyn 1991). *Cercopithecus m. kandti* is restricted to Virunga Mts of SW Uganda, NW Rwanda and E DR Congo (Aveling 1984, Twinomugisha 2000), and possibly Nyungwe N. P., E Rwanda (A. Plumtre & B. Kaplin pers. comm.). Distribution of *C. m. schoutedeni* limited to Idjwi I. in L. Kivu (DR Congo) and small area to north (Lernould 1988). *Cercopithecus m. kolbi* confined to Kenya Highlands (Kingdon 1971, De Jong & Butynski 2009). *Cercopithecus m. monoides* in E Tanzania to the coast and bounded in the north by the Pangani R. and by *C. m. albogularis* whose range extends into SE Kenya (Lernould 1988, De Jong & Butynski 2009). *Cercopithecus m. albogularis* also on Unguja I. (formally Zanzibar). *Cercopithecus m. moloneyi* in vicinity of L. Rukwa, southern L. Tanganyika and NE Zambia (Lernould 1988). In Malawi *C. m. francescae* replaces *C. m. moloneyi* in north from Chombe Mt and is replaced by *C. m. erythrarchus* south of Ntchisi Mt (Ansell & Dowsett 1988). Exact boundary between coastal distributions of *C. m. monoides* and *C. m. erythrarchus* in N Mozambique unknown (Lernould 1988). *Cercopithecus m. erythrarchus* extends down eastern seaboard of southern Africa, including the eastern highlands of Zimbabwe, but not south of Umfolozi R. Remnant population of *C. m. erythrarchus* on Bazaruto I., S Mozambique (Downs & Wirminghaus 1997). Both *C. m. erythrarchus* and *C. m. labiatus* found in South Africa, but latter subspecies confined to higher-altitude forests and coastal forests of afromontane origin to ca. 33°S, Eastern Cape Province (Lawes 1990a).

Habitat In all types of evergreen forest from primary and secondary lowland rainforest, riverine, swamp, gallery, coastal, through montane forest, including bamboo zone, and up to 3800 m on Rwenzori Mts, Uganda (A. Plumtre pers. comm.). Prefers primary forest, but also in secondary forest, logged forest and thicket (Chapman *et al.* 2000, Fashing *et al.* 2012). More tolerant of poor habitat quality than most guenons, accounting for wide African distribution and use of diverse forest types (Lawes 1990a, Thomas 1991). Only forest guenon with an extensive range outside lowland rainforest. Occupies three broad forest types, many subspecies occurring in at least two: (1) afromontane (*stuhlmanni*, *schoutedeni*, *boutourlinii*, *doggetti*, *kandti*, *kolbi*, *francescae*,

albogularis, *labiatus*); (2) central lowland forests (*stuhlmanni*, *doggetti*, *maesi*, *heymsi*, *opisthostictus*, *moloneyi*, *albogularis*, *mitis*); and (3) Indian Ocean coastal lowland and riparian forests (*zammaranoi*, *albotoxatus*, *albogularis*, *monoides*, *erythrarchus*) (Stott 1960, Butler 1966, Kingdon 1971, Bolton 1973, Colyn 1988, Gippoliti 2003, De Jong & Butynski 2009). *Cercopithecus m. stuhlmanni* is a denizen of larger lowland and montane forests. *Cercopithecus m. kolbi* occupies montane forests of the Kenya Highlands and ventures into pine (*Pinus* spp.) plantations adjacent to forest (De Vos & Omar 1971, Maganga & Wright 1991); it shares this behaviour with *C. m. francescae* and *C. m. labiatus* (Von dem Bussche & Van der Zee 1985, Beeson 1987). *Cercopithecus m. kandti* inhabits montane forests of the Virunga Mts, including the bamboo zone (Aveling 1984). *Cercopithecus m. doggetti* uses mature montane forests, bamboo forest, and papyrus swamps in marshy lowlands, but is more common in moist valley and riverine forest (*Macaranga* spp.) (Kaplin 2001). *Cercopithecus m. albotoxatus* in riparian forest patches along the middle and lower Tana R. and in coastal forests north of the Tana Delta (Butynski & Mwangi 1994). Subspecies in coastal lowland forest use coastal thicket where it is adjacent to high forest. *Cercopithecus m. erythrarchus* in a variety of forest types from coastal lowland forest and thicket, to riverine, swamp, deciduous dry and coastal dune forest on the mainland (Lawes 1992), and in low-quality swamp forest and mixed woodland on Bazaruto I. (Downs & Wirminghaus 1997). *Cercopithecus m. labiatus* in afromontane forests only (Lawes 1990a).

Abundance A shy and sometimes difficult species to observe, but nevertheless common throughout the geographic range. Can be a pest around lodges, human habitation and gardens (Chapman *et al.*

1998). Occurs at moderate density – 0.7 ind/ha (0.05–2.0) or 4.3 groups/km² (0.4–9.0) – over most of its range (Aldrich-Blake 1970, Moreno-Black & Maples 1977, Rudran 1978b, Schlichte 1978, Scorer 1980, Rodgers & Homewood 1982, Van der Zee & Viljoen 1984, Butynski 1990, Lawes *et al.* 1990, Thomas 1991, Cordeiro 1992, Kaplin & Moermond 1998, Kaplin 2001). At 1.2 ind/ha in gallery forest along the Tana R., Kenya (Butynski & Mwangi 1994). At greatest density in montane forests of East and central Africa (1.2–2.2 ind/ha; De Vos & Omar 1971, Beeson 1987, Cords 1987b, Fashing & Cords 2000, Twinomugisha 2000, Cords & Chowdhury 2010), and coastal forests of S Mozambique and Maputaland (>2.0 ind/ha; KwaZulu–Natal; Lawes 1992). At these localities *C. mitis* is usually the only resident guenon species. Low-density populations (<0.3 ind/ha) inhabit deciduous dry sand forests and riverine forests in southern Africa (Lawes 1992). Low-density populations (<0.2 ind/ha) also found in secondary forest in the Ituri Forest (DR Congo) (Thomas 1991). Abundance varies within the same forest over space and time. For example, in Kibale N. P., Uganda, there is more than a ten-fold difference in density between the Kanyawara population (0.65 ind/ha) and the Ngogo population (0.05 ind/ha; Butynski 1990). Abundance may be reduced by forest disturbance, at least partly because of effect on food supply. Abundance data lacking for populations in Ethiopia, along most of the eastern seaboard and for mountains of E Tanzania.

Adaptations Flexible dietary and habitat preferences make *C. mitis* a versatile and widely distributed species. Occasionally comes to the ground, but shares adaptations for arboreal life with other strictly arboreal primates – grasping hands, long tail for balance, and relatively short stocky forelimbs and long slender hindlimbs for jumping and bracing movement in forest canopy. An adult ♂ *C. m. stuhlmanni* at Governors' Camp, Mara, S Kenya, frequently swam ('dog paddled') ca. 25 m across the Mara R. (D. Richards pers. comm. to T. Butynski). Similarly, an adult *C. m. albitorquatus* seen swimming a ca. 35 m-wide channel in the Tana Delta, Kenya (Q. Luke pers. comm. to T. Butynski).

Can ferment foods in both the foregut and hindgut allowing considerable dietary flexibility. Possesses large caecum and colon in hindgut (Bruerton & Perrin 1988, 1991). Haustrum-like sacculations in caecum provide microhabitats for numerous symbiotic bacteria (Bruerton *et al.* 1991). Food can be directed into caecum via muscular valve (Bruerton & Perrin 1988) or allowed to pass by into colon. Slowed passage rate of food in caecum allows microbial fermentation, which facilitates digestion of fibrous foods like leaves (Bruerton & Perrin 1988, Bruerton *et al.* 1991). Foregut (stomach) digestion of fruits and hindgut (caecum and colon) fermentation of leaves allow a broad diet. No other cercopithecoid monkey, with possible exception of Allen's Swamp Monkey *Allenopithecus nigroviridis*, which shows signs of incipient sacculization of the stomach (Hill 1966), has similar gut adaptations. Capacity for folivory is one reason *C. mitis* copes better in secondary and/or logged forest than other guenon species (Rudran 1978a, Struhsaker 1978a, Thomas 1991). Like other Cercopithecidae, *C. mitis* uses cheek pouches for temporarily storing food, especially fruits. Activity is related to ambient temperature. Sunning behaviour common when cold – early mornings, after rainstorms and at higher altitudes. Less active when it is warmer, leading to a diurnal activity cycle with periods of rest most common at midday, especially on sunny, hot, days. Populations that include

Lateral, palatal and dorsal views of skull of Samango Monkey *Cercopithecus mitis labiatus*.

much low-quality food in the diet spend more time resting, probably to facilitate caecal fermentation of food (Lawes & Piper 1992).

Vocalizations, especially low frequency booms by adult ♂♂, involve large bilobed laryngeal air sacs that develop at puberty. This species is more sensitive than humans to both low (125–250 Hz) and high (8–16 kHz) frequencies, which correspond with some of their vocalizations (Brown & Waser 1984).

Foraging and Food Omnivore. Feeds primarily on fruit (ca. 40% of diet) (Cords 1987b, Butynski 1990, Lawes 1991) but much time spent foraging for invertebrates. Has most general diet of the guenons; includes fruit, leaves, flowers, stems, galls, bark, gum, fungi, invertebrates and occasionally small vertebrates (Butynski 1982c). Prefers ripe over unripe fruit and fleshy fruits over seeds (Lawes 1991, Kaplin & Moermond 1998, Kaplin *et al.* 1998). Targets fruit rich in sugars. Favours fig (*Ficus*) trees and follows seasonal fruit availability and distribution in the home-range. Includes more leaf material in diet than most guenon species (15–52%) (Cords 1987b), particularly during periods of fruit shortage, or where there are low densities of fruiting tree species (Beeson 1987, Lawes 1991, Twinomugisha 2000). *Cercopithecus m. francescae* (Zomba Plateau, Malawi) can survive on little or no fruit for months by eating leaves (52% of diet) (Beeson 1989). In Virunga Mts *C. m. kandti* subsists on bamboo *Sinarundinaria alpina* shoots, young culms and young leaves, combining this with fruits from tree species common in the bamboo zone (Twinomugisha 2000). Prefers young leaves and new shoots to mature leaves, as well as leaves low in fibre and high in protein (Lawes 1991). Although a large number of plant species may be included in the annual diet (from 57 at Cape Vidal, South Africa, to 104 at Kakamega, Kenya), on average 64% (44–94%) of monthly plant diet

derives from as few as five plant species or ten species-specific food items (Rudran 1978a, Cords 1986, Lawes 1991). Overlap in use of specific food items between consecutive months is ca. 40% on average (Rudran 1978a, Cords 1986, Beeson 1989, Lawes 1991), but may be as low as 25% (Lawes 1991) and as much as 99% between months (Beeson 1989). Adult ♂♂ include more fruit (ca. 60%) in their diet than ♀♀ (ca. 47%) or subadults (ca. 34–59%). Females and subadults have similar diets although subadults may eat fewer leaves and more insects (Rudran 1978b, Cords 1986, Lawes 1990b).

Insects and other animal prey provide a more readily digestible source of protein than leaves. Insects can form a large part of the diet (30–45%; Butynski 1990) but mostly comprise 5–20% of the diet (Rudran 1978b, Schlichte 1978, Beeson 1987, Cords 1987b, Lawes 1991, Beeson *et al.* 1996, Kaplin & Moermond 1998, Kaplin *et al.* 1998, Kaplin 2001). Populations that eat large amounts of insects often eat proportionally less leaves and vice versa (Beeson 1987, Kaplin *et al.* 1998, Twinomugisha 2000). In seasonal forests, such as those in southern Africa, insects are less abundant during winter (May–August); here *C. mitis* includes slightly more leaves and flowers in the diet than most other populations (Lawes 1991). Capable of catching and eating other animal prey and occasionally known to eat birds' eggs (Wahome *et al.* 1988), birds (Rudran 1978b, Cordeiro 1994), reptiles (small snakes and lizards, Wahome *et al.* 1988), small mammals such as bats (M. Cords pers. obs.), rodents (Wahome *et al.* 1988), squirrels (Mizuno *et al.* 1976, M. Cords pers. obs.) and even galagos (Butynski 1982a). Meat-eating is coincident with periods when fruit and young leaves are scarce (Butynski 1982a, Wahome *et al.* 1988). 'Wadging', the intermixing and chewing of leaves with meat, is reported for *C. mitis*, the only primate other than the Robust Chimpanzee *Pan troglodytes* that is known to do this (Butynski 1982a). As for other species of guenons, there is no evidence of cooperative hunting tactics, or meat-sharing behaviour, and vertebrate prey are opportunistically gathered (Butynski 1982c).

Feeding is usually concentrated in early morning, mid- to late-morning and the last hours of the day (Lawes & Piper 1992). The inbetween periods are spent resting and on social activities such as grooming. Group movements are coordinated and begin with directed movements of a few individuals, usually adult ♀♀, who are followed by the rest of the group. Group members may occupy several trees while feeding. Day range length is ca. 500–1900 m and averages 1100 m/day (Aldrich-Blake 1970, Rudran 1978a, Schlichte 1978, Beeson 1987, Cords 1987b, Butynski 1990, Lawes 1990b). A relatively small area (ca. 25%) of the home-range is used on any day, and consecutive daily ranges are often mutually exclusive (Rudran 1978b, Schlichte 1978, Cords 1987b, Butynski 1990, Lawes 1990b). Some *C. mitis* populations show a tendency to split into smaller satellite groups of 4–5 individuals during daily movement (Aldrich-Blake 1970, McMahon 1977, Moreno-Black & Maples 1977, Van der Zee & Viljoen 1984). This behaviour may be especially common for larger groups (M. Cords pers. obs.).

Foraging behaviour differs among sites and between seasons, depending on food availability. *Cercopithecus mitis* move more systematically about their home-range when fruit is scarce, ranging widely over a period of days, and selecting the most nutritious items from a broader spectrum of lower-quality foods such as mature leaves (Schlichte 1978, Scorer 1980, Beeson 1989). They may also travel longer distances to reach pockets of food outside their usual range (Omar & de Vos 1970, Schlichte 1978, Scorer 1980), such as young pine trees (from which they eat the cambium; Von dem Bussche & Van

Four subspecies of Gentle Monkeys *Cercopithecus mitis*.

Top to bottom: Doggett's Silver Monkey Cercopithecus mitis doggetti.

Moloney's Monkey Cercopithecus mitis moloneyi. Tanzanian Sykes's Monkey Cercopithecus mitis monoides. Kolb's Monkey Cercopithecus mitis kolbi.

der Zee 1985, Beeson 1987), flowering Black Wattle *Acacia mearnsii* plantations, or isolated fig trees. When fruit availability is low, but not critically so, they range less widely, have a clumped pattern of range use, use all available foods and have a diverse diet (Rudran 1978a, Butynski 1990, Lawes *et al.* 1990). If fruit is abundant they range widely, returning to favoured food species on consecutive days and/or sleep nearby to feed in a favoured tree in the morning. They are

fairly selective of items and have a less diverse diet than when fruit is less available (Rudran 1978b, Cords 1987b, Butynski 1990, Lawes *et al.* 1990). Where there is a marked seasonal difference in food availability (e.g. L. Kivu, DR Congo – *C. m. maesi*, Schlichte 1978; Zomba Plateau, Malawi – *C. m. francescae*, Beeson 1989) they range less widely when food is most abundant and day-range area decreases.

Social and Reproductive Behaviour Adult ♀♀ and young in permanent groups whose members are typically dispersed <100 m in daylight hours. Large groups may spread 200–300 m. At night individuals huddle in subgroups of 2–4, and groups are more cohesive. Typically, one resident ♂ accompanies each group, though influxes of ♂♂ occur regularly during the breeding season in some populations (Henzi & Lawes 1987), with individual ♂♂ shadowing or joining groups for periods of several hours to several months (Cords 2000c). Non-resident adult ♂♂ may be solitary, or form loose all-male associations (2–12 members) with flexible membership, especially in dense populations (Cords 2000c, Macleod 2000). Females are strictly philopatric (Cords & Chowdhury 2010). Subadult ♂♂ invariably transfer from natal group, but emigration is not closely tied to aggression from the resident ♂ (Ekernas & Cords 2007).

Group size is typically 10–25 individuals (mean 18, 3–65; Butynski 1990, Lawes 1992, M. Cords pers. obs.). Groups typically ca. 40% (31–75%) adult ♀♀ and 55% (21–69%) immatures. Adult to young ratio in heterosexual groups highly variable (range 0.33–2.60, median 0.82 across six populations). Group fission occurs when groups become larger than population norm. Resulting sister-groups divide original range, and develop antagonistic relations within one month after the fission (Cords & Rowell 1986). Group ♀♀ observed to cooperate to kill an unfamiliar adult *C. mitis* ♀ that entered their territory (Payne *et al.* 2003b).

Except for play, which occurs almost exclusively among immatures, most amicable interactions involve adult ♀♀. Allogrooming is the most frequent, occurring on average once per two hours, and accounting for 5–10% of daylight hours (Lawes & Piper 1992, Cords 2000a, Payne *et al.* 2003a). Adult ♀♀ do not groom all group members, nor do they groom their 'grooming partners' equitably (Cords 2000a, Payne *et al.* 2003b). Mothers groom their own offspring more often than they groom other juveniles (Cords 2000b). Adult ♀♀ frequently groom each other reciprocally. Group ♂ groomed more than he grooms in return. In some, but not all, populations grooming distributions among ♀♀ are rank-related, although grooming is not necessarily exchanged for feeding tolerance (Payne *et al.* 2003a, but see Cords 2000a). Nose-to-mouth sniffs, brief touches and coalition formation are rarer forms of amicable behaviour among ♀♀ and immatures. Direct amicable interactions (grooming, mounting) among adult ♂♂ are rare, especially in the proximity of ♀♀.

Aggressive behaviour includes chases, slaps, grappling fights, bites and threats such as head-bobbing, glaring, bounding displays in branches, and growling. Submissive behaviour includes flight, cowering, presenting the hindquarters and vocalizations like geckering, trilling and screaming. Aggression is rare among adult ♀♀, occurring once per 2.2 hours on average in a group (Cords 2000a, Payne *et al.* 2003a). Half of agonistic encounters involve aggressive behaviours; most of the remaining cases are approach–retreat interactions, with some spontaneous submission. Most within-group aggression is associated with fruit feeding (Rudran 1978b, Payne 1999, Cords

2000a, Pazol & Cords 2005). Adult ♀♀ can be arranged in shallow but stable dominance hierarchies but the advantages of high rank remain obscure (Pazol & Cords 2005). Aggression among ♂♂ is especially common during the mating season. Chases, ambushes and fights occur especially often during multimale influxes; resident ♂♂ usually prevail against visitors in such interactions.

In most populations, groups are territorial in the sense of defending a specific area (typical home-range about 15–25 ha, range 8–253 ha), even though range overlap with neighbouring groups may be extensive (98%) in high-density populations (Lawes & Henzi 1995), or minimal (<1%) in low-density populations (Butynski 1990). Boundary disputes involve mainly ♀♀ and may last up to an hour, with opposing phalanxes advancing and retreating with aggressive growls and chirps; physical fights are rare. Adult ♂♂ typically watch and vocalize (boom), and are seldom involved in aggression outside the mating season. Juvenile ♂♂ may take these opportunities to play with peers in other groups. Aggressive inter-group encounters often end with a frenzy of intra-group grooming (Cords 2002a, Payne *et al.* 2003a).

Both ♂♂ and ♀♀ may solicit copulations. Males head-flag ♀♀. Females head-flag, present and pucker to ♂♂. Persistent following is typical of courtship. Males may threaten ♀♀ who follow too persistently. Copulations may involve multiple mounts, especially when harassed by juveniles (mostly ♂♂). Older juvenile ♂♂ often shadow group's resident ♂. Ejaculatory pause is more likely if ♀♀ initiate the copulation (Cords *et al.* 1986).

Vocal repertoire includes at least ten calls (Marler 1973, Gautier 1988, Brown 1989b, Grant 1992). Only adult ♂♂ give loud-calls, including resonant 'booms' (100–150 Hz, 88 db at 2 m). 'Booms' given in response to various sources of disturbance (other ♂♂, other groups, falling branches and trees, thunder claps), also in response to prolonged (particularly loud and strained) adult ♀♀ grunts and immature trills, and sometimes for no discernible reason. Usually only one boom is given, but one group adult ♂ in Kibale N. P. typically gave a series of two booms separated by ca. 5 sec (T. Butynski pers. comm.). Only adult ♂♂ give sharp hacking 'pyows' (125–400 Hz, 100 db at 2 m). Pyows are usually given in a staccato sequence typically with 3–7 'pyows' spaced 6–10 seconds apart (Brown 1989b, Grant 1992), given as intra-group rallying call and during inter-group encounters; and 'ka'-train (a 1–5 sec series of 5–10 low frequency, resounding 'ka's, sometimes beginning with a single 'pyow'), given most often in alarm to raptors. The 'ka' and 'pyow' calls are occasionally given singly. While all three loud-calls carry over several hundred metres, only 'ka'-trains and 'pyows' are easy to locate. 'Pyows' can be heard by the human ear to at least 1 km. 'Pyow's, and possibly booms, are individually distinctive (Butynski *et al.* 1992, M. Cords pers. obs.). Adult ♂♂ also emit distinctive nasal screams when losing a fight against another ♂ ('waa!' call of Marler 1973). Females and juveniles give a harsh, rapid 'ah-ah' or a bird-like chirp or click when alarmed by predators or aroused at members of other groups, 'growl' as a threat to conspecifics, and 'gecker' to indicate submission to group mates. In *C. m. stuhlmanni* 'trills' also indicate submission, and may grade into 'screams' (M. Cords pers. obs.). Subadults and adult ♀♀ emit 'grunts', as contact calls (Marler 1973). In *C. m. labiatus/erythrarchus*, trills and grunts both appear to function as contact calls, with grunts less frequent and more likely to occur in times of tension (M. Lawes pers. obs.).

Relations with sympatric primate species vary from wary avoidance (of baboons *Papio* spp. and Robust Chimpanzees), to

occasional association (with Guerezas *Colobus guereza*, Eastern Gorillas *Gorilla beringei*, drill-mangabeys *Cercocebus* spp., baboon-mangabeys *Lophocebus* spp., red colobus monkeys *Procolobus* spp., savanna monkeys *Chlorocebus* spp., De Brazza's Monkey *Cercopithecus neglectus* and L'Hoest's Monkeys *Allochrocebus lhoesti*) (T. Butynski pers. comm.) to long-lasting (up to 12 h), coordinated association (with Red-tailed Monkeys *Cercopithecus ascanius*; Cords 1987b). Most inter-specific aggressive interactions involve only a few individuals, with outcomes determined by relative body size. Associations with *C. ascanius* involve entire groups of each species. Some associations appear random, while others result in improved protection from predation and more efficient foraging for shared foods (Cords 1987b). In associated groups, *C. ascanius* ♂♂ interpose 'hacks' (also termed 'pops') between *C. mitis* 'pyows'. Direct behavioural interaction includes mostly aggression, but juveniles also play. Some associations involve an adult ♂ from one species joining a heterosexual group of the other. Such ♂♂ often solicit grooming from heterospecific ♀♀, and in several populations are known to breed with them, producing fertile hybrids (Detwiler 2002, 2010, De Jong & Butynski 2010b). *Cercopithecus mitis* respond to alarm calls of non-primate vertebrates, such as antelopes, squirrels and birds.

Reproduction and Population Structure In captivity, mean ovarian cycle is 32 days (18–50 days, five ♀♀, $n = 59$ cycles; Else *et al.* 1985) and median is 30 days (19–57 days, six ♀♀, $n = 72$ cycles; Rowell 1970b). Females usually conceive on first cycle of season, although oestrogen titres and sexual behaviour may be elevated beforehand. Menses is difficult to detect; length averages 5.3 days in captivity (Else *et al.* 1985). Sexual receptivity is not closely tied to ovulation. Oestrus lasts 1–28 days ($n = 58$ periods; Pazol 2003). Gestation is ca. 176 days (95% C. L. = 162 and 190 days, $n = 21$) for wild *C. m. stuhlmanni* ♀♀.

Births occur seasonally from Nov to Mar, although in well-studied equatorial populations births recorded in all months (Butynski 1988). In Kakamega Forest, births occur during all months, but there is a peak during the 3-month period of Jan–Mar (dry season) when 64% of the births occurred. Only 9% of the births occurred during the 5-month period of Jun–Oct (wet season, $n = 347$; Cords & Chowdhury 2010). Late gestation and early lactation correspond with periods of fruit and invertebrate availability. About one-third to half of ♀♀ in a group give birth each year. Inter-birth intervals are typically 24–54 months if the first infant survives, and 14–20 months if the first infant dies (Cords & Rowell 1987, Butynski 1990). Mean inter-birth interval 27.9 months (7.2–81.9, $n = 256$ intervals; Cords & Chowdhury 2010). Occasional twins are born, but both may not survive (M. Cords pers. obs.). Newborns weigh ca. 400 g (Omar & De Vos 1971). Sex ratio at birth 1 : 1, but for breeding adults is biased toward ♀♀. Infant mortality (first 12 months) is typically 18–25% (Butynski 1990, M. Cords pers. obs.), although individual groups may show values three times greater if infanticide is common. In Kakamega Forest, 72% of infants survived to 1 year ($n = 341$; Cords & Chowdhury 2010).

Young infants are carried almost constantly by their mothers for the first two weeks but juvenile or subadult ♀ babysitters may carry infants only 2–3 days old. Contact time between mother and infant drops to 50% at 6–10 weeks, and to <10% by 15–22 weeks. Infants swallow first food from fifth week (Foerster & Cords 2002). Suckling can continue for up to 2.5 years (Macleod 2000). Males have a growth spurt at 6–8

years (Rowell & Richards 1979), at which time they leave the natal group (Ekernas & Cords 2007). Females reach adult size around 6.5 years; mean age at first birth is 7.2 years (4.6–10.8, $n = 66$; M. Cords pers. obs.). In Kakamega Forest, youngest ♀ to give birth was 4.6 years and oldest was ca. 26 years. Many ♀♀ in wild live to 20 years, and some live to >32.5 years (Cords & Chowdhury 2010).

Males compete for mates by taking over groups as sole resident, sneaking copulations when non-resident, or joining a group temporarily during a breeding season multimale influx (Henzi & Lawes 1987, 1988, Cords 1988). Influxes are more likely in populations where ratio of ♂♂ to groups in the population is high and when oestrus is synchronous among group ♀♀ (Henzi & Lawes 1988, Cords 2002b). During influxes, ♂♂ may solicit ♀♀ from the edge of the group with head-flagging and jumping displays; ♀♀ may leave their group for several hours to accompany an influx ♂. Males often show scars and missing or stiff digits from fights during the breeding season. Wounds may sometimes be severe and fatal. Adult ♂♂ probably experience higher age-specific mortality rates than adult ♀♀ (Macleod *et al.* 2002).

Resident ♂ tenure varies from a few months to six years (Butynski 1990, Cords 2002b). New resident ♂♂ are sometimes infanticidal (Butynski 1982b, Macleod *et al.* 2002, Cords & Chowdhury 2010, Cords & Fuller 2010). Infanticide may be thwarted by ♀ counter-aggression. Females show situation-dependent oestrus in response to presence of unfamiliar ♂♂, and may mate before the start of ovulatory cycles associated with the mating season, and even while pregnant (Pazol *et al.* 2002, Pazol 2003). Females return quickly to oestrus after death of an infant, but may not be fertile. Females appear to prefer some ♂♂ to others, and actively pursue them; they can deter unwanted ♂ suitors by sitting down. Oestrous periods are longer during ♂ influxes than when only one ♂ is resident.

Predators, Parasites and Diseases Confirmed predators include Afrian Crowned Eagles *Stephanoaetus coronatus* (van Jaarsveld 1984, Cordeiro 1992, Mitani *et al.* 2001, M. Macleod & H. Payne pers. comm.), Gaboon Vipers *Bitis gabonica* (Foerster 2008), Domestic Dogs *Canis familiaris* (T. Butynski pers. comm.), Golden Cat *Profelis aurata* (J. Rowing in Boy 2003) and Robust Chimpanzees (Hosaka *et al.* 2001). Humans kill *C. mitis* for meat, skins and to protect food and forestry crops (Wolfheim 1983). In undisturbed populations, *S. coronatus* appears to be the most important predator. Predation by Leopards *Panthera pardus* and Golden Cats *Profelis aurata* is likely, and predation by Central African Rock Pythons *Python sebae* and Black Mambas *Dendroapsis polylepis* has been suggested (Foerster 2008). *Cercopithecus mitis* gives alarm calls in responses to various species that resemble their confirmed and suspected predators, but which are unlikely to be dangerous, such as mongooses, medium-large birds that soar (small raptors, hornbills, turacos), African Palm Civets *Nandinia binotata* and Lord Derby's Anomalure *Anomalurus derbianus*. They also respond with alarm to various snakes, such as cobras, mambas and adders, which are potentially dangerous.

Various parasitic infections, confirmed in wild populations, including lice, ticks, gastrointestinal flukes, nematodes (Allen & Lawrence 1936, Else *et al.* 1982, T. Gillespie pers. comm.), protozoa (Freeland 1981, Appleton *et al.* 1994) and a simian immunodeficiency virus (Hirsch *et al.* 1993a). Captive *C. mitis* suffer from hypertension and a condition like human pre-eclampsia (blood poisoning during

Doggett's Silver Monkey *Cercopithecus mitis doggetti*.

pregnancy) (Benirschke & Kaufmann 2000). Infection from wounds is a cause of death, especially for adult ♂♂ who fight over ♀♀.

Conservation IUCN Category (2012): *C. mitis* is Least Concern. The threatened subspecies are *C. m. albоторquatus* (Vulnerable), *C. m. boutourlinii* (Vulnerable), *C. m. kandti* (Endangered), *C. m. labiatus* (Vulnerable), *C. m. schoutedeni* (Critically Endangered) and *C. m. zammaronoi* (Critically Endangered). Both *C. m. francescae* and *C. m. mitis* are Data Deficient. CITES (2012): Appendix II.

Greatest threat is destruction and fragmentation of forest habitat for agriculture. Many larger forests inhabited by *C. mitis* have been extensively logged and are secondary forest. Although this species

tolerates low quality and disturbed habitat better than most monkeys, it nevertheless is at lower densities in these habitats (Skorupa 1986, Johns & Skorupa 1987, Thomas 1991, Lawes 1992, Chapman *et al.* 2000). In spite of wide geographical range, *C. mitis* shows poor local colonizing ability in response to forest fragmentation and seldom occupies small (<50 ha) forest patches (Lawes *et al.* 2000, Chapman *et al.* 2003). Dietary flexibility may allow *C. mitis* to persist in disturbed patches longer than most primates, resulting in reluctance to move and increased vulnerability to local extirpation (Lawes 2002). Given a limited capacity for rescuing isolated populations (Cowlshaw & Dunbar 2000), the rate at which forests are destroyed and fragmented will ultimately determine the status and persistence of *C. mitis*. In some

highly fragmented forest archipelagos (e.g. afromontane forests of KwaZulu–Natal) *mitis* exists as relict non-equilibrium metapopulations in gradual, and probably irreversible, decline (Lawes *et al.* 2000).

Generalized guenon *Cercopithecus* sp.

Tentative phylogenetic tree for Cephus Monkeys Group *Cercopithecus (cephus)* (partly after Tosi *et al.* 2005).

The *Cercopithecus (cephus)* Group (or Superspecies) of small, arboreal African monkeys is the largest, most diverse and colourful of all African forest monkeys. This group embraces six species: the Moustached Monkey *Cercopithecus (cephus) cephus*, Sclater's Monkey *Cercopithecus (cephus) sclateri*, Red-eared Monkey *Cercopithecus (cephus) erythrotis*, Red-tailed Monkey *Cercopithecus (cephus) ascanius*, Lesser Spot-nosed Monkey *Cercopithecus (cephus) petaurista* and the Red-bellied Monkey *Cercopithecus (cephus) erythrogaster*. Taken as a whole, these rather small monkeys (3–5 kg) are confined to the main forest blocks where they exhibit similar behaviour and occupy a consistent niche within diverse primate communities. They range over the entire equatorial belt excepting the isolated eastern forests of the Indian Ocean coast and forests of the Eastern Arc Mountains of Kenya and Tanzania.

All species in the *C. (cephus)* Group are arboreal, with grizzled brownish backs and crowns and long tails that are either red or longitudinally bicoloured. In spite of their extraordinarily diverse and colourful face patterns, molecular studies confirm the close relationship of species and position them as possibly the most recently evolved of all guenon lineages (Ledbetter 1981, Muleris *et al.* 1986, Dutrillaux *et al.* 1988b, Ruvoilo 1988, Disotell & Raaum 2002, Moulin *et al.* 2008). Purvis (1995) indicates that *C. (cephus)* may have diverged from a *C. mitis*-like lineage at about the time of the first Glacial, 3–2.5 mya. This probably has a bearing on the high degree of face-pattern differentiation between broadly allopatric populations because glacial periods would have fragmented forests and the monkey populations inhabiting them (see below).

The recent discovery that Campbell's Monkey *Cercopithecus (mona) campbelli* has the same number of chromosomes (66) as members of the *C. (cephus)* Group has important implications for understanding evolution of the *C. (cephus)* Group. That the *C. (mona)* Group evolved

Distribution in the Central Forest Block of some taxa of the Cephus Monkeys Group *Cercopithecus (cephus)*.

Middle, left to right: Moustached Monkey *Cercopithecus cephus*. Centre: Congo Basin Red-tailed Monkey *Cercopithecus ascanius whitesidei*. Schmidt's Red-tailed Monkey *Cercopithecus ascanius schmidt*.

Bottom, left to right: Black-nosed Red-tailed Monkey *Cercopithecus ascanius atrinasus*. Black-cheeked Red-tailed Monkey *Cercopithecus ascanius ascanius*. Katanga Red-tailed Monkey *Cercopithecus ascanius katangae*.

before *C. (mona) campbelli* suggests that *campbelli* is the most basal member of the *C. (cephus)* Group (Moulin *et al.* 2008). Alternatively, *C. (m.) campbelli* might have acquired its current molecular profile through recent hybridization. Which explanation is correct remains to be determined.

In the field the *C. (cephus)* monkeys are readily recognized by their staccato, chirping alarm calls and alert, active demeanour: they have a faster metabolism and are active for more hours per day than many other guenon species (Struhsaker & Leland 1979). Comparing *C. (c.) ascanius* with Gentle Monkeys *Cercopithecus (nictitans) mitis*, the same study also demonstrated a five-fold increase in the time the former spent scanning their surroundings, suggesting that members of the *C. (cephus)* Group are more visually oriented than other guenons. They typically inhabit lowland and medium-altitude forests with high temperatures and well-distributed rainfall, and forage at all but the lowest levels of the forest. Marked differences in population density correlate with the presence or absence of other species, notably members of the *C. (mona)* Group and talapoin *Miopithecus* spp., with which there are substantial overlaps in habitat and diet. Thus *C. (c.) ascanius* in Uganda can reach densities of 140–175/km² while *C. (c.) cephus* in multi-species communities in Gabon live at less than one-third that density (Quris 1976, Struhsaker & Leland 1979, Gautier-Hion 1980, 1988, Sheppard 2000).

Feeding mainly on small, whole fruits and seeds, they also catch and consume arthropods, up to 20% in some samples (Struhsaker 1978a, Cords 1986, Gautier-Hion 1988). Relatively small body size allows *C. (cephus)* monkeys to forage on finer branches than larger species and their exceptional agility permits capture of active insects.

Groups of *C. (cephus)* monkeys generally number 10–40 individuals, usually attended by one adult ♂. They resemble the

Tonal contrasts on facial masks of some taxa of the Cephus Monkeys Group *Cercopithecus (cephus)*:

- (a) Eastern Lesser Spot-nosed Monkey *Cercopithecus petaurista petaurista*.
- (b) Western Lesser Spot-nosed Monkey *Cercopithecus petaurista buettikoferi*.

- (g) Black-nosed Red-tailed Monkey *Cercopithecus ascanius atrinasus*.

Facial zones, with light and dark foci, of species in the Cephus Monkeys Group *Cercopithecus (cephus)*.

members of the larger-bodied *C. (nictitans)* Group in many aspects of their morphology and behaviour and, in several respects, appear to be a juvenilized (neotenous), more recently evolved, branch of, or even within, the same lineage; for example, the adult males' loud-calls are similar but the smaller vocal apparatus of *C. (cephus)* cannot generate the volume or depth of *C. (nictitans)* calls (Gautier 1988).

Members of the *C. (cephus)* Group have unusually numerous short-wave cones in their eyes (Mollon 1989). This indicates relatively high sensitivity to colour and space perception. This helps confirm their greater use of and reliance on visual signals, a variation in colour sensitivity that is also found in South American primates (Mollon *et*

Cheek-hair arrangement on facial masks of some taxa of the Cephus Monkeys Group *Cercopithecus (cephus)*:

al. 1984, Sumner & Mollon 2003). The faces of *C. (cephus)* monkeys are of special interest because colour and pattern differences within the *C. (cephus)* radiation are exceptionally diverse and can differ from species to species as much as, or more than, the face patterns of more distantly related African monkeys. The biogeographic implication is that ancestral *C. (cephus)* monkey populations became fragmented, presumably due to cooling and drying during the first (and presumably subsequent) ice ages. If isolation coincided with early phases of facial pattern formation, minor discrepancies in visual appearance might have become progressively elaborated into major differences in pattern. Other features of their biology show no comparable divergence among species.

Cercopithecus (cephus) monkey face patterns tend to emphasize cheeks or noses and exhibit a geometry of design comparable with that of birds (Hill & McGraw 2006; figures pp. 363–5). The patterns are associated with species-specific head 'flagging' or signalling behaviour and one particular movement, a gesture of active 'eye-avoidance', appears to have driven the evolution of face patterns in *C. (cephus)* monkeys (Kingdon 1980, 1988b, 1997, 2007). Eye-avoidance gestures function during the contact, greeting, appeasement and courtship gestures of many primates. Indeed, for many mammals the gesture of avoiding eye-contact appears to be of great social utility and functional significance (Chance 1962, Kleiman & Eisenberg 1973). The eye-contact avoidance gesture serves to inform a conspecific viewer that, unlike a 'starrer', the head-avert is not socially threatening (Kingdon 1982, 1988b) and thus helps mediate the 'fission–fusion' systems typical of most higher primate societies (Marler 1961, 1968). In the case of

Schematic rendering of tonal contrasts on the sides of the head in three species of the Cephus Monkeys Group *Cercopithecus (cephus)* and charts of the head's traverse during ritualized head-flagging:

- (a) Red-eared Monkey *Cercopithecus erythrotis*.
- (b) Cephus Monkey *Cercopithecus cephus*.
- (c) Lesser Spot-nosed Monkey *Cercopithecus petaurista*.

C. (cephus), members of a group tend to forage quite independently in large, dispersed formations and the need for a conciliatory signal becomes particularly acute for ♂♂ that are seeking oestrous partners amongst the scattered and independent ♀♀. Reassuring gestures are also likely to operate when dispersed group members hastily come together to repel conspecifics from their territory or gather in sleeping trees for the night. *Cercopithecus (cephus)* monkey head movements, and the facial 'flags' that advertise them, appear to have evolved to translate subtle head movement and short-range facial expression into bolder, long-range signals.

The facial patterns of *C. (cephus)* have evolved, step by step, from progressive elaboration of small tonal differences in hair and skin. The diagrams on page 364 illustrate how visually diverse patterns have been built out of relatively minor expansions and contractions of light and dark foci. These face patterns remain the principal means of identifying species and subspecies within the *C. (cephus)* Group.

Jonathan Kingdon

Cercopithecus cephus MOUSTACHED MONKEY

Fr. Moustac; Ger. Blaumaulmeerkatze

Cercopithecus cephus (Linnaeus, 1758). Systema Naturae, 10th edn, 1: 27. Africa.Red-tailed Moustached Monkey *Cercopithecus cephus cephus* adult male.*Cercopithecus cephus***Geographic Variation**

- C. c. cephus* Red-tailed Moustached Monkey. Cameroon, Equatorial Guinea (Rio Muni), Congo and Gabon to right bank of Ogooué R. Skin of nose bluish-grey. Distal ca. 75% of tail bright orange-red.
- C. c. cephodes* Grey-tailed Moustached Monkey. Gabon on the left bank of the Ogooué R. Skin of nose bluish-grey. Distal ca. 75% of tail dark brown dorsally and greyish ventrally, darkening towards tip.
- C. c. ngottoensis* White-nosed Moustached Monkey. SW Central African Republic and NE Congo between Sangha R. and Lobaye R. Skin of nose white. Distal ca. 75% of tail orange-red.

Taxonomy Polytypic species. The nominal species within the *C. (cephus)* Group or Superspecies. Three subspecies are recognized (Groves 2001, 2005c, Grubb *et al.* 2003, Oates 2011); Red-tailed Moustached Monkey *C. c. cephus*, Grey-tailed Moustached Monkey *C. c. cephodes* and White-nosed Moustached Monkey *C. c. ngottoensis*. Synonyms: *buccalis*, *cephodes*, *gabonensis*, *inobservatus*, *ngottoensis*, *pulcher*. Chromosome number: $2n = 66$ (Dutrillaux *et al.* 1988b, Moulin *et al.* 2008).

Description Medium-sized monkey with long tail and brightly coloured face pattern, including white 'moustache'. Sexes similar in colour but adult ♀ weighs ca. 70% as much as adult ♂. Facial skin bright blue with bold white chevron ('moustache') below nose; black between chevron and upper lip. Cheek-ruffs yellow. Temples black. Crown and back reddish-brown agouti graduating into dark grey on outer surfaces of lower limbs. Throat, chest, belly and inner surfaces of limbs pale grey. Tail colour varies with subspecies (see Geographic Variation). Blue colour of the face poorly developed in newborn infants.

Similar Species Parapatric species in the *C. (cephus)* Group are similar in size and body colouring but all have highly distinctive face patterns.

Cercopithecus erythrotis. Sympatric with *C. c. cephus* over small area on left bank of Sanaga R. No white moustache. Nose and ears red.

Distribution Endemic to western central Africa. Throughout the forest block (05°N to 05°S) limited by Sanaga R. in north-west, Atlantic Ocean in west, Congo–Ubangi R. in east and Congo R. in south. See Geographic Variation.

Habitat Secondary and primary forests, riverine forest, gallery forest and thicket from sea level to at least 900 m (Gautier-Hion *et al.* 1981, Tutin *et al.* 1997b). Habitat preferences related in part to fruit availability and to anti-predator strategies (Gautier-Hion *et al.* 1981). Forests with dense undergrowth, encumbered by lianas and tangles

Blue and white pigmented skin on Red-tailed Moustached Monkey *Cercopithecus cephus cephus* face. Under the fur, the skin is all blue except for a white 'moustache', lips and upper eyelids (right).

preferred, especially during the day resting period. Forests with open understorey preferred at night. Annual rainfall 1400 mm to >4000 mm.

Abundance Often common. Number of individuals/km² varies from three to ten (C Gabon), 26 (Dja Reserve, Cameroon), 31 (Monte Alén N. P., Equatorial Guinea), 53 (Odzala N. P., Congo) and 66 (Ngotto Forest, Central African Republic; Brugière 1988). Abundant in some natural forest fragments; 30.2 ind/km² (Tutin 1999). Lowest densities occur in primary forests with open understorey. Densities low in riverine forests.

Adaptations Diurnal and arboreal. Mainly found in low and middle forest strata. Found at less than 15 m high in forest about 60% of time and at less than 10 m 30% of time. Immatures come to the ground for short periods to forage for insects or to play, especially during the hot hours of the day (Gautier-Hion *et al.* 1981, Quris *et al.* 1981). Alert monkey that is more visually oriented than species of the Nictitans Group *Cercopithecus (nictitans)*. This visual bias may be linked with greater use of visual signals. Striking facial patterns correlated with head-flagging displays (Kingdon 1980, 1988b, 1997, 2007). Vocal sacs smaller than for other guenons. As a result, calls specific to adult ♂♂ are not loud (Gautier 1974). Vocal repertoire includes about 28 sounds belonging to nine basic call types (Gautier 1978). Prone to form polyspecific associations, especially with Putty-nosed Monkeys *Cercopithecus nictitans*, with which *C. cephus* shares similar cohesion calls and alarm calls.

Foraging and Food Omnivorous. Fruit, seeds, leaves and animal matter constitute diet. Fruit pulp from about 100 plant species can make up to 80% of diet. Fruit of preferred species have brightly coloured pulp rich in water and sugar or possess arils high in protein and fatty acid. Invertebrates contribute 13% of ♂ diet and 25% of ♀ diet (Gautier-Hion 1980, Sourd & Gautier-Hion 1986). Time spent feeding on insects varies from 24% in adult ♂♂ and 38% in adult ♀♀ to 50% in immatures (Quris *et al.* 1981). Females capture more mobile prey (e.g. Orthoptera) than ♂♂ (more caterpillars and spiders). Seasonal variations in diet greater for ♂♂ than for ♀♀.

During the season of fruit scarcity, ♀♀ maintain the same amount of fruit in their diet whereas ♂♂ eat less fruit and more leaves (Gautier-Hion 1980). In natural forest fragments, home-range size can be <10 ha. Here diet is similarly dominated by fruit but shows strong month-to-month variations and, when fruit is scarce, large quantities of insects are eaten (Tutin 1999). Forages in groups. Most fruit-feeding occurs in high strata (mean 19 m) in early morning and late afternoon. Forages for insects in lower dense forest strata (mean 11 m; Quris *et al.* 1981), mostly in the middle of the day. Groups range on average 1.2 km/day. Territories 35–90 ha (Gautier-Hion *et al.* 1981). Monkeys use their cheek-pouches to collect fruit quickly in tree canopies before seeking safer locations in densest vegetation to eat.

Social and Reproductive Behaviour Social. Group size is 5–22 individuals; mean among sites = 6.4 ind/group (n = 10 in Lopé Reserve, Gabon, Ham 1994), 9.6 (n = 14 in Lopé Reserve, White 1994), 9.3 (n = 17 in Odzala N. P., Maisels 1995); 15 (n = 4 in Ngotto Forest, A. Gautier-Hion pers. obs.); 11.5 (n = 5 in NE Gabon, Gautier-Hion & Gautier 1976, Gautier-Hion *et al.* 1981). Only bisexual groups occur, with one adult ♂, several adult ♀♀ and immatures of both sexes. During the mating period, solitary ♂♂ may live at periphery of bisexual groups and copulate with ♀♀ (A. Gautier-Hion pers. obs.). Bisexual groups are territorial. Inter-group encounters may lead to violent fighting by adult ♀♀ and subadults while adult ♂♂ sit high in trees, barking (Gautier-Hion *et al.* 1999). *Cercopithecus cephus* in polyspecific associations during 38% of encounters in Odzala N. P., 53% in Ddja Reserve, 56% in Lopé Reserve, 76% in Monte Alén N. P., 83% in Ngotto Forest (Gautier-Hion 1996) and 88% in NE Gabon (Gautier-Hion 1968). Bi-specific associations with *C. nictitans*, tri-specific associations with *C. nictitans* and *C. pogonias*, and quadri-specific associations with *C. nictitans*, *C. pogonias* and Grey-cheeked Mangabeys *Lophocebus albigena* are most common. In these associations, *C. cephus* benefits from more efficient location of fruit (and thus a more diversified fruit diet) and from collective defence against predators (Gautier-Hion *et al.* 1983). Male *C. pogonias* give alarm call to aerial predators and *C. cephus* ♀♀ and immatures give alarm calls to terrestrial predators. In addition, the

heaviest ♂♂ of *C. nictitans* and *L. albigena* sometimes actively attack African Crowned Eagles *Stephanoetus coronatus* (Gautier & Gautier-Hion 1983, Gautier-Hion & Tutin 1988).

In *C. cephus* groups, only the adult ♂ gives the 'mpack' loud-call. This call helps to bring territorial conflicts or alarm situations to an end. In polyspecific associations, loud-calls of other species appear to stimulate vocal activity in *C. cephus* ♂♂. This species rarely initiates group movements. During alarm situations, the adult ♂ will also give 'hack' calls whereas ♀♀ and immatures give high-pitched 'chirps'. When moving or foraging, ♀♀ and immatures give soft, low-pitched 'grunts' (Gautier 1978, Gautier & Gautier-Hion 1983).

Reproduction and Population Structure Life history parameters poorly known in the wild. In Gabon, births occur from Dec to Mar (n = 10; Gautier-Hion 1968). In captivity, sexual maturity of ♂♂ occurs at about six years; accompanied by an increase in body weight. Sexual maturity of ♀♀ at about four years (Gautier-Hion & Gautier 1976). No obvious sexual swelling. Menses sometimes visible. Oestrous periods signalled by characteristic posture, including buttock presentation, erected tail and pout face. Gestation lasts ca. 165 days. A single young is born. Birth-weight 320 g (n = 1 ♂; A. Gautier-Hion pers. obs.). Estimates from wild specimens ca. 260–320 g (n = 10; Gautier-Hion 1968). In captivity a still-living ♂ is 33 years old and a still-living ♀ is 28 years. This ♀ reproduced nine times with a mean inter-birth interval of 19.2 months (11–33). First baby was stillborn. Last baby born when mother was 20 years of age (A. Gautier-Hion pers. obs.). Ratio ♂ : ♀ is 1 : 2.8 and ratio adults to immatures 1 : 2.13 (n = 17 groups with a mean size of 9 individuals; Maisels 1995). Ratio ♂ : ♀ 1 : 4.8 and adults to immatures 1 : 2 in one group of 15 individuals (Quris *et al.* 1981).

Predators, Parasites and Diseases Main predators are humans and *S. coronatus*. Leopard *Pantherus pardus* is a known predator (Henschel *et al.* 2005, 2011). Other predators likely include large snakes. The secretiveness of *C. cephus* and their association with large groups of Northern Talapoin Monkeys *Miopithecus ogouensis* helps them survive near villages. No information on parasites or diseases.

Conservation IUCN Category (2012): Least Concern. *C. c. ngottoensis* is Data Deficient. CITES (2012): Appendix II.

Populations locally reduced due to hunting by humans. Censuses conducted at five-year intervals in Ngotto Forest indicate that, following hunting, *C. cephus* density decreased by a factor of 2.5 (D. Brugière pers. comm.).

Measurements

Cercopithecus cephus

HB (♂♂): 480 mm, n = 4

HB (♀♀): 440 mm, n = 7

Cercopithecus sclateri SCLATER'S MONKEY

Fr. Cercopithèque de Sclater; Ger. Sclater-Meerkatze

Cercopithecus sclateri Pocock, 1904. Abstr. Proc. Zool. Soc. Lond. (1904) (5): 18. Type locality not known (see below).Sclater's Monkey *Cercopithecus sclateri* adult male.

Taxonomy Monotypic species. Member of *Cercopithecus* (*cephus*) Group, or Superspecies. Although Pocock (1904) gave an accurate description of a distinctly new form of monkey based on a single specimen, when Schwarz (1928b) published his revision of the genus *Cercopithecus*, the type skin was still the only specimen available. Schwarz argued that it represented a specimen of the Red-eared Monkey *Cercopithecus erythrotis*, in which the black pigment is reduced, and he synonymized *sclateri* with what he called *Cercopithecus cephus erythrotis*.

Hayman (quoted in Sanderson 1940: 649–651) reported on a second specimen received by the British Museum in 1935, collected in Okigwi Division, Nigeria. This specimen was identical to the type and convinced Hayman that *sclateri* was a distinct and well-defined taxon, which he treated as a subspecies of *C. erythrotis*.

Hill (1966) also recognized *sclateri* as a subspecies of *C. erythrotis*, and included a specimen from Obubra, E Nigeria, in the taxon. He noted, however, that this specimen had a brick-red nose and red ear-tufts, and that it 'possibly pertains to (*erythrotis*) *camerunensis*'. He mistakenly stated that Obubra lies west of the Cross R., when in fact it is located on the river's east bank; therefore the Obubra specimen (with no collection or specimen number) seems most likely to have been an example of the Cameroon Red-eared Monkey *C. erythrotis camerunensis*. Kingdon (1980) considered *sclateri* sufficiently distinct from *erythrotis* to be regarded as a species rather than a subspecies.

Type specimen (that died in the London Zoological Gardens) said to have come from 'Benin' (Pocock 1904). This must refer to Benin in present-day Nigeria, since, as of 1904, the former Dahomey had yet to be renamed 'Benin'. Groves (2001, 2005c) gives the type locality as 'Benin City', but this is unlikely to be correct as Benin City is west of the Niger R. It is much more likely that the type was obtained in Benin City or the surrounding region, but originated east of the Niger R. (Oates & Anadu 1989). No wild population of *C. sclateri* is known west of the Niger R., where the Red-bellied Monkey *Cercopithecus erythrogaster* occurs. Synonyms: none. Chromosome number: not known.

Description Small, long-tailed guenon, similar in bodily proportions to other members of the *C. (cephus)* Group. Sexes alike except adult ♀ smaller. In captivity, adult ♀ weighs ca. 70% as much as adult ♂. Upper nose creamy-white to varying shades of yellow-orange, forming a distinctive triangular 'nose spot'. Skin of muzzle, including tip of nose, pale pink. Cheek-tufts lemon-yellow. Diadem gold-flecked; gold-flecking results from hairs banded alternately with black and gold. Crown bordered posteriorly with a black band, which is broadest behind the ears. Ears fringed with white hairs. Throat white, but no distinctive, dense 'ruff' as in *C. erythrogaster*. Back, flanks, outer limbs and dorsal proximal surface of tail have 'agouti' appearance (i.e. hairs grey at base, banded yellow and black towards tip). Belly grey, speckled with agouti. Undersurface of proximal half of tail rust-red. Distal half of tail typically greyish-white with charcoal tip, although there is considerable variation in this feature. Pelage colour and pattern of juvenile same as that of adult. Newborn lacks facial hair, but colouration over rest of body resembles that of adult.

Geographic Variation Intra-population variation in pelage, especially nose colour and extent of red on tail, but no obvious geographical pattern of variation.

Similar Species

Cercopithecus erythrogaster. SE Togo, S Bénin and SW Nigeria. In Nigeria west and west-north-west of *C. sclateri*, with small area of sympatry. Hybridization on eastern edge of Niger Delta in Bayelsa State. No nose-spot, no white on ears, no red on tail.

Cercopithecus erythrotis. S and E Nigeria, Cameroon coast and Bioko I., Equatorial Guinea; *C. sclateri* occurs to west of lower Cross R. and *C. erythrotis* to east, with no good evidence of sympatry. Nose-spot and ears red, tail mostly red.

Distribution Endemic to SE Nigeria. Rainforest BZ. Restricted to forests between Niger R. and Cross R., SE Nigeria. Extent of occurrence: ca. 28,500 km² (Baker & Olubode 2008). Occurrence confirmed close to left bank of Niger R. at 05° 39' N, 06° 39' E and close to right bank of Cross R. at 05° 22' N, 08° 04' E (Oates & Anadu 1989, Oates *et al.* 1992), as well as coastal freshwater swamp forest (Gadsby 1989, Tooze 1996b), freshwater swamp forest located just inland from coastal mangroves (Powell 1995, Tooze 1996a, Baker & Olubode 2008) and north-east as far as 06° 16' N, 08° 11' E, in gallery forest in derived savanna zone (Baker & Olubode 2008). Many of the inhabited forests are small fragments within a largely agricultural landscape.

Kingdon (1980) not only shows the location of the 'Benin' specimen (see Taxonomy), but also indicates the locations of two hybrid specimens from near the Cross R.; one of these is placed near Obubra and is probably Hill's (1966) specimen of *C. erythrotis camerunensis* and thus likely not a hybrid. Powell (1995) and Baker (2005) report an area of sympatry between *C. erythrogaster* and *C.*

sclateri on the eastern edge of the Niger Delta, east-north-east of Yenagoa in Bayelsa State (ca. 04° 54–59' N, 06° 20–25' E). In 1999 the Centre for Education, Research and Conservation of Primates and Nature (CERCOPAN) in Calabar, Nigeria, held two captives that originated from this area; they have features intermediate between *C. sclateri* and *C. erythrogaster*, presumably resulting from hybridization.

Current distribution of *C. sclateri* probably similar to its historical distribution, but populations are today highly fragmented as a result of widespread replacement of natural forest by farms, plantations and human settlements.

Habitat Lowland moist forest, including seasonally flooded swamp forest on eastern edge of Niger Delta and fringing forests along waterways. Predominantly in low-lying areas (<400 m asl). Mean annual rainfall within the species' range varies from ca. 1500 mm in the north to >3000 mm in the south. Mean annual temperatures range from 22 °C to 38 °C. Within this area there is typically one dry season, from Nov or Dec through Mar. At inland locations in E Nigeria, between Niger R. and Cross R., most of the natural forest has been replaced by farmland; here a few relict populations of *C. sclateri* survive in gallery forest, farm bush, forest fragments, and isolated tree groves where local human communities regard this monkey as sacred (Oates *et al.* 1992, Baker & Olubode 2008).

Abundance Though now rare or absent across much of its presumed original range because of regional habitat loss, this species is still relatively common in several locations. In one survey (n = 24 forest sites) *C. sclateri* was one of the two most frequently encountered primates (0.18 detections/km walked) (Baker & Olubode 2008). In a site where the species is considered sacred (Lagwa, Imo State) the population in 2005 was ca. 124 individuals in 15 groups (Baker *et al.* 2009). In another sacred site (Akpugoeze, Enugu State) a 2006 population estimate was 193 individuals in 20 groups (Baker *et al.* 2009). This is similar to a 1994 estimate for this population of 199 individuals in 12 groups (Tooze 1994). In Edumanom F. R., Bayelsa State, model-weighted occupancy yielded 3.7 groups/km² (95% C.I. yielded 1.4–7.7 groups/km²), or 3.1 groups/km² after adjusting for groups that straddled sample-plot boundaries (Baker *et al.* 2011).

Adaptations Diurnal and arboreal. Like other members of the *C. (cephus)* Group *C. sclateri* is a small, agile monkey. Often uses mid- to low-canopy levels; mean height = 11.5 m (S.D. = 5.1, range 6–21, n = 14 sightings); mean height of trees in which sightings occurred = 15.4 m (S.D. = 4.6, range 10–22) (Baker & Olubode 2008). Behaviour and ecology of *C. sclateri* have not been the subjects of an extended field study.

Foraging and Food Omnivorous. Not systematically studied. Diet, home-range size and foraging behaviour probably similar to other members of the *C. (cephus)* Group. Diet likely comprised mostly of fruits, insects and young foliage. In villages where *C. sclateri* is considered sacred, these monkeys feed largely on plants cultivated by humans, such as Cassava *Manihot esculenta*, Papaya *Carica papaya*, Maize *Zea mays*, Banana and Plantain *Musa* spp., Mango *Mangifera indica* and Oil Palm *Elaeis guineensis*.

Cercopithecus sclateri

Social and Reproductive Behaviour Social. In Lagwa, Imo State, mean group size ca. 8.3 individuals (S.D. = 3.3, range 4–14, n = 15 groups), with dependent infants comprising 12% of population; in Akpugoeze, Enugu State, mean group size ca. 9.7 (S.D. = 4.2, range 4–19, n = 20 groups), with infants making up 8% (Baker *et al.* 2009). Tooze (1994) found a mean group size in Akpugoeze of 16.6 individuals (8–28, n = 12 groups), with infants comprising ca. 17%. Adult ♂ loud-calls usually come from only one location in a group, suggesting that one-male groups are the norm. Alarm call a rapidly repeating, nasal, high-pitched 'squeak'. Adult ♂ loud-call a low-pitched, rapidly repeating, nasal, snort-like vocalization. There is no information on reproductive behaviour.

Reproduction and Population Structure No information, but probably similar to other members of the *C. (cephus)* Group.

Predators, Parasites and Diseases No detailed information available, but humans are currently the most important predator of *C. sclateri*. African Crowned Eagles *Stephanoetus coronatus* prey on other members of the *C. (cephus)* Group elsewhere, but *S. coronatus* now extirpated across all or most of the range of *C. sclateri*. No information on diseases and parasites.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Most remaining populations are not only hunted, but also occur in a highly fragmented pattern due to habitat destruction. Survival of *C. sclateri* likely related to its small size, adaptability and cryptic nature; such factors allow these monkeys to persist in small areas of degraded habitat and make them difficult to hunt. This species also provides lower return-on-investment for shotgun hunters (Baker & Olubode 2008). The largest contiguous forests holding populations of *C. sclateri* (and thus perhaps the largest remaining populations of the species) are the 310 km² Stubbs Creek F. R., Akwa Ibom

State, which, in the early 1990s, contained ca. 80 km² of relatively undisturbed swamp forest (Gadsby 1989, Oates 1990, Tooze 1995), and the 87 km² Edumanom F. R. and 90 km² Upper Orashi F. R. in the E Niger Delta. These reserves offer no protection against hunting and little to no protection against logging. In the villages of Akpugoeze and Lagwa, where *C. sclateri* is held as sacred, there is a traditional ban on the hunting of this species. However, these beliefs are likely eroding, and the habitat available to the monkeys is already small and declining (Oates *et al.* 1992, Tooze 1994, Baker *et al.* 2009). Conservation-awareness efforts were initiated in both Lagwa and Akpugoeze in 2006. Surveys conducted in Akpugoeze in 1989, 1994, 2004 and 2006 indicate that the *C. sclateri* population has remained stable at ca. 200 monkeys (population estimates, respectively: 180–225, 199, 187 and 193) (Baker *et al.* 2009).

Measurements

Cercopithecus sclateri

HB (♂ ♂): 373, 375 mm, n = 2

Cercopithecus erythrotis RED-EARED MONKEY (RED-NOSED MONKEY)

Fr. Moustac à oreilles rouges; Ger. Rotohrmeerkatze

Cercopithecus erythrotis Waterhouse, 1838. Proc. Zool. Soc. Lond. 1838: 59. Fernando Po (=Bioko I.), Equatorial Guinea.

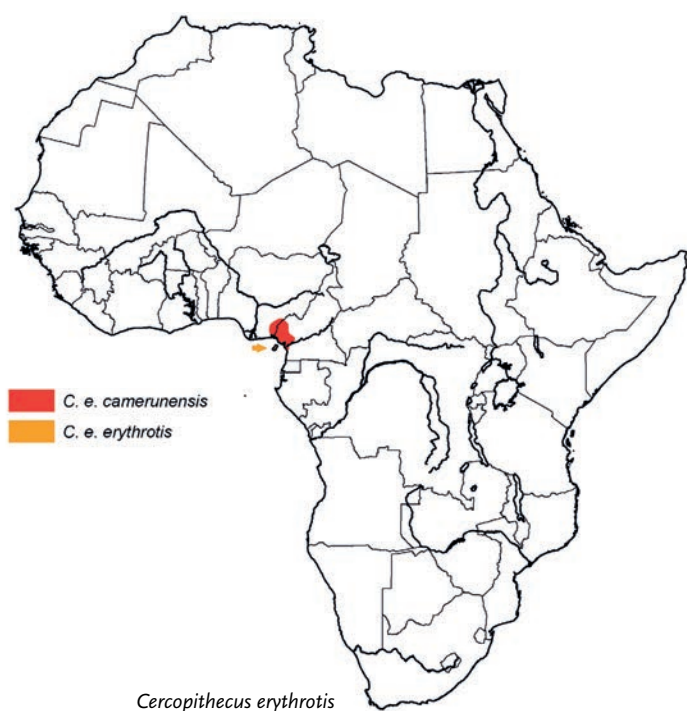

Red-eared Monkey *Cercopithecus erythrotis* adult male.

Taxonomy Polytypic species within the *Cercopithecus (cephus)* Group (or Superspecies). The more recent taxonomic history is summarized by Grubb *et al.* (2003). Although Waterhouse (1838) and Schwarz (1928b) considered *C. erythrotis* as most closely related to the Moustached Monkey *Cercopithecus cephus*, Hill (1966) regarded the Red-tailed Monkey *Cercopithecus ascanius* as the closest relative. Struhsaker (1969, 1970) and Gartlan & Struhsaker (1972) considered *C. cephus* to be conspecific with *C. erythrotis* based on their identical vocal repertoires, the frequent occurrence of intermediate forms on the left bank of Sanaga R., and strong similarities in their ecology and behaviour.

Sclater's Monkey *Cercopithecus sclateri*, once considered a subspecies of *C. erythrotis* (e.g. Dandelot 1974, Napier 1981, Wolfheim 1983, Lee *et al.* 1988, Lernoould 1988), now widely recognized as a full species (Kingdon 1980, Oates 1996a, Grubb *et al.* 2000). We follow Kingdon (1997), Groves (2001, 2005c), Grubb *et al.* (2003) and Oates (2011) in recognizing two subspecies for *C. erythrotis*. Synonyms: *camerunensis*. Chromosome number: 2n = 66 (Muleris *et al.* 1985, Dutrillaux *et al.* 1988b).

Description Medium-sized, long-tailed monkey with red nose, ears and tail. Sexes alike but adult ♀ smaller, being about 84% the weight of adult ♂. Facial skin purplish. Eyelids and region around mouth and front of nose with pink skin. Nose-spot triangular and red. Ears prominent, bright rusty-red with well-developed red tufts. Cheeks white to pale cream or bright yellow (depending on subspecies), tapered to a point below the ear. Brow, temples and region between cheeks and throat black, contrasting strongly with the cheeks. Chin, throat, ventrum and inner legs with off-white to medium-grey hair and showing pale lilac skin. Crown, nape, shoulders, back, flanks and upper limbs dark grey to almost black, grizzled yellowish. Hairs of dorsum grey at base with three pairs of alternating red and black bands (Groves 2001). Lower outer limbs dark grey to blackish, not grizzled. Hands and feet blackish. Distal edge of rump, perineal region and scrotum bright red. Tail mostly

bright red above but 25–30% of proximal upper side is colour of back and distal ca. 30 mm is blackish. Tail with faint, thin, dorsal stripe along entire length except at base and tip.

Young infants duller than adult and with less defined patterning but soon acquire adult pattern. Young juveniles have full adult pattern but lack ear-tufts and have chin and throat pure white (Hill 1966). One ca. three-month-old *C. e. erythrotis* with finer, more fuzzy pelage than adult, and with cheeks, brow and dorsum much more heavily grizzled light yellow than adult (T. Butynski pers. obs.).

Geographic Variation

C. e. erythrotis Bioko Red-eared Monkey: Bioko I., Equatorial Guinea. Smaller body (HB adult ♂ <500 mm, see Measurements). Overall tints appreciably darker. Cheeks white to pale yellow.

C. e. camerunensis Cameroon Red-eared Monkey. Extreme SE Nigeria and SW Cameroon. Larger body (HB adult ♂ >500 mm, see Measurements). Overall tints appreciably lighter. Cheeks bright yellow.

Similar Species

Cercopithecus sclateri. SE Nigeria west of lower Cross R. Parapatric, perhaps sympatric in vicinity of Cross R. Nose and ears with little or no red. Tail mostly off-white.

Cercopithecus cephus. Sympatric over small area on left bank of Sanaga R. Moustache white. Nose and ears not red.

Distribution Endemic to Bioko I., extreme SE Nigeria and SW Cameroon. Rainforest and Afromontane–Afroalpine BZs. Over most of Bioko I., being absent only from areas with a high human population density (Butynski & Koster 1994, González-Kirchner 1996). On mainland from north of upper course of Cross R., SE Nigeria (05° 22' N, 08° 04' E and 06° 11' N, 08° 04' E), southwards to just south of Sanaga R., SW Cameroon (03° 32' N, 09° 37' E and 05° 12' N, 13° 31' E). Present south of Sanaga R. (near Tinaso;

03° 37' N, 09° 57' E) where it interbreeds with *C. cephus* (Struhsaker 1970).

Habitat Moist forest. On mainland in primary and secondary riverine, lowland, mid-altitude and montane forest as well as seasonally flooded swamp forest. Prefers immature forest (Struhsaker 1969, Gartlan & Struhsaker 1972, Lee *et al.* 1988). Habitats at two sites in SW Cameroon are described in detail by Gartlan & Struhsaker (1972). Occurs from near sea level to >900 m. Mean annual rainfall over the range is from ca. 1400 to >8600 mm.

On Bioko I., *C. erythrotis* occurs in forest from sea level to 2600 m, then to the top of Pico Basilé (the highest point on Bioko at 3011 m) where present in the subalpine zone (which is dominated by grass *Festuca* sp., and by the shrubs *Hypericum revolutum* and *Erica mannii*; Butynski & Koster 1994, T. Butynski pers. obs.). Preferred habitat on Bioko is primary lowland forest, a vegetation type that covers about 39% (795 km²) of the island (González-Kirchner 1996). Present where mean annual rainfall ranges from ca. 2000 mm on the north coast to >10,000 mm (perhaps 14,000 mm) on the SW coast (which may be the wettest site in Africa). The wet season is Apr–Oct and the dry season is Nov–Mar. Temperatures range from ca. 34 °C on the coast to probably near freezing on top of Pico Basilé.

Abundance In Lombé part of Douala-Edéa Reserve, Cameroon, density was 2–3 groups/km² during the mid-1970s (D. McKey cited in Lee *et al.* 1988). In Korup N. P., W Cameroon, one study estimated 0.3 groups/km² (Edwards 1992), while a second study, in 2004–05, based on 320 km of foot transect, estimated 0.05–0.34 groups/km² (Linder & Oates 2011). Still widespread and, apparently, fairly common in the Yabassi region north of the Sanaga R., SW Cameroon (Dowsett-Lemaire & Dowsett 2001). For four primate communities in Cameroon, *C. erythrotis* groups accounted for 8–21% of 304 groups encountered (Gartlan & Struhsaker 1972).

Of seven species of monkeys on Bioko I., the most common and widespread is *C. erythrotis*. Of 108 groups of monkeys encountered during an island-wide survey in 1986, 48 (44%) were *C. erythrotis* (Butynski & Koster 1994). During a 2008 survey in the Gran Caldera de Luba, SW Bioko, *C. erythrotis* accounted for 40% of 62 groups of monkeys (six species) encountered. On the south slope of Pico Basilé, 60% of the 35 groups encountered during a 2008 survey were *C. erythrotis*. At Badja North, south-west Bioko, 33% of 105 groups encountered in 2009, and 32% of 91 groups encountered in 2010, were *C. erythrotis* (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. obs.).

In 1986 *C. erythrotis* on Bioko was encountered at the rate of 0.13 groups/km during the island-wide survey that involved 373 km of foot census, much of which was through heavily hunted areas (Butynski & Koster 1994). Other encounter rates on Bioko are as follows: 0.57 groups/km in 2008 along 44 km of transect in Gran Caldera de Luba; 0.43 groups/km in 2008 along 49 km of transect on south slope of Pico Basilé; and 0.72 groups/km in 2009 along 48 km of transect and 0.58 groups/km in 2010 along 50 km of transect at Badja North (T. Butynski, G. Hearn, M. Kelly & J. Owens pers. obs.). These last-mentioned three sites are remote and receive relatively low levels of hunting. Also, there has been little to no anthropogenic impact on the habitats at these sites. As such, these encounter rates are likely close to what can be expected for undisturbed populations of *C. erythrotis*.

In 1992 in the Arihá area on the coast of SE Bioko, *C. erythrotis* was encountered at a rate of 0.14 groups/km during 100 km of foot survey. Density here was estimated at 0.26–0.39 ind/km². Here *C. erythrotis* was the third most common monkey (behind Crowned Monkey *Cercopithecus pogonias* and Putty-nosed Monkey *Cercopithecus nictitans*) (Maté & Colell 1995).

Adaptations Diurnal and arboreal. As with other *C. (cephus)* Group species, *C. erythrotis* is a very visually alert monkey. Its short-range visual signals include rapid head-shaking. The horizontal orientation of facial stripes, and the vivid red ears and nose, serve to make the rapid shaking of the head highly conspicuous. Likewise, there are repetitive behaviour patterns to suggest that postures and movements of the bright red tail provide information about dominance ranking (Kingdon 1980, 1997, 2007). The likely function of these signals is discussed on pages 364–5. Species-specific behaviour of *C. erythrotis* has yet to be studied in detail but preliminary observations indicate that it resembles that of other *C. (cephus)* Group species in its more obvious features (Struhsaker 1970, Gartlan & Struhsaker 1972, T. Butynski pers. obs.).

In Cameroon, groups of *C. erythrotis* are frequently in polyspecific association with *C. nictitans* and *C. pogonias*, and sometimes also associates with Mona Monkeys *Cercopithecus mona* and Preuss's Monkey *Allochrocebus preussi*. At Idenau in polyspecific association during 96% of group encounters ($n = 27$), and at Southern Bakundu Reserve in polyspecific association during 78% of group encounters ($n = 222$) (Gartlan & Struhsaker 1972). The possible predation and foraging advantages for the formation and maintenance of polyspecific associations among groups of primates of different species has been much discussed (e.g. Gartlan & Struhsaker 1972, Gautier-Hion 1988, Struhsaker 2000a) and will not be reviewed here.

On Bioko groups of *C. erythrotis* form polyspecific associations with Pennant's Red Colobus *Procolobus pennantii*, Black Colobus *Colobus satanas*, *C. pogonias*, *C. nictitans* and *A. preussi* (T. Butynski pers. obs.). During a 1986 survey, *C. erythrotis* groups were in polyspecific association on six (15%) of 41 encounters but much of this survey was conducted in heavily hunted areas where primate densities were low and where, in some cases, *C. erythrotis* was the only monkey species present (Butynski & Koster 1994). A 1992 study of an undisturbed community of primates on SW Bioko found *C. erythrotis* groups ($n = 16$) to be in polyspecific association on 50% of encounters (Struhsaker 2000a). During a 2008 study of the high density, but somewhat hunted, primate community within the Gran Caldera de Luba, only two (8%) of the 25 groups of *C. erythrotis* encountered were in polyspecific association (T. Butynski, G. Hearn & J. Owens pers. obs.).

On Bioko the two primary natural predators of forest monkeys are absent, namely the Leopard *Panthera pardus* and African Crowned Eagle *Stephanoaetus coronatus*. This might account for the low incidence of polyspecific association for *C. erythrotis* on Bioko relative to the mainland. In areas where human hunters are also largely absent, *C. erythrotis* is frequently seen on the ground (Butynski & Koster 1994, Struhsaker 2000a).

The range of habitats and altitudes occupied by *C. erythrotis* on Bioko is far greater than on the mainland. The reasons for this remain unknown. A study of the great ecological plasticity shown by this species on Bioko could shed considerable light on the environmental

Red-eared Monkey *Cercopithecus erythrotis* adult male.

Typical head-flagging sequence in Red-eared Monkey *Cercopithecus erythrotis* adult male (2.1 seconds duration).

conditions that restrict the distribution and abundance of *C. erythrotis*, as well as illuminate the dynamics of ecological partitioning among *Cercopithecus* spp. in general.

Foraging and Food Omnivorous. Foraging behaviour and diet yet to be systematically studied. In Cameroon *C. erythrotis* fairly frequently seen on the ground but generally a species of the lower strata of the forest. Travels and feeds at lower heights than *C. pogonias* or *C. nictitans*, with 50% of feeding below 15 m (Gartlan & Struhsaker 1972). A list of 15 species of plants eaten by *C. erythrotis* at Southern Bakundu F. R. is provided by Gartlan & Struhsaker (1972). Fruits are, by far, the most frequently recorded plant part eaten. On Bioko found on the ground during 5% of encounters during surveys, at 1–10 m above the ground during 42% of encounters, at 10–20 m during 33% of encounters, at 20–30 m during 13% of encounters, and >40 m (in emergents) during 7% of encounters ($n = 153$; González-Kirchner 1996). A study on the coast of SE Bioko found *C. erythrotis* at 10–20 m above the ground during ca. 72% of encounters (Maté & Colell 1995). On Bioko feeds near villages on bananas *Musa* sp., Cocoa *Theobroma cacao* and Oil Palm *Elaeis guineensis* fruits (Butynski & Koster 1994, González-Kirchner 1996). Wild fruits eaten include *Antidesma laciniatum*, *Allanblackia montecola*, *Antrocaryon klaineianum*, *Sterculia tragacantha* and *Ficus sur* (K. Nowak, E. Good & T. Butynski pers. obs.). Also feeds on flowers of *A. montecola*, *Psychotria* sp. and *H. revolutum*. Much of the time spent foraging involves searching for invertebrates, especially within dry, curled, leaves (T. Butynski pers. obs.).

Social and Reproductive Behaviour Social. In Cameroon group size ranges from ca. 4 to >29 animals ($n = 4$, Struhsaker 1969). S. Gartlan (pers. comm. to Wolfheim 1983) reported group size as 30–35 animals. Few group size data available for Bioko; Maté & Colell (1995) give group size at 8–12 animals (but no sample size provided). T. Butynski (pers. obs.) has the impression that most groups comprise 10–20 animals. Both in Cameroon and on Bioko there is no indication that groups have more than one adult ♂ (Struhsaker 1969, T. Butynski pers. obs.).

Solitary ♂ ♂ common, at least at some sites. Of 48 encounters with *C. erythrotis* on Bioko in 1986, seven (15%) were thought to be with solitary ♂ ♂ (Butynski & Koster 1994). Similarly, of 20 encounters with *C. erythrotis* on Bioko in 1992, four (20%) were believed to be with solitaires. Of 20 encounters with *C. erythrotis* in Korup N. P., two (10%) were believed to be with solitaires (Struhsaker 2000a). Preliminary observations on the social behaviour of *C. erythrotis* in Cameroon are presented in Struhsaker (1969) and in Gartlan & Struhsaker (1972).

The vocal repertoire of *C. erythrotis* includes 'screams', 'screeches', 'growls', 'chirps', 'twitters', 'grunts', 'trills', 'chutters' and 'hacks' (Struhsaker 1970, Gautier 1988, T. Butynski pers. obs.). Chirps, twitters, grunts, trills and chutters given only by adult ♀ ♀ and immatures. Chirps and twitters are given primarily in situations of alarm, such as towards a human observer or other potential predator (e.g. African Crowned Eagle). Grunts facilitate group cohesion. Chutters given during intra- and inter-group agonistic encounters. The hack is the loudest call and is given by adult ♂ ♂ and, perhaps, large subadult ♂ ♂. None the less, this call can not be heard much beyond 100 m and is, therefore, not nearly as loud as the loud-calls of most other *Cercopithecus* spp. Hacks are generally given at the rate of ca. 1/sec, but to 2/sec when the ♂ is especially excited. Hacks often grade into a series of hack-trains and sharp, soft, 'aints', in a manner similar to Gentle Monkey *Cercopithecus mitis* (T. Butynski pers. obs.). Hacks are typically given in alarm situations and often immediately after the (louder) hacks of *C. nictitans*, *C. pogonias* or *C. mona*, but rarely precedes them (Struhsaker 1970, T. Butynski pers. obs.). Also given after *C. pogonias* booms. The hack sounds distinctly different from the 'pop' of *C. ascanius* and not nearly as loud. Overall, *C. erythrotis* is notably less vocal than other *Cercopithecus* spp. (Dowsett-Lemaire & Dowsett 2001, T. Butynski pers. obs.). Struhsaker (1970) suggests that *C. erythrotis* may not be territorial. If so, this may be related to the absence of a far-carrying loud-call in this species.

Reproduction and Population Structure No information available from the wild. Probably similar to other members of the *C. (cephus)* Group. Captive ♀ ♀ indicate oestrus to adult ♂ ♂ through an arched back and tail-up presentation of the genitalia while at the same time puckering their lips (J. Kingdon pers. obs.).

Predators, Parasites and Diseases Few data available on predation. Humans are, by far, the most important predator, both on Bioko and on the mainland. Probable main natural predators on the mainland are African Crowned Eagles, Leopards, African Golden Cats *Profelis aurata*, Robust Chimpanzees *Pan troglodytes*, Central African Rock Pythons *Python sebae* and Nile Crocodiles *Crocodylus niloticus*. African Crowned Eagles are likely the most significant natural predator of *C. erythrotis* on the mainland (Struhsaker 2000a).

Except for *P. sebae*, all of these natural predators are absent from Bioko. Drill *Mandrillus leucophaeus*, which are present over much of the range of *C. erythrotis*, may kill and eat small monkeys but there are, as yet, no records for this. No data available on parasites and diseases. *Cercopithecus erythrotis* lives to at least 14.2 years in captivity (Jones 1962). No information on diseases and parasites.

Conservation IUCN Category (2012): Vulnerable. CITES (2012): Appendix II.

Hunting for the commercial bushmeat trade, and habitat degradation, loss and fragmentation, are the main threats, both on Bioko (Butynski & Koster 1994, Hearn *et al.* 2006) and in Nigeria and Cameroon (Wolfheim 1983, Lee *et al.* 1988, Bowen-Jones & Pendry 1999, Waltert *et al.* 2002, Oates *et al.* 2004, Linder & Oates 2011). Most of the historic range is now highly fragmented and degraded within an anthropogenic landscape in which it is likely that almost all remaining populations are hunted. The survival of *C. erythrotis* is, however, assisted by the animal's small size, cryptic behaviour, ability to survive in small forests near agriculture and human settlement, and considerable ecological and behavioural plasticity. On Bioko, this species is better able to survive sustained hunting than any of the other species in the primate communities in which it occurs (Koster & Butynski 1994, González-Kirchner 1996).

On Bioko fairly abundant in the Gran Caldera & Southern Highlands Scientific Reserve (510 km²) and Pico Basilé N. P. (330 km²). Neither area is, however, effectively managed and, as such, all primates are heavily hunted. In 2005 the number of *C. erythrotis* carcasses counted at the Malabo Bushmeat Market was ca. 1750. The total number killed by bushmeat hunters on Bioko during 2005 is estimated to be ca. 4000. The average price paid in 2006 in the Malabo Bushmeat Market for an adult *C. erythrotis* was ca. US\$ 29. The number of *C. erythrotis* on Bioko in 2006 was estimated at 20,000 individuals, down roughly 35% since 1986 (Hearn *et al.* 2006).

In Nigeria found in Cross River N. P., Mbe Mountains, and Afi River F. R. In Cameroon present within South Bakundu Reserve, Douala-Edéa Reserve, Korup N. P. and, apparently, also the Makombé Forest (ca. 600 km²), Ndokbou Forest (>1000 km²) and Ebo Forest (ca. 1400 km²) in the Yabassi area (Dowsett-Lemaire & Dowsett 2001). Probably also present in the following forests: Obudu, Takamanda, Ejagham, Mone Mta Ali, Banyang-Mbo, Rumpi Hills, Mokoku, Bambuko, Mouyaka, Dibombe, Mababe, Mungo and Bakala.

Priority actions for the long-term conservation of this species are to (1) stop the hunting of this species for the bushmeat trade and (2) conduct surveys to better determine the current distribution and abundance of this species, particularly in the Yabassi area.

Measurements

Cercopithecus erythrotis

C. e. erythrotis

HB (♂ ♂): 420 (390–500) mm, $n = 66$

Cercopithecus ascanius **RED-TAILED MONKEY**

Fr. Ascagne; Ger. Kongo-Weißnasenmeerkatze

Cercopithecus ascanius (Audebert, 1799). Histoire Naturelle des Singes et des Makis 4(2): 13. Lower Congo R., NW Angola.

Red-tailed Monkey *Cercopithecus ascanius*.

Taxonomy Polytypic species within the *Cercopithecus* (*cephus*) Group (or Superspecies). Encompasses five distinct geographic types with an unresolved taxonomy. Lacking detailed information about their distributional boundaries, it is unknown if the various types intergrade, are parapatric or sympatric. Some types, therefore, could be distinct species, especially the Schmidt's Red-Tailed Monkey *Cercopithecus ascanius schmidtii* (Sarmiento *et al.* 2001), but without taxonomic resolution all types are referred here, for practical reasons, to five subspecies (Kingdon 1997, Gautier-

Hion *et al.* 1999, Groves 2001, 2005c, Grubb *et al.* 2003): *C. a. ascanius*, *C. a. atrinatus*, *C. a. katangae*, *C. a. schmidtii*, *C. a. whitesidei*. Synonyms: *atrinatus*, *cirrhorhinus*, *enkamer*, *histrio*, *ituriensis*, *kaimosae*, *kassaiensis*, *katangae*, *melanogenys*, *montanus*, *mpangae*, *omissus*, *orientalis*, *pelorhinus*, *picturatus*, *rutschuricus*, *sassae*, *schmidtii*, *whitesidei*. Many synonyms lack locality data and thus have no subspecific resolution. Chromosome number: 2n = 66 (Chiarelli *et al.* 1979a, Moulin *et al.* 1985, Dutrillaux *et al.* 1988b).

Description Medium-sized, arboreal, long-tailed monkey with heart-shaped, white, yellow, orange or black nose-spot and partially red or orange-red tail, depending on subspecies. Sexes identical in colour of pelage, but adult ♂ has bluer skin on face and on loins than adult ♀. Weight of average adult ♀ ca. 75–80% that of average adult ♂. Adult ♂ has proportionately larger canines. Most subspecies have temporal rosette (hair whorl), variably coloured sub-ocular patch and fronto-temporal band, and black band on cheek and lower jaw. Bare facial skin, blue or purple, less commonly brown/black. Ear helix can have tuft of orange-red or white hairs. Undersurface of throat, body, limbs and proximal tail white, cream or light grey. Dorsum of head, body, limbs and proximal tail agouti; individual hairs translucent, light grey or light brown at base grading into black distally. Distal black half of each hair has one to four orange, straw-yellow or cream bands. According to number, width, spacing and colour of bands dorsum takes on an olive-brown hue, with yellow and red highlights on head and body, respectively. Outer hindlimbs usually lighter in colour than outer forelimbs. Hands and feet, including digits, covered dorsally by black to dark brown hairs, variably single-banded. Distal two-thirds of tail ventrum red or orange hairs. Tail tip usually black dorsally, but ventrally, orange banding of black hairs can produce red highlights. Pedal hairs longer than manual ones, and latter can be sparse on middle and distal phalanges. Exposed skin

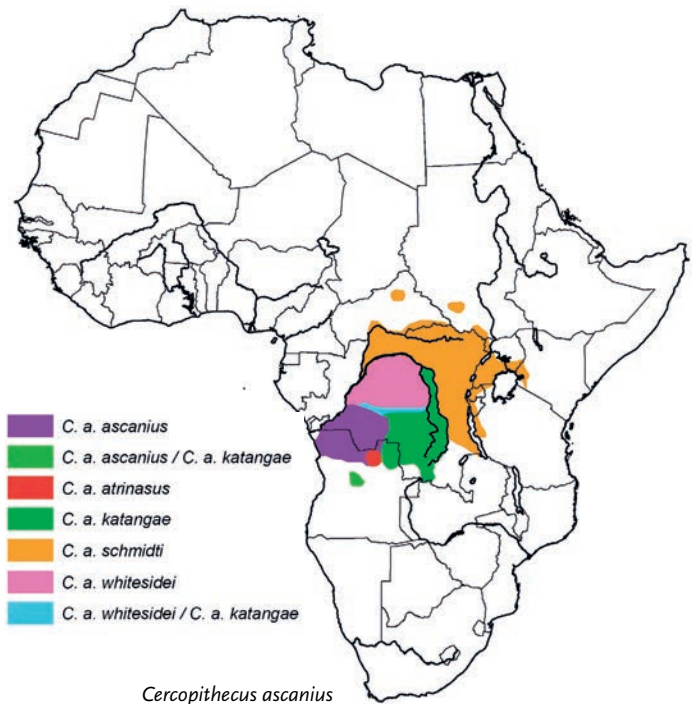

and ischial callosities brown to black. Scrotal skin varying shades of blue. Tail long (ca. 167% of HB). Upper-limb length (humerus + radius) averages 79% of lower-limb length (femur + tibia). Third finger longest, followed by fourth, second and fifth finger. Third and fourth toe sub-equal in length and considerably longer than sub-equal second and fifth toes. Natal pelage soft, woolly, greyish-brown. Nose-spot faint. No red in tail. Palm and sole skin pink. Facial skin much lighter blue than in adult. Adult colour pattern appears as early as three weeks (Haddow 1952), and is fully developed by time first deciduous molars erupt.

Geographic Variation Five subspecies currently recognized (Kingdon 1997, Gautier-Hion *et al.* 1999, Groves 2001, 2005c, Grubb *et al.* 2003). Range limits roughly coinciding with major rivers.

C. a. ascanius Black-cheeked Red-tailed Monkey. South of lower Congo R. and Kasai R., DR Congo, below 500 m. West of Kwilu (Cuilo) R., DR Congo. Eastern and southern extent poorly known. At ca. 15° E and ca. 08° S, but may reach west (left) bank of Kwilu (Cuilo) R., Angola, ca. 19° E where it intergrades with *C. a. atrinasus*. Reports of *C. ascanius* west of upper Kwango (Cuango) R. possibly place these monkeys as far as 11° S (Machado 1969). Cheek-whiskers black. Nose-spot white. Temporal whorl cream. Fronto-temporal band broad and black. Shoulders black. Tail dorsum maroon-red over distal ca. 66–75%. Tail ventrum orange-red over distal ca. 75%. Ears with long, bushy red hairs between helix and anti-helix. Shoulder colour distinguishes *C. a. ascanius* from all other subspecies except *C. a. atrinasus*. Synonyms: *melanogenys*, *picturatus*.

C. a. atrinasus Black-nosed Red-tailed Monkey. In small area (ca. 2500 km²) in extreme north-west Lunda District, Angola, around Wamba R. and Lué R. Fully within *C. a. ascanius* distribution (Machado 1969). Although Zova (08°07' S, 18°04' E, 850 m), the type locality, is near DR Congo border (Machado 1969), this subspecies not reported from DR Congo. Nose-spot and chin black. Upper lip dark brown. Distinct subocular patch absent. Otherwise, resembles *C. a. ascanius* (Machado 1965, 1969). Black nose spot distinguishes *C. a. atrinasus* from all other subspecies. Synonyms: none.

C. a. katangae Katanga Red-tailed Monkey. Mainly south of Equator between Kasai R. and Lualaba R., DR Congo, at 500–1300 m. North of Equator between Lualaba R. and Lomami R., DR Congo, reaching juncture of these rivers at 00°28' N. In west, northern limit is fork of Sankuru R. and Kasai R. Centrally, northern limit is between Sankuru R. and Lomami R. (Machado 1969) around headwaters of Lukenie R. in area of transition with *C. a. whitesidei*. In Angola crosses upper Kasai R. as far west as right bank of upper Kwilu (Cuilo) R. where supposedly mixes with *C. a. atrinasus* (Machado 1969). Local people report *C. a. katangae* at 11° S across central and E Angola and as far west as upper Cuanza R. (Machado 1969), but these might be *C. a. ascanius*. At ca. 11°14' S in NW Mwinilunga District, N Zambia (Ansell 1978). Black fronto-temporal band deficient. Subocular patch and temporal whorl present. Black band on cheek and lower jaw tapering posteriorly. Facial skin dark blue to purple. Tail dorsum dark brown to black. Absence of red on tail dorsum distinguishes *C. a. katangae* from all other subspecies. Synonyms: none.

C. a. schmidtii Schmidt's Red-tailed Monkey. Widest geographic and altitudinal distribution (400–2500 m) of the five subspecies. North of Congo R., east of lower Ubangi R. and Lualaba R., and mainly west of east flank of Western (Albertine) Rift Valley. In small patches of isolated habitat between L. Kyoga and northern shore of L. Victoria. East to Mau Forest, Kenya, reaching west flank of Eastern (Gregory) Rift Valley. In Uganda northern limit is Victorian Nile. West of Western Rift Valley north of Uele R., and Mbomu R. to ca. 06° N in S Sudan and 08°10' N in Central African Republic (Kock 1969, Fay 1988). South along either side of L. Tanganyika reaching Mt Wansisi on the east at ca. 06°45' S (Kano 1971) and Marungu Mts on west at ca. 08° S (Matschie 1893). No information from areas west of Marungu Mts regarding possible overlap with *C. a. katangae*. Cheek-whiskers white. Temporal whorl and subocular patch absent. Ear-tufts usually white but may be orange or red. Tail ventrum grey on proximal one-third. Any one of these characters distinguishes *C. a. schmidtii* from all other subspecies. White proximal tail ventrum in animals from north bank of Congo R. suggests admixture with *C. a. whitesidei*. Synonyms: *enkamer*, *ituriensis*, *kaimosae*, *montanus*, *mpangae*, *orientalis*, *rutschuricus*, *sassae*.

C. a. whitesidei Congo Basin Red-tailed Monkey. Mainly south and east of Congo R. and west of Lomami R., DR Congo, below 500 m. Lukenie R. is southern boundary, but monkeys fitting this description known south of Lukenie R. grading into *C. a. katangae* and *C. a. ascanius*. Yellow (not orange) nose-spot in animals from between Lomami R. and Lualaba R. could indicate transition zone with *C. a. katangae* (Colyn 1988). Monkeys with white tail ventrum from right bank of Congo R. suggest it crosses the Congo R. and interbreeds with *C. a. schmidtii*. Resembles *C. a. katangae*, but distinguishable from all other subspecies by chestnut-red middle third of tail dorsum, and yellow, orange or red nose-spot. Synonyms: *cirrhohinus*, *kassaicus*, *omissus*, *pelorhinus*.

Similar Species Allopatric species belonging to the *Cercopithecus* (*cephus*) Group are similar in size and body colouring but all have a highly distinctive face colour pattern. Sympatric monkeys of the *Cercopithecus* (*mona*) Group, notably Dent's Monkey *Cercopithecus denti* and Wolf's Monkey *Cercopithecus wolffi*, are similar in size but are unlikely to be confused with this species.

Distribution Endemic to forests of tropical Africa. Rainforest, and Afromontane–Afroalpine BZs. East of lower Congo R. and lower Ubangi R. North of Ubangi R. above bend. Northern, eastern and southern limits marked by absence of moist forests, long dry season and decreased rainfall. From N Angola, DR Congo and Central African Republic eastwards to W Kenya and NW Tanzania. Claimed distribution west of Sangha R., Cameroon, and NE border of Congo probably based on misidentifications (Colyn 1999). Absence from forest block between Sangha R. and Ubangi R. (Colyn 1999), and from mangrove and swamp forests circumscribing Congo R. Delta, linked to presence of Moustached Monkey *Cercopithecus cephus*. Reported *C. ascanius* × *C. cephus* hybrids over large areas of Sangha–Ubangi Forest (Colyn 1994) apparently misidentifications (Colyn 1999). See Geographic Distribution for details of distributions of the subspecies.

Habitat Mostly occupies wet (>1300 mm mean annual rainfall) lowland, swamp, gallery, lakeshore, mid-altitude and montane forests from 0 to 2500 m asl, including forest islands, degraded forest and secondary forest. Ranges into *Brachystegia* woodland (eastern shore L. Tanganyika), undifferentiated woodlands, exotic plantations (e.g. Blue Gum *Eucalyptus* spp.), and dryer forest (1100–1300 mm mean annual rainfall) adjoining moist forest habitat. Inhabits small forest patches devoid of other monkeys. Absent from the interior of primary forests where secondary vegetation is uncommon (Schouteden 1944a). Spends most time in lower and middle forest strata (10–20 m), but occasionally seen on ground (Haddow 1952, Gathua 2000a).

Abundance *Cercopithecus a. schmidtii* in East Africa is often most abundant at forest edge and in secondary forest, unless disturbance is extreme. Density ca. 8–184 ind/km² (1.0–13.3 groups/km²) (Cords 1987b, Plumptre & Reynolds 1994, Fashing & Cords 2000, Mitani *et al.* 2001, Fashing *et al.* 2012). Within the same forest, density can vary three-fold across distances of <20 km. Effects of logging disturbance are not consistent across forests. In Budongo F. R., Uganda, density higher in heavily logged (46–60 ind/km²) than in unlogged (8–19 ind/km²) forest (Plumptre & Reynolds 1994, Sheppard 2000). In Kibale N. P., Uganda, highest group densities in lightly logged forest (4.8–11.5 groups/km²), intermediate densities in unlogged forests (3.8–5.6 groups/km²), and lowest densities in heavily logged forests (1.0–2.5 groups/km²; Chapman & Lambert 2000). Variation in density across forests with similar disturbance histories is also considerable. For example, densities in unlogged forests range from 8.3 ind/km² (Budongo F. R.; Plumptre & Reynolds 1994) to 162 ind/km² (Kibale N. P.; Mitani *et al.* 2001).

Adaptations Diurnal and arboreal. Main diurnal activities are foraging and feeding (26–69%), resting (9–59%), moving (5–40%), and various social behaviours (1–8%) (Struhsaker 1980, Cords

Congo Basin Red-tailed Monkey *Cercopithecus ascanius whitesidei* variant morph.

1987b, Jones & Bush 1988, Kirathe 1996, Worch 2002). Locomotion involves mainly climbing and quadrupedal walking, running and leaping on supports 6–25 cm in circumference (Gebo & Chapman 1995). Activity peaks in early morning and late afternoon.

Like all cercopithecines, *C. ascanius* possesses highly innervated, glandular cheek-pouches that probably aid in food processing and digestion. Cheek-pouches serve to reduce feeding competition and predation risk (Lambert 2004). As for other guenons, slow gut passage rates probably facilitate digestion of high fibre diets and detoxify plant secondary compounds, permitting dietary flexibility (Lambert 2002). Small body size allows exploitation of tree periphery, with movement between trees, and foraging in parts of trees where sympatric primates are less agile and/or unable to secure stable supports (E. E. Sarmiento pers. obs.).

Foraging and Food Frugivore-insectivore. Information on foraging and food comes almost entirely from studies of *C. a. schmidtii* in W Kenya and SW Uganda. Daily travel distance 1–2 km and averages ca. 1.5 km, enabling daily coverage of a large portion of home-range (Cords 1987b, Struhsaker & Leland 1988, Gathua 2000a). Group home-ranges 15–67 ha (Mizuno *et al.* 1976, Struhsaker & Leland 1988, Gathua 2000a).

Feeding peaks in early morning and later afternoon, undeterred by rain. Some group members forage or feed at all times of day. Fruit-feeding most common in early morning and late afternoon, leaf-feeding most common at midday. Invertebrate-feeding most common from 08:00–16:00h, and relatively rare later in day (Cords 1987b). Most invertebrate prey (60–65%) collected from foliage (Struhsaker 1978a, Cords 1987b). Search methods include careful turning and unrolling of leaves, with most prey captured directly by mouth, and less commonly by hand. Faster capture techniques allow *C. ascanius* to feed on more mobile prey than sympatric Blue Monkeys *Cercopithecus mitis stuhlmanni*.

Major diet items are fruit (35–61%), invertebrates (mainly insects; 14–31%) and young leaves (7–33%) from trees and lianas (Cords 1987b, Chapman & Chapman 2000, Gathua 2000a). Figs

Ficus spp. are a major fruit class. Prefer ripe to unripe fruit, and leaves with high protein:fibre ratios (Dominy & Lucas 2001). Eats unripe fruit when ripe fruit unavailable (Conklin-Brittain *et al.* 1998). Large seeds are spat out (Lambert & Garber 1998). Will feed on cotyledons and herbs from ground (Gathua 2000a). Flowers, nectar, mature leaves, stems, gum, bark, fungi and shed snake skin make up remainder of known diet. One report of successful hunting of African Green Pigeons *Tieron calva* (Furuichi 2006). Raids Banana *Musa* spp., Mango *Mangifera indica*, Guava *Psidium guajava* and Maize *Zea mays* crops (Naughton-Treves *et al.* 1998). One ♀ observed to drink own urine (Lambert 2000).

In Kakamega Forest, Kenya, *C. ascanius* feeds on up to 98 wild plant species/year, but depends on relatively few plants at any one time. Top ten plant species provide 68–97% of monthly plant-based diet, with *Heinsenia diervilleoides*, *Ficus exasperata*, *Strychnos usambarensis* and *Trilepisium madagascariense* among most important sources across multiple months (Cords 1984b, Gathua 2000a). Proportions of major food items comprising diet can vary from month to month by factors as great as 2.3 for fruits, 3.7 for leaves and 5.0 for invertebrate prey (Cords 1986, Gathua 2000a). When fruit consumption is low, *C. ascanius* feeds primarily on invertebrates, young leaves, flowers or seeds (Cords 1987b, Gathua 2000a). In Kakamega Forest and Kibale N. P., major food items often not consumed in proportion to relative abundance (Gathua 2000a, Chapman *et al.* 2002).

Adult ♂♂ eat more fruit but fewer leaves and invertebrates than adult ♀♀. Juveniles eat more fruit but fewer insects and leaves than adults (Cords 1986). Infants ingest solid food at ca. 2 months (Haddow 1952). They suckle frequently during their first six months and may still suckle occasionally at 1.5 years (M. Cords pers. obs.). Yearlings acquire most of their own food.

Social and Reproductive Behaviour Social. Information on social behaviour comes almost entirely from *C. a. schmidtii* studied in W Kenya and SW Uganda. Typical group size is 25–35 members (3–50; Cords 1987b, Struhsaker 1988, Gathua 2000a), but groups of 10–15 also exist where density is low (Fay 1988, McGraw 1994, Sheppard 2000, Detwiler 2010). Large groups (>50 animals) will fission, with resultant groups dividing original home-range (Struhsaker & Leland 1988, Windfelder & Lwanga 2002). Crop-raiding parties of up to 200 members (Haddow 1952) probably include several groups. Groups usually include one adult resident ♂. Adult ♀♀ make up, on average, 36% of group, and immatures the remaining 60%. During annual mating season, up to six adult ♂♂ per month can join group. Groups in which four adult ♂♂ resided simultaneously for >1 year have been reported (Central African Republic; Galat-Luong 1975). Males leave natal groups as subadults (>4 years old), and can spend >3 years away from groups containing *C. ascanius* ♀♀ (Struhsaker & Pope 1991), living either alone or in loose ephemeral associations. Females remain in natal groups for life.

Intra-group amicable behaviours are more frequent than aggressive behaviours and include grooming and sitting in contact. Grooming bouts in which adult ♂♂ receive grooming from other group members, and adult ♀♀ groom each other, occur disproportionately often (Struhsaker & Leland 1979). Play-wrestling and chasing are most common among young animals. Aggressive behaviour includes shaking of head and forequarters, stare-threats, aggressive growls, chases and contact fights with slapping and biting.

Schmidt's Red-tailed Monkey *Cercopithecus ascanius schmidtii*.

Most agonistic interactions comprise two individuals. Overlap of group home-ranges is 0–64%. Groups defend territorial boundaries with aggressive inter-group encounters once every 3–6 days, and more frequently after group fissions (Cords 1987b, Struhsaker & Leland 1988, Windfelder & Lwanga 2002). Females involved much more than ♂♂ in inter-group aggression. Occasionally adjacent groups do not interact, or they supplant one another without obvious aggression.

Pre-copulatory behaviour includes persistent following by either partner, head-flagging by ♂♂ and lip-puckering by ♀♀. Copulations often involve multiple mounts with intromission and thrusting before final mount ending in a coital pause, possibly associated with ejaculation. Vaginal semen plugs often visible after copulation. Juveniles frequently harass copulating partners and sometimes disrupt copulation. Males gain reproductive access to ♀♀ in several ways. Some ♂♂ take over groups aggressively to become sole residents. Resident ♂♂ occasionally copulate with ♀♀ from neighbouring groups. Non-resident ♂♂ sometimes join a heterosexual group for a few days to several months during the mating season. Often several ♂♂ join a group at once, resulting in a multimale influx. Influx ♂♂ usually confine their visits to just one heterosexual group in a given year (Jones & Bush 1988, Struhsaker 1988). During influx, fights between ♂♂ are frequent, and can lead to severe wounds. Initially ♀♀ respond to incoming ♂♂ with varying degrees of aggression and tolerance, but often mate with multiple ♂♂ (up to five) in a given oestrous period. Influx ♂♂ copulate less frequently than the resident ♂ (Cords 1984a, Struhsaker 1988). Only ♂♂ with full adult body size seen to copulate. Within a month after group takeover, the sole resident ♂ sometimes kills (and eats) young infants. Loss of the suckling infant probably hastens the mother's return to oestrus and increases the infanticidal male's chance of siring offspring (Leland *et al.* 1984). Group members resist infanticide with counter-aggression

Schmidt's Red-tailed Monkey *Cercopithecus ascanius schmidtii* subadult male.

(Struhsaker 1977). Newborns are highly attractive to older group members, especially adult ♀♀ and juveniles. Group members often nuzzle and handle infants but seldom remove them from their mother before 1–2 months of age. Attractiveness to group members diminishes as natal pelage disappears, although juveniles carry and cuddle older infants. Adult ♂♂ seldom interact directly with infants. Infants older than six months are seldom carried (Struhsaker & Pope 1991, Gathua 2000a).

At least eight vocalizations recognized (Marler 1973, Struhsaker 1977, Gautier 1988). Adult ♂♂ give three loud-calls. Short cough-like 'hack' or 'pop' often given during group disturbances, repeated rapidly when group is alarmed, often interposed between 'pyows' of sympatric *C. mitis* ♂♂. 'Ka', a low-pitched (1.15–1.39 kHz) call given singly or in rapid sequence of 2–7 calls (average 4.1, $n = 12$, 'ka-train'; Marler 1973), is usually a response to large raptors (Cords 1987b). Prolonged 'waa' nasal scream sometimes given during male–male fights (Struhsaker 1977, Cords 1984b). Female and juvenile calls lower in volume than those of adult ♂♂. 'Phrased grunts' given during and preceding active periods (feeding, moving). Shrill, bird-like 'chirps' often given repeatedly when alarmed by a predator or during territorial encounters. Searing, high-pitched 'trills' (3.93 kHz mean top frequency, range 2.6–5.0, $n = 14$; Marler 1973) given as submission signals and as vocal exchange when caller is alert but not moving quickly. During aggressive encounters, adult ♀♀ and juveniles often threaten each other with growls, and scream shrilly if attacked. *Cercopithecus mitis* have a similar vocal repertoire but *C. ascanius* calls generally lower in volume and higher-pitched.

Cercopithecus ascanius often forms mixed-species associations with individuals or groups of other guenon species, and with Guerezas *Colobus guereza*, Ashy Red Colobus *Procolobus rufomitratus tephrosceles* and Grey-cheeked Mangabeys *Lophocebus albigena* (Cords 1987b, Chapman & Chapman 2000, Teelen 2007). In East Africa they avoid De Brazza's Monkeys *Cercopithecus neglectus* and Robust Chimpanzees

Pan troglodytes (Struhsaker 1981a, Wahome *et al.* 1993). Solitary *C. a. whitesidei* sometimes travel with Gracile Chimpanzees (Bonobos) *Pan paniscus* (Maté *et al.* 1996). Associations reduce predation risk and facilitate finding food (Struhsaker 1981a, Cords 1987b). Behavioural interactions with association partners most often involve aggression but also include play and grooming (Struhsaker 1981a, Cords 1987b, Gathua 2000b). Because of relatively small body size, *C. ascanius* usually loses inter-specific aggressive confrontations with sympatric primates. *Cercopithecus ascanius* responds to alarm calls from sympatric monkeys, birds (e.g. Crested Guinea Fowls *Guttera pucherani*, Black-and-white-casqued Hornbills *Bycanistes subcylindricus*, Great Blue Turacos *Corythaeola cristata*) and duikers (e.g. Blue Duiker *Philantomba monticola*, Peter's Duiker *Cephalophus callipygus*) (Struhsaker 1981a, T. Butynski pers. comm., M. Cords pers. obs.). Duikers and *G. pucherani* occasionally move beneath *C. ascanius* groups to eat dropped fruits (Struhsaker 1981a).

Cercopithecus a. schmidtii hybridizes with *C. mitis* in three forests in Uganda and one in Tanzania. Hybrids with *C. m. stuhlmanni* rare in Budongo F. R., Itwara F. R. and Kibale N. P., where only 2–10 hybrids were identified. Hybrids with Doggett's Monkey *C. m. doggetti* much more common in Gombe Stream N. P. (18% of all individuals in groups including *C. m. doggetti* or *C. ascanius*). As deduced from physical appearance and ♀ hybrid maternity, hybrids are fertile, backcross with either parental species, and reside in groups of either parental type. In Kibale N. P., hybrids known to reside only in *C. a. schmidtii* groups (Struhsaker *et al.* 1988). At Budongo F. R. and Gombe Stream N. P., hybrids are in groups of either parental species as well as in mixed-species groups (Aldrich-Blake 1968, Detwiler 2002, Detwiler *et al.* 2005, E. Sarmiento pers. obs.). Genetic studies documenting ♂ hybrid paternity are wanting.

Reproduction and Population Structure Females are in oestrus (accept and/or solicit copulation) for, on average, 6.9 days (1–28, $n = 10$ periods). Most ♀♀ solicit copulations more than once during an annual mating season of up to nine months, with ca. 11–60 day intervals of non-acceptance. Mating appears not to be closely tied to ovulation, and ♀♀ sometimes mate when pregnant (Cords 1984a). No external signs of ovulation or menses observed. Gestation length not known. Mean weight of *C. a. katangae* newborns is 257 g (245–265, $n = 3$) (E. E. Sarmiento pers. obs.). Births most common during 2–6 month period corresponding with end of wet season and subsequent dry season (Nov–Feb) for *C. a. schmidtii* in East Africa (Cords 1984a, Butynski 1988), and end of dry season and subsequent wet season (Apr–Nov) for a compiled sample of *C. a. schmidtii*, *C. a. katangae* and *C. a. whitesidei* from around Bondo (03° 29' N, 23° 24' E), Kisangani (00° 19' N, 25° 19' E) and Kindu (02° 33' S, 25° 33' E), DR Congo (Gevaerts 1992). Peak birth periods correspond with high fruit and arthropod abundance in East Africa (Butynski 1988). Degree of birth seasonality can differ from group to group within a single forest, or annually for populations as a whole (Struhsaker 1997).

In Kakamega Forest, ♀♀ are usually >4 years old when they first give birth (M. Cords pers. obs.), and are only known to give birth to one offspring. Inter-birth intervals average 54 months (49–60, $n = 3$) when previous infant survives >12 months, and 25 months (12–50, $n = 3$) when previous infant dies <2 months after birth (Cords & Rowell 1987). Birth rates vary from group to group within a forest

Schmidt's Red-tailed Monkey *Cercopithecus ascanius schmidtii*.

(0.36–0.74 births/adult ♀/year), with higher birth rates in groups with more stable adult ♂ membership (Kibale N. P.; Struhsaker & Leland 1988). In Kakamega Forest 70–85% of newborns survive to one year of age (Cords 1984a, Cords & Rowell 1987). Assuming a 1 : 1 sex ratio at birth, only ca. 19% of ♂♂ and ca. 60% of ♀♀ live to adulthood. Adult ♀♀ outnumber adult ♂♂ 3 : 1 (Kibale N. P.; Struhsaker & Pope 1991).

Predators, Parasites and Diseases Predators include African Crowned Eagles *Stephanoaetus coronatus* (Mitani *et al.* 2001), Leopards *Panthera pardus* (Kingdon 1984) and Robust Chimpanzees (Nishida *et al.* 1979). In Ituri Forest, DR Congo, ca. 4% of the prey items in Leopard scat were *C. ascanius* (Hart, J.A. *et al.* 1996). Humans also kill *C. ascanius* for food, fur, or as vermin. In response to predators and to species physically resembling predators, *C. ascanius* usually gives

alarm calls and plummets into denser vegetation. Groups known to mob cats (Struhsaker 1981a) and adult ♂♂ rush *S. coronatus* (Leland & Struhsaker 1993).

Osteoarthritis, hypertension, and kidney, heart, spleen, liver and alimentary tract diseases in natural populations (Haddow 1952). Parasitic and commensal infections include nematodes (*Enterobius* sp., *Oesophagostomum* sp., *Streptopharagus* sp., *Strongyloides fulleborni*, *Trichuris* sp.), a Dicrocoeliid liver fluke, tapeworm (*Bertiella* sp.) and protozoans (*Chilomastix mesnili*, *Cryptosporidium* sp., *Entamoeba coli*, *Entamoeba histolitica*, *Entamoeba hartmanni*, *Iodamoeba butschlii*, *Giardia lamblia*, *Hepatozoon* [*Plasmodium*] *kochi*); Haddow 1952, Gillespie *et al.* 2004, Salzer *et al.* 2007, Kooriyama *et al.* 2010). Viral infections include Yellow Fever (Haddow 1952). Simian immunodeficiency virus, tumours and yeast (*Cryptococcus*) infections in captives (Verschoor *et al.* 2004, Cooper *et al.* 2005, Bronson & Mankowski 2006).

Conservation IUCN Category (2012): Least Concern. *Cercopithecus a. atrinatus* is Data Deficient. CITES (2012): Appendix II.

IUCN conservation category is based on supposition that all types belong to one species and this is probably not the case. Population numbers of *C. a. ascanius* and *C. a. atrinatus* are unknown and likely to be low. Taxonomic resolution, therefore, is of utmost importance to the conservation of *C. ascanius*. Threatened most by habitat degradation, agricultural encroachment and forest exploitation. Heavy logging reduces population densities for decades (Chapman *et al.* 2000). Suffers from retaliatory hunting by farmers because of crop-raiding and, in DR Congo, from commercial hunting. *Cercopithecus ascanius* is alert and fast-moving, characteristics that make it relatively difficult to hunt. This, together with a small body size, probably makes *C. ascanius* one of the least attractive African primates to hunt (Butynski & Sanderson 2007).

Measurements

Cercopithecus ascanius

Cercopithecus a. ascanius

HB (♂ ♂): 497 (445–545) mm, n = 3

Cercopithecus petaurista LESSER SPOT-NOSED MONKEY

Fr. Pétauriste; Ger. Kleine Weißnasenmeerkatze

Cercopithecus petaurista (Schreber, 1774). Die Säugethiere 1: 97, 185. 'Guinea'.

Eastern Lesser Spot-nosed Monkey *Cercopithecus petaurista petaurista*.

Taxonomy Polytypic species (Napier 1981, Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003, Oates 2011). Member of the *Cercopithecus (cephus)* Group or Superspecies. Originally described by Schreber as *Simias petaurista* from a type locality listed simply as 'Guinea'. No type specimen available. As noted by Hill (1966) and Oates (1988b), Schwarz (1928b) wrongly regarded members of this species as subspecies of Putty-nosed Monkey *Cercopithecus nictitans*. Synonyms: *albinasus*, *buettikoferi*, *fantiensis*, *pygrius*. Chromosome number: 2n = 66 (Dutrillaux 1988b, Romagno 2001).

Description Small, long-tailed, arboreal monkey with white nose. Sexes similar in colour. Adult ♀ weighs ca. 66% as much as adult ♂ (Oates *et al.* 1990). Face black with white stripe extending from temple laterally and inferior to the ear. Superior ridge of pinna has white tuft. Crown, back, thigh, arm and tail are predominately olive-green or khaki. Mid to lower back reddish in some forms. Individual hairs flecked with black and yellow, particularly on crown above orbits. On the limbs the khaki coat graduates to grey distally.

Eastern Lesser Spot-nosed Monkey *Cercopithecus petaurista petaurista*.

Left: Western Lesser Spot-nosed Monkey *Cercopithecus petaurista buettikoferi*.
Right: Eastern Lesser Spot-nosed Monkey *Cercopithecus petaurista petaurista* adult male.

towards hands and feet. Ventral surfaces of throat, chest, limbs and tail are white or cream. Infant has colour and pattern of adult.

Geographic Variation

C. p. petaurista Eastern Lesser Spot-nosed Monkey. From Sassandra R., Côte d'Ivoire, to W Togo. Margins around orbit completely black.

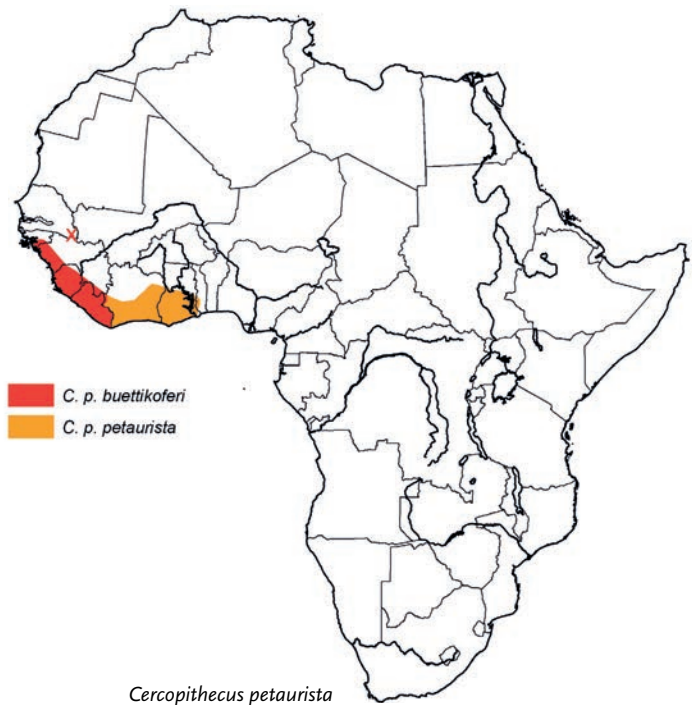

C. p. buettikoferi Western Lesser Spot-nosed Monkey. From Sassandra R. to Guinea (possibly). Margins around infero-lateral orbital rim khaki-coloured.

Subspecies range demarcation debated. Napier (1981) states that Sassandra R. approximates the subspecies boundary. Oates (1988b) states that the boundary is the Cavally R. on the Liberia–Côte d'Ivoire border. The ranges of *buettikoferi* and *petaurista* overlap between the Cavally R. and Nzo R., where intermediate individuals (e.g. BMNH 1956.309) have been collected (Oates 1988b, Groves 2001). Specimens reported from the Guinea-Bissau archipelago (Monard 1938, Frade 1949) may be from introduced populations.

Similar Species

Cercopithecus nictitans stampflii. Sympatric. Body larger and coat darker. Ventrums black. No white stripe on lateral sides of face.

Cercopithecus erythrogaster. Allopatric. Ventrums varies from grey to red. No white stripe on lateral sides of face. White spot on nose absent in some forms.

Cercopithecus petaurista

Distribution Endemic to West Africa. Rainforest BZ. Common and widespread in most forest types from Sierra Leone to W Togo. Presence of mainland populations north-west of Sierra Leone is unclear (Oates 1988b). Groves (2005c) states that Gambia is this species' western limit, though Starin (1989) does not cite it among the five cercopithecids in this country. Dupuy (1972) reports E. Brewer's sighting of *C. nictitans* in Casamance, Senegal, near the Gambia border, but these might be *C. petaurista*. He also reports that *C. nictitans* (perhaps *C. petaurista*) is known from Guinea-Bissau and Guinea. Surveys in Kounounkan Forest, Guinea (Barnett *et al.* 1994), failed to locate *C. petaurista*. Gippoliti & Dell'Omo (2003) report *C. petaurista* in Guinea Bissau. First record of *C. p. petaurista* in Tambacounda region, SE Senegal, reported in 2005 (Pruetz *et al.* 2010). See Geographic Variation.

Habitat Primary forest is preferred habitat but populations abundant in disturbed (secondary) forest throughout range (Coe 1975, Harding 1984a, Sayer & Green 1984, Barnett & Prangley 1997, Grubb *et al.* 1998, McGraw *et al.* 1998b, McCullough 2004, Gonedélé Bi *et al.* 2006). In thick stands of palms in Guinea-Bissau. Occurs between 500 and 800 m asl on Mt Nimba. A frequent crop-raider (Mackenzie 1952), *C. petaurista* thrives in abandoned farm clearings and young successional forest (Fimbel 1994b); adaptable to multiple habitat types.

Abundance Surveys in Sierra Leone, Côte d'Ivoire and Ghana (Oates 1988b, McGraw *et al.* 1998b, Gonedélé Bi *et al.* 2006) suggest that *C. petaurista* is one of the most abundant forest monkeys in West Africa due to its ability to exploit areas of secondary growth. On Tiwai I., Sierra Leone, densities are 3.3–4.0 groups/km² or 46–56 individuals/km² (Oates *et al.* 1990). At Taï N. P., Côte d'Ivoire, in protected primary forest, *C. petaurista* ranks second in number of group encounters ($n = 427$) and fourth in number of individual encounters ($n = 7455$) out of seven species (Galat & Galat-Luong 1985). Density here is 21 ind/km² (Buzzard 2006c).

Lateral and palatal views of skull of Lesser Spot-nosed Monkey *Cercopithecus petaurista* adult male.

Adaptations Diurnal and arboreal. Generalized skeleton typical of tree-dwelling guenons (Gebo & Sargis 1994). Cryptic, cautious monkey that prefers the forest understorey and areas of dense, secondary growth. In undisturbed forest, spends >75% of time in understorey; rarely ascends to top of high canopy trees (Galat & Galat-Luong 1985, McGraw 2000). Locomotion tends to be slow, cautious and deliberate, which accords well with its overall cryptic life-style (McGraw & Zuberbühler 2007). Predominantly quadrupedal (71%) with moderate amounts of climbing (19%) and leaping (10%) ($n = 512$; McGraw 2000). Inter-membral index of 81 (Fleagle 1999). As is typical of forest guenons, *C. petaurista* spends the majority of time in trees during all activities. In primary forest, uses large boughs (10–29%), branches (including lianas) (49–55%) and twigs (24–39%) (Galat & Galat-Luong 1985, $n = 1199$; McGraw 2000), with almost no differences between young and adults nor between adult ♂♂ and adult ♀♀ (Galat 1983). Like all cercopithecines, uses cheek-pouches to store food while foraging (Buzzard 2006a). When cheek-pouches are expanded, white throat region becomes prominent, resembling a snowball. Activity budget of one group at Tai Forest is feeding (38%), resting (32%), social (4%), travelling (7%) and foraging (18%) (McGraw 2000). An able swimmer, with young occasionally playing in rivers and streams.

Foraging and Food Omnivorous. Foraging is generally slow and cautious. Small body size allows individuals of all ages to easily acquire food from terminal branches and twigs as well as from larger supports (Galat & Galat-Luong 1985). Feeding (38%) and foraging (18%) comprise largest portion of activity budget ($n = 2042$, McGraw 2000). Diet varies seasonally (Galat & Galat-Luong 1985, Buzzard 2006b). Annual diet at Tai is comprised of leaves 40%, fruit 34%, 12% insects, flowers 6%, and other 8% (Buzzard 2006a, b, $n = 924$). Foliage and fruit from lianas are especially important (Buzzard 2006a). Key food items in primary forest include *Saccoglottis gabonensis*, *Dialium aubrevillei* and *Memecylon lateriflorum*

(Buzzard 2006b). At Tai, *C. petaurista* forages in more dispersed groups than sympatric Campbell's Monkey *Cercopithecus campbelli* and Diana Monkey *Cercopithecus diana* (McGraw 2000, McGraw & Zuberbühler 2007). Two groups at Tai had an average daily travel distance of 1051 m (S.D. 263, $n = 77$ days; Buzzard 2006c). Home-ranges at Tai were ca. 41–69 ha (Galat & Galat-Luong 1985, $n = 1$; Buzzard 2006b, c, $n = 2$). Home-ranges overlapped 64% those of neighbouring groups (Buzzard & Eckardt 2007). At Dezidougou, Côte d'Ivoire (80 km east of Bouake), G. Galat & A. Galat-Luong (pers. obs.) radio-tracked a group that moved through 94 ha of cultivated fields and young secondary growths.

Social and Reproductive Behaviour Social. At Tai, groups average 10.5–11.3 individuals (4–24, $n = 25$ groups) and usually contain one adult ♂, several breeding ♀♀ and their offspring (Galat & Galat-Luong 1985, Buzzard & Eckardt 2007). One group, after a ♂ take-over, contained two adult ♂♂ for five months of a 17 month study (Buzzard & Eckardt 2007). One group at Tiwai I. comprised 14 animals (Oates *et al.* 1990). The core of the group consists of related ♀♀; ♂♂ disperse from their natal groups. One solitary adult ♂ observed (Galat & Galat-Luong 1985). During movement young cling to their mother's ventrum until about six months of age. Individual members make frequent, soft, 'wurring' contact calls to maintain group cohesion. Adult ♂♂ produce loud-calls resembling a 'hiccup-growl', often in duets with *C. campbelli* (McGraw & Zuberbühler 2007, 2008). Adult ♂ loud-call is most similar to that of Red-bellied Monkey *Cercopithecus erythrogaster* (Gautier 1988). Non-resident adult ♂♂ may move alone or with groups of Olive Colobus *Procolobus verus* or Western Red Colobus *Procolobus badius*.

At Tai, inter-group encounters are four times more common among *C. petaurista* groups than among *C. campbelli* groups. During encounters, members typically ignore each other and aggressive interactions are rare. Aggressive encounters usually occur at feeding sites; adult ♂♂ take active roles including giving loud-calls and head bobs directed at the other group (Buzzard & Eckardt 2007). Agonistic interactions with *C. campbelli* and *C. diana* are frequent (McGraw & Zuberbühler 2007). *Cercopithecus petaurista* occasionally groom *P. verus* and *P. badius*, as well as by other *Cercopithecus* spp. Form polyspecific associations with all other monkeys especially *C. campbelli*, *C. diana* and *P. verus* (Galat & Galat-Luong 1985, Buzzard & Eckardt 2007, McGraw & Zuberbühler 2007, 2008, Buzzard 2010).

Reproduction and Population Structure Poorly known. No visible changes in sexual skin of ♀♀ are apparent. Gestation period is seven months. Single births are the norm. Preliminary evidence indicates that births occur year round. A captive ♀ lived to 29 years (Hill 1966).

Predators, Parasites and Diseases Frequently preyed upon by African Crowned Eagles *Stephanoetus coronatus* (Shultz *et al.* 2004, McGraw *et al.* 2006, Shultz & Thomsett 2007). Occasionally eaten by Robust Chimpanzees *Pan troglodytes* (Boesch & Boesch-Achermann 2000) and Leopards *Panthera pardus* (Hoppe-Dominik 1984, Zuberbühler & Jenny 2002, 2007). Easily and often hunted by humans. Infants and juveniles are frequently kept by villagers (McGraw *et al.* 1998b, McGraw 2007b). As *C. petaurista* are still found in sacred forests and other forests near villages. As healthy

carriers, they play a major role in Yellow Fever outbreaks in the forest–savanna contact area (Galat & Galat-Luong 1997). During a Yellow Fever outbreak in Côte d'Ivoire, a survey of primates found 64% had antiamaril antibodies, 30% of which with high titre ($n = 24$ monkeys; Lhuillier *et al.* 1982). No simian immunodeficiency virus detected (Bibollet-Ruche *et al.* 2004, Apetrei *et al.* 2005).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

This is probably the most common monkey in West Africa, although its numbers are undoubtedly decreasing owing to habitat loss and hunting for the bushmeat trade.

Measurements

Cercopithecus petaurista

HB (♂ ♂): 492 (440–527) mm, $n = 10$

HB (♀ ♀): 411 (290–493) mm, $n = 9$

T (♂ ♂): 712 (523–787) mm, $n = 10$

T (♀ ♀): 649 (556–690) mm, $n = 9$

HF (♂ ♂): n. d.

HF (♀ ♀): 121 mm, $n = 1$

E (♀ ♀): 35 mm, $n = 1$

WT (♂ ♂): 4.4 (3.9–5.0) kg, $n = 13$

WT (♀ ♀): 2.9 (2.3–3.8) kg, $n = 7$

Various localities. HB & T (Napier 1981), HF & E (Hill 1966), WT (Oates *et al.* 1990)

Key References Buzzard 2006a, b, c; Galat & Galat-Luong 1985; McGraw 2000; McGraw & Zuberbühler 2007; Oates 2011; Oates *et al.* 1990.

Cercopithecus erythrogaster WHITE-THROATED MONKEY (RED-BELLIED MONKEY)

Fr. Cercopithèque à ventre rouge; Ger. Rotbauchmeerkatze

Cercopithecus erythrogaster Gray, 1866. Proc. Zool. Soc. Lond. 1866: 169. 'West Africa'.

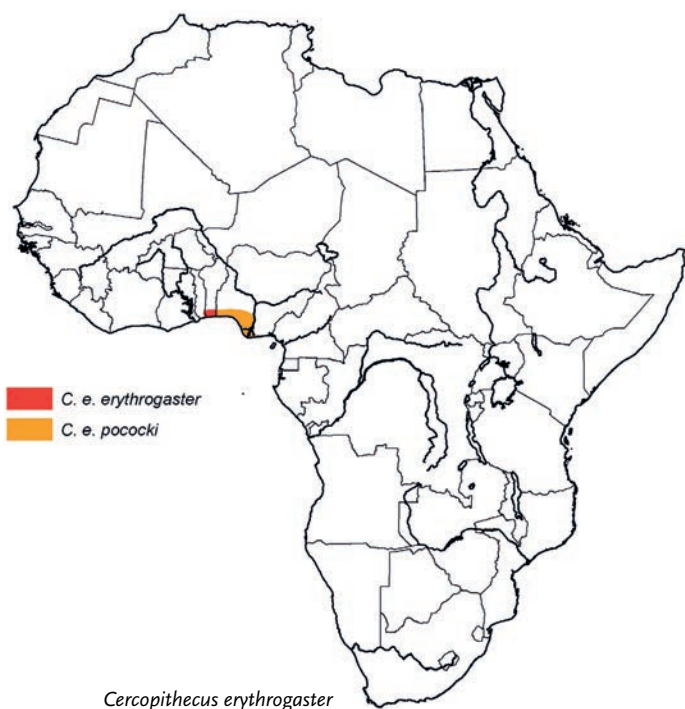

Red-bellied Monkey *Cercopithecus erythrogaster erythrogaster* adult male.

Taxonomy Polytypic species. Member of the *Cercopithecus* (*cephus*) Group or Superspecies (Kingdon 1980, Groves 2001, 2005c, Grubb *et al.* 2003, Oates 2011). Hill (1966) followed Booth (1956a) in placing *C. erythrogaster* in the *Cercopithecus* (*petaurista*) Superspecies; Booth excluded Moustached Monkey *Cercopithecus cephus* and Red-eared Monkey *Cercopithecus erythrotis* from this species, but Hill excluded only *C. cephus*. Most authorities now recognize the affinities of all these forms, of which *C. cephus* was the first-named.

Schwarz (1928b) listed *erythrogaster* as a subspecies of the Putty-nosed Monkey *Cercopithecus nictitans*, and he later (Schwarz 1954) argued that *Cercopithecus signatus* is a synonym of *C. erythrogaster*. However, *C. erythrogaster* and *C. nictitans* are broadly sympatric in W Nigeria and are clearly separate species. Oates (1985) notes that the three museum specimens assigned to *signatus* are very different from *erythrogaster* and may be hybrids between *C. nictitans* and some member of the *C. cephus* group. Two subspecies of *C. erythrogaster* are recognized, Red-bellied Monkey *C. e. erythrogaster* and Nigeria White-throated Monkey *C. e. pococki* (Grubb *et al.* 2003, Groves 2005c, Oates 2011). Synonyms: none. Chromosome number: $2n = 66$ (Moulin *et al.* 2008).

Description Small, long-tailed monkey with prominent white ruff on front and sides of neck and gold-flecked diadem. Sexes alike but adult ♀ smaller than adult ♂. Cheek-tufts of light yellow-and-black banded hairs. Diadem distinct; gold-flecked, edged black, the result of 2–3 mm long golden-yellow bands about 5 mm below the tip of black hairs. Throat with prominent white ruff extending onto sides of neck. Back, flanks, outer proximal limbs and dorsal proximal surface of tail reddish-brown with olive tinge. Lateral surfaces of forearms black or dark brown. Ventrums bright rust-red or brownish-grey, depending on the subspecies. Tail with pale greyish-white ventral surface and dark tip. Viewed in the dense forest understorey, this monkey appears dark, with only the white throat, gold crown patch and light tail undersurface standing out. Infant pelage like adult but paler and less well demarcated (P. Neuenchwander & J.-M. Lernoould pers. comm.).

Geographic Variation

C. e. erythrogaster Red-bellied Monkey. S Bénin and far eastern edge of Togo. Ventrums bright rust-red.

C. e. pococki White-throated Monkey. SW Nigeria and Niger Delta. Ventrums brownish-grey, sometimes with slight reddish tinge. Although the name 'pococki' was used on the label of the holotype in the British Museum (Natural History) by J. G. Dollman, and referred to by Napier (1981), it was not validated until 1999 (Grubb *et al.* 1999).

Similar Species

Cercopithecus petaurista. Not sympatric with *C. erythrogaster*, but present to the west from Senegal to W Togo. Nose-spot, ears, stripe below the ears and belly white.

Cercopithecus sclateri. Possibly sympatric with *C. e. pococki* in east. SE Nigeria, between Niger R. and Cross R. Nose-spot and ears white. Muzzle pinkish. Ventral surface of proximal part of tail red.

Distribution Endemic to E Togo, S Bénin and S Nigeria. Rainforest BZ. Restricted to dry and, particularly, moist forest. In Togo restricted to the Togodo Faunal Reserve (310 km²) adjacent to the Bénin border. In Bénin in Lama Forest (a forest relict in the Dahomey Gap), in Lokoli Forest, in several small forest patches in the lower Ouémé R. Valley (most of which are sacred groves), along Okpara R. and Mono R., and possibly at Banon (08° 29' N) (Oates 1996b, Sinsin *et al.* 2002a, Campbell *et al.* 2008b, Nobimè *et al.* 2009, 2011). In Nigeria on both sides of Niger R., from near Ijebu-Ode in the west to Orashi R. at eastern edge of Niger Delta in east (Oates 1985, Powell 1995). On west bank of Orashi R., in vicinity of Upper Orashi F. R., there may be a hybrid zone between *C. e. pococki* and *C. sclateri* (see *C. sclateri* profile).

Current distribution of *C. e. pococki* in Nigeria is probably similar to historical distribution, but populations are today greatly fragmented due to forest destruction for agriculture. Distribution of

C. e. erythrogaster in Bénin and Togo is much smaller than its presumed historical distribution, with area of occurrence in Bénin in 2000 estimated at 24% of its extent in 1950 (Sinsin *et al.* 2002b).

Habitat Lowland moist and dry semi-deciduous forest, gallery forest and (in the Niger Delta and Ouémé R. Valley) seasonally flooded swamp and marsh forest (Oates 1985, Sinsin *et al.* 2002b, Nobimè *et al.* 2009). *Cercopithecus e. erythrogaster* can also survive in small patches of secondary vegetation in a fragmented landscape (Hanon 2001, Campbell 2005). Annual rainfall within the species' range is from ca. 1100 mm in S Bénin (where there are two dry seasons) to >2500 mm in the Niger Delta (where only Nov–Feb are relatively dry). *Cercopithecus erythrogaster* typically frequents the lower levels of the forest canopy, and dense tangled growth in canopy gaps and along rivers. Altitudinal range ca. 0–400 m.

Abundance Common in suitable habitat when hunting pressure is low. The second most frequently encountered monkey in Okomu N. P., SW Nigeria, where, in 1994 there were >30 ind/km² (Robinson 1994). In Okomu N. P., in 2008–09, 0.11 groups/km (2.7 group/km²; Akinsorotan *et al.* 2011). In Lama Forest, ca. 10.4 ind/km² in 'dense' (= mature) forest and 7.5 ind/km² in disturbed forest (Goodwin 2006). Throughout its range, however, *C. erythrogaster* is now generally rare due to intense commercial hunting. There are >3400 *C. erythrogaster* in the core of Okomu N. P. (the former Wildlife Sanctuary) (Robinson 1994), while estimates for the Lama Forest are 300–800 individuals (Kassa 2001, Campbell 2005, Goodwin 2006).

Adaptations Diurnal and arboreal. Like other members of the *C. (cephus)* Group, this small, highly arboreal monkey is an agile quadruped, walking, running and climbing quietly through the forest on small and medium-sized supports. *Cercopithecus erythrogaster* appears to have high aural and visual acuity. Will quickly drop out of sight on detecting approaching humans, and creep away silently through the lower canopy (Robinson 1994).

Foraging and Food Omnivorous. Foraging and feeding behaviour of *C. erythrogaster* have not been the subject of systematic study. In a few sightings of undisturbed wild animals in Nigeria, they forage (as a group) in a dispersed fashion, carefully searching for such food items as small fruits and insects (Oates 1985). In Lama Forest, fruit (especially *Mimusops andongensis* and *Diospyros mespiliformis*) is the predominant food item, while groups living in sacred groves raid farm crops (Sinsin *et al.* 2002b). Often in close association with other monkeys, especially Mona Monkey *Cercopithecus mona*; in 127 sightings of *C. erythrogaster* in Lama Forest, in association with *C. mona* on 50% of occasions (Goodwin 2006).

Social and Reproductive Behaviour Lives in social groups, but group size not accurately measured; no groups yet habituated to humans, and the species is cryptic in its behaviour. In Nigeria most groups probably range in size from 5 to 20; average group size may be <10 at Okomu (Mason 1940, Oates 1985, Robinson 1994). In S Bénin group size estimated to average five individuals, with a range of 2–12 (Campbell 2005). Adult ♂♂ have a distinctive low frequency, guttural, 'croaking' (or 'growling') loud-call, similar to that of Lesser Spot-nosed

White-throated Monkey *Cercopithecus erythrogaster*.

Monkey *Cercopithecus petaurista* (Oates 1985). In Lama Forest these calls commonly follow the loud-calls of ♂ *C. mona* (Goodwin 2006). Loud-calls usually come from only one location in a group, suggesting that one-male groups are the norm. Solitary adult ♂♂ occasionally seen. No details of reproductive behaviour available, but *C. erythrogaster* likely resembles other members of the *C. (cephus)* Group.

Reproduction and Population Structure No information.

Predators, Parasites and Diseases No information available, but humans are the most important predator at the present time. African Crowned Eagle *Stephanoaetus coronatus* prey on other members of the *C. (cephus)* Group elsewhere, but they are now rare within the range of *C. erythrogaster*.

Conservation IUCN Category (2012): Vulnerable. Endangered as *C. e. erythrogaster* and Vulnerable as *C. e. pococki*. CITES (2012): Appendix II.

Due to habitat destruction and modification, remaining populations occur in a fragmented pattern, and almost all are hunted. The largest remaining population of *C. e. erythrogaster* is probably in Lama Forest (163 km²), Bénin, whose 'Noyau Central' (48 km², of which 19 km² is natural forest) is managed by the Office National du Bois; some smaller populations in Bénin receive protection through their occurrence in sacred groves. The largest population of *C. e. pococki* is in the central part of the Okomu F. R., Edo State, Nigeria, which became a Wildlife Sanctuary in 1985 and a National Park in 1999 (the

original size of Okomu F. R. was 1200 km², but much of this area is now plantations and farms; the National Park covers ca. 181 km²). *Cercopithecus e. pococki* also occurs in Omo F. R., Ogun State, Nigeria, where a protected area is planned. The largest area of continuous forest remaining within the range of *C. erythrogaster* is in the Niger Delta; this forest contains no protected area and has been everywhere modified by logging, but hunting pressure is lower there than in other parts of S Nigeria.

Measurements

Cercopithecus erythrogaster

HB (♂): 457 mm, n = 1

Suborder STREPSIRRHINI – Strepsirrhines: Lemurs, Lorises, Pottos, Galagos

Strepsirrhini É Geoffroy, 1812. Ann. Mus. Hist. Nat. Paris 19: 156.

Tentative phylogenetic tree for the African lorisoids Lorisoidea (after Masters *et al.* 2007).

Nasal structure in (left) Strepsirrhines and (right) Haplorhines (after Martin 1990).

The Strepsirrhini are arboreal primates with typically monkey-like hands and woolly coats but most have pointed, scent-sensitive noses. Their unfortunate name means ‘twist-nosed’ while their popular vernacular name, ‘prosimian’, meaning ‘monkey-forerunner’, has the misleading implication of animals frozen in a time-warp. In reality they are distinctive and successful members of many modern ecological communities.

Commonly grouped under the appellation of Prosimii (Simpson 1945), the reasons for abandoning this name have been discussed in the profile for order Primates. We, in common with most contemporary workers, use É. Geoffroy’s (1812b) ‘Strepsirrhini’ to embrace all the lemurs, lorises, pottos and galagos. Strepsirrhini is generally thought also to embrace the fossil families Adapidae, Notharctidae and Sivaladapidae. When fossil adapids are excluded, the remaining extant strepsirrhines are sometimes described as ‘Lemuriloriformes’ (Groves 2001), but for the purposes of any classification of living primates, this taxon can be taken as synonymous with Strepsirrhini.

Phylogenies based on molecular clocks come up with different dates for divergence of strepsirrhines from anthropoid primates during the Cretaceous, from as early as 90 mya (Douady & Douzery 2003, Bininda-Emonds *et al.* 2007), to 87 mya (Perelman *et al.* 2011), to 80 mya (Arnason *et al.* 1998), while phylogenies based on a sparse fossil record suggest divergence well after the Cretaceous–Tertiary Boundary (‘K–T Boundary’), 65 mya; Gingerich & Uhen 1994, Wible *et al.* 2007). Substantial differentiation among fossil primates by the Paleocene make the later dates less plausible but both the time and place for strepsirrhine origins remain uncertain.

There are two major groups of African strepsirrhines (or ‘lemuriforms’). Groves (1989) allocated them both to the family Lorisidae, with the potto and allies in the subfamily Lorisinae and galagos in the subfamily Galaginae. He subsequently (Groves 2001) upgraded Galagonidae to familial rank, separating the African members of the Loridae into the subfamily Perodicticinae while

Potto *Perodicticus potto* infant showing very supple vertebral column and exceptionally flexible limbs.

Lorinae embraced all the Asiatic lorises. We here follow this change in ranking, although in line with Opinion 1995 of the International Commission on Zoological Nomenclature (2002), we revert to the names Lorisidae, Lorisinae, Galagidae and Galaginae. The change in ranking reflected new molecular discoveries that imply that some of the detailed resemblances between African and Asiatic Lorisidae are essentially convergent. Exactly how the Perodicticinae relate to the Asian lorises and when there was an inter-continental exchange still remains uncertain and controversial.

The galagos are arboreal walkers and leapers with long tails, elongated hindlegs and relatively large ears. The potto group are arboreal clingers and climbers with short tails, limbs of equal length and relatively short ears. Both groups are wholly nocturnal, have round heads, pointed muzzles, forward-facing eyes, a moist nose and a cleft, 'tied' upper lip. They are distinct from other primates in the structure of their placenta, retina, inner ear, blood circulation and digestion. All species have modified lower incisors, which form a fur comb (in some species the incisors also form a sharp chisel). In this respect modern strepsirrhines differ from all early fossil 'prosimians', none of which show modified lower incisors. Hands, feet and nails have been modified in various minor ways but all have a spatulate, fur-grooming claw on the second digit of the foot. These specializations, known to be very ancient within living lineages, serve to keep the woolly fur in good condition. Prosimian fur is important not only as a typical mammalian insulator but also as an indicator of sexual, social and individual status through its role as a scent-dispenser for a variety of secretions produced by glands, excreta, skin and hair

Strepsirrhine hand and foot (exemplified by Spectacled Lesser Galago *Galago matschiei*).

follicles. Scent plays a major, but incompletely understood, part in their social and territorial behaviour. The periodic activity and localized occurrence of some of these odours have been investigated with interesting implications for intra-specific sexual and social communication. For example, Yasuda *et al.* (1961) found hair follicles rich in glycogen and phosphorylase but physiological activity was intermittent. Likewise, Montagna & Yun (1962) found phosphatase activity was strongly acidic on the face and feet of pottos while other parts of the body were alkaline.

Moulting of the fur occurs in most, probably all, lemuriforms and is linked with reproductive cycles and nutritional status. Moulting, skin glands and other scents, and modifications to the front teeth in the lower jaw, the sub-lingual denticle and grooming claw are all physiological and anatomical adaptations that owe their development to natural selection for a set of sensory and communicative behaviours unique to modern prosimians. Those behaviours are inseparable from many of the features that we use to define and describe the Strepsirrhini.

In general, nocturnal primates are less sensitive to colour, some having monochromatic vision, others being dichromatic (greens

LEFT: Schematic side view of tongue denticle and procumbent incisors of *Potto Perodicticus potto*.

ABOVE: Denticle's resting position is under the tongue and behind the lower incisors.

and blues), but have greater sensitivity (are better able to see under minimal natural lighting).

The African and Madagascan branches of Strepsirrhini are estimated (by molecular clocks) to have diverged 60 mya (Pennisi (2007) or 68.7 mya (Perelman *et al.* 2011) in the mid-Palaeocene. Living African strepsirrhines show many resemblances with Asian and Malagasy forms and detailed research on which traits are convergent and which are inherited commonalities remains an ongoing task. For example, African dwarf galagos *Galagoides* show many close similarities with the Malagasy mouse lemurs *Microcebus*, while African squirrel galagos *Sciurocheirus* resemble Malagasy sportive lemurs *Lepilemur*. Galagos and lemurs even show some resemblances with totally unrelated marsupials in Australia and South/Central America. Such detailed convergences are relevant to the very subtle differences among some African galago species and help explain the large number of cryptic species revealed in recent years. These resemblances also suggest that the generalized body-form typical of the earliest arboreal mammals has remained under tight constraints in small, nocturnal species, so that phylogenetically distant taxa can look superficially very similar.

In the profiles that follow, limb proportions, body measurements and subtle differences in minor anatomical structures have been examined in exceptional detail because these otherwise generalized arboreal climbers and jumpers have been modified to perform various, still further specialized functions.

Fruit and animal foods are combined in different ratios by all lemuriforms (Chivers *et al.* 1975). Few rely heavily on fruits and this may be due to competition, not only from diurnal birds and mammals but also from fruit bats, which are better adapted to seeking out all major sources of ripe fruits. Many lemuriforms eat tree exudates (gums) to a greater or lesser extent. These not only serve as a 'filler', permitting them to survive long periods of food shortage, but may also provide scarce nutrients. Some species appear to possess a special capacity to digest this low energy food (Smith

Diagrams of main socio-sexual interaction between Pottos *Perodicticus potto*.

Both sexes have richly innervated and super-sensitive neuchal spines, skin and genitalia in these chemically complex areas.

Above: Two ♂♂ (occasionally ♀♀) butt neck/shoulders.

Middle: Individuals confront passively. Potential for aggression or closer contact.

Below: 'Hugging' in which genitalia and associated glands are stimulated by neuchal spines: behaviours and morphology that are still a challenge to science.

& Montgomery 1959, Caton *et al.* 2000). Buffered by gums, many lemuriforms are well-adapted gleaners of marginal resources (both fruit and animal) in the face of much competition. Predation, mainly by diurnal and nocturnal raptors and arboreal carnivores, appears to be a major constraint on the ecological success of all prosimians.

Of special interest is apparent competitive exclusion between the Potto *Perodicticus potto* and the two greater galagos, Large-eared Greater Galago *Otolemur crassicaudatus* and Small-eared Greater Galago *Otolemur garnettii* (Butynski & De Jong 2007). The Potto is mainly an equatorial rainforest animal, while the two greater galagos occupy a wider range of forests and woodland habitats in eastern and southern Africa. This pattern broadly coincides with the centre-west/south-east divide discussed in Volume I, Chapter 6, pp. 79–84. In spite of these ecological and biogeographic differences there seems to be substantial coincidence in habitat and habits, and detailed comparative studies have yet to be made. Although primarily an equatorial forest group, a few galago species have adapted to acacia, commiphora and other dry-country bushlands and woodlands, including some in semi-temperate, southern latitudes. Their dependence on forests, woodlands and bush lands for food and shelter seems to have precluded them from crossing the desertic barriers that confine them to Africa. Thus, there are no extant lemuriforms on the Arabian Peninsula.

Jonathan Kingdon & Colin P. Groves

Infraorder LORISIFORMES – Lorisiforms: Lorises, Pottos, Galagos

Lorisiformes Gregory, 1915. Bull. Geol. Soc. Amer. 26: 436.

Lorisiformes, one of three infraorders within the Strepsirrhini, embraces 18 (described and named) species of galagos, family Galagidae, and ten or more lorises, family Lorisidae. Galagos are exclusively African, while the lorises includes at least seven Asiatic species. The divergence between African and Madagascan strepsirrhines is thought to be during the mid-Palaeocene, 60–70 mya (Pennisi 2007, Perelman *et al.* 2011).

The main characteristics of the Strepsirrhini are the shape of the external nose and the possession of a so-called ‘toilet-claw’ on the second digit of the foot, as described under suborder Strepsirrhini; also, in two of the three infraorders (Lemuriformes and Lorisiformes), but not in the third (Chiromyiformes), the possession of a dental comb, consisting of the lower incisors and canines. Lorisiformes are distinguished by the structure of the bony ear region; the tympanic ring is not enclosed in the auditory bulla as in the other two infraorders, but is at its mouth, while the bulla itself is divided into anterior and posterior chambers.

Asian lorises are distinguished from the African genera by a number of skull features, notably the more tubular orbits and the more marked prolongation of the tympanic ring into a tube. In Africa and in Asia there is a ‘fat genus’ (*Perodicticus*, *Nycticebus*) and a ‘thin genus’ (*Arctocebus*, *Loris*). The relative sizes and build of these two morphs involve dietary differences (the fat ones are more frugivorous, the thin ones more insectivorous), and aspects of the structure of the teeth converge accordingly. Characteristics separating loris and lemur groups were first listed by Gregory (1915) and Weber (1928) but Charles-Dominique & Martin (1970) noted that the course of the carotid artery and form of the orbit in lorises was shared with the Malagasy dwarf and mouse lemurs (Gheirogaleidae), raising issues about the monophyly of the Malagasy lemurs.

Colin P. Groves & Jonathan Kingdon

Superfamily LORISOIDEA – Lorisoids: Lorises, Pottos, Galagos

Lorisoidea Gray, 1821. London Medical Repository 15: 298.

There are two families of Lorisoidea in Africa: Lorisidae (containing *Perodicticus* and *Arctocebus*) and Galagidae (containing *Otolemur*, *Sciurocheirus*, *Galago*, *Euoticus* and *Galagoidea*). Groves (2001) placed these non-Malagasy strepsirrhines in their own infraorder, Loriformes (which, since Opinion 1995 was issued, must become Lorisiformes). In this volume the next highest rank (superfamily) is here recognized, which (again following Opinion 1995) is to be called Lorisoidea. The Lorisoidea differ from the Malagasy superfamilies Lemuroidea and Daubentonioidea primarily in the structure of the auditory bulla. In the Malagasy strepsirrhines the bulla is a simple globular structure, so large that it extends lateral to the tympanic ring, which is consequently incorporated into it. In the Lorisoidea, on the other hand, the bulla is smaller, with the tympanic ring at its mouth and forming a short

tube; and behind the bulla, the mastoid region and the bone medial to the bulla are noticeably inflated. The internal carotid system does not pass through the bulla; in this, the Lorisoidea are convergent with one of the Malagasy families (Cheirogaleidae), and in addition there is an arterial rete. Of the two families, the Galagidae are confined to Africa, whereas the Lorisidae have Asian representatives as well (although very different from the African genera). The Galagidae have hindlimbs that are much longer than the front limbs, large ears that project noticeably from the head, and long tails (>130 mm). The Lorisidae have limbs subequal in length, small ears that are mostly hidden by fur, and short tails (<130 mm).

Colin P. Groves

Family LORISIDAE
LORISIDS: LORISES, POTTO, ANGWANTIBOS

Lorisidae Gray, 1821. London Medical Repository 15: 298.

| | | |
|----------------------------------|-----------------------------|--------|
| <i>Perodicticus</i> (1? species) | Potto | p. 393 |
| <i>Arctocebus</i> (2 species) | Angwantibos (Golden Pottos) | p. 399 |

The African Lorisidae (subfamily Perodicticinae) embraces two established genera: *Perodicticus* for the Potto (which may eventually be shown to include more than one species) and *Arctocebus* for two accepted species of angwantibo. A third genus, *Pseudopotto*, has been proposed on the basis of skeletal remains of only two captive specimens. Opinions are sharply divided on its recognition, with Sarmiento (1998c) regarding the specimens as aberrant Pottos, while others (Bearder 1998, Groves 1998) regard the characteristics, as described, as being sufficiently distinctive to merit provisional recognition, while others (e.g. Grubb *et al.* 2003) regard recognition as premature, the course adopted here.

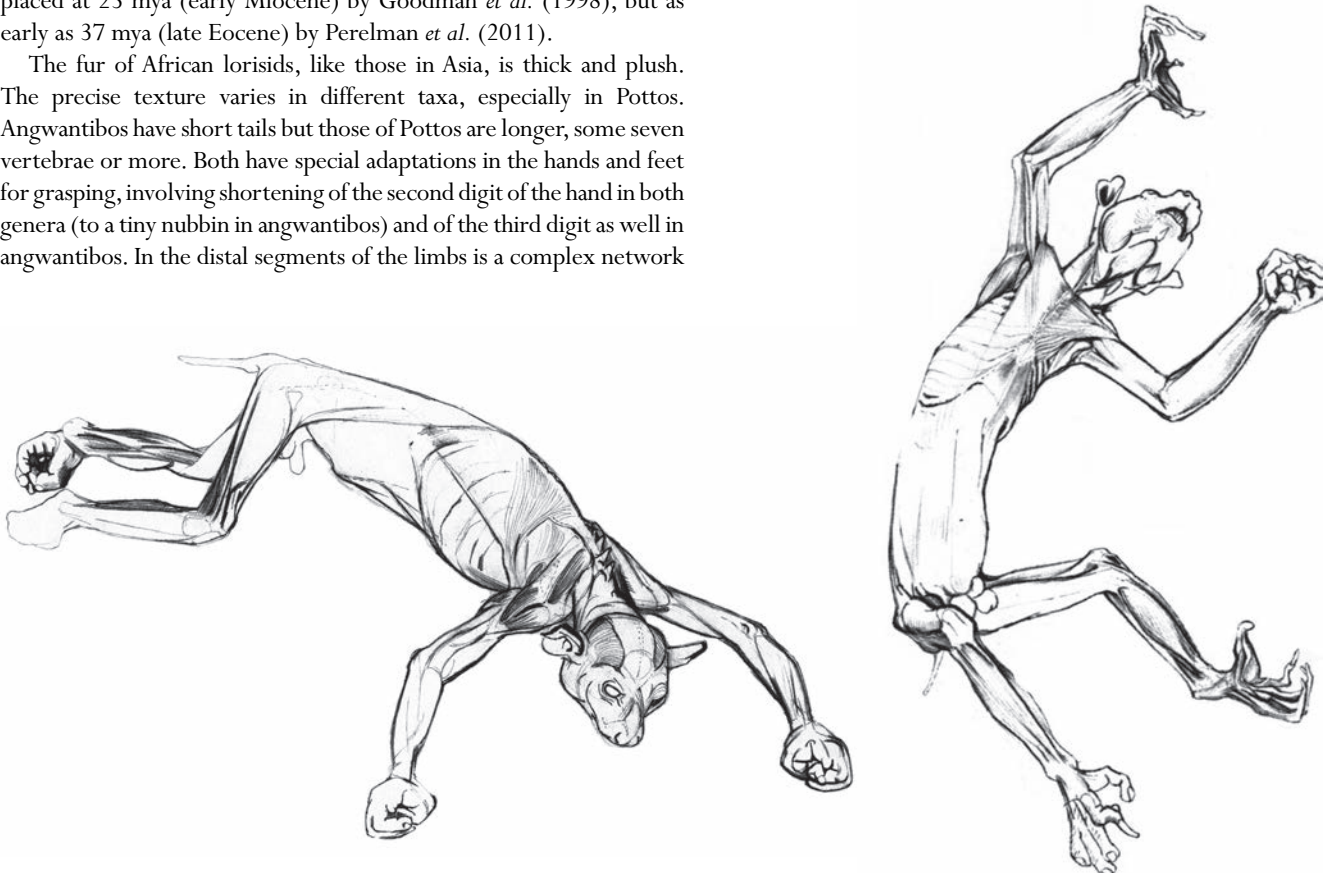

The African Lorisidae are restricted to the rainforest belt. Pottos occur throughout the zone, whereas angwantibos are restricted to west-central African region, between the Niger R. and Congo R., the region to which the primate genera *Sciurocheirus*, *Euoticus* and *Mandrillus* are likewise restricted. The diversity of African lorisids is about equivalent to that of those in Asia (subfamily Lorinae); reconsiderations of the taxonomy in both continents is gradually yielding evidence of more species than have customarily been recognized. The Lorisidae split to Perodicticinae and Lorisinae was placed at 23 mya (early Miocene) by Goodman *et al.* (1998), but as early as 37 mya (late Eocene) by Perelman *et al.* (2011).

The fur of African lorisids, like those in Asia, is thick and plush. The precise texture varies in different taxa, especially in Pottos. Angwantibos have short tails but those of Pottos are longer, some seven vertebrae or more. Both have special adaptations in the hands and feet for grasping, involving shortening of the second digit of the hand in both genera (to a tiny nubbin in angwantibos) and of the third digit as well in angwantibos. In the distal segments of the limbs is a complex network

of blood vessels called *rete mirabile*, in which exchange of arterial and venous blood enables the extremities to grip tightly on branches for long periods without fatigue. Indeed, the name ‘Potto’ derives from a Ghanaian name ‘Aposo’, which means ‘tenacious’ (Smeenck *et al.* 2006). Lorisids are enabled in this way to keep hold of branches and remain completely still, or move very slowly, or more quickly but with a gliding motion, which enables them to escape detection by potential predators and by animal prey alike. This contrasts markedly with the leaping and running of galagos.

Molecular data agree with anatomical data that phylogenetic relationships in the Lorisidae separate the two African genera in one clade from the two Asian genera in another. Thus, the evolution of a fat and a thin genus has proceeded independently on each continent. We follow Groves (2001, 2005c) and Grubb *et al.* (2003) in recognizing the following: Calabar Angwantibo *Arctocebus calabarensis*, Golden Angwantibo *Arctocebus aureus* and Potto *Perodicticus potto*. We think it highly likely that there are more than one species in *Perodicticus* (Oates 2011) and we defer judgement on the validity of *Pseudopotto martini*. The peculiarities of each genus are described in the appropriate profile.

Colin P. Groves & Thomas M. Butynski

Myology of Potto *Perodicticus potto*.

Subfamily PERODICTICINAE – African Lorises: Potto, Angwantibos (Golden Pottos)

Perodicticinae Gray, 1870. Catalogue of Monkeys, Lemurs and Fruit-eating Bats in the Collections of the British Museum, pp. 69, 93.

Potto *Perodicticus potto*.

Subfamily endemic to the moist forests of tropical Africa from Guinea (perhaps Guinea-Bissau) eastwards to C Kenya (Hill 1953, Wolfheim 1983, Jenkins 1987, Oates 1996a). Two genera (*Perodicticus* and *Arctocebus*) and three species recognized by most authorities (Groves 1993, Oates 1996a, Kingdon 1997, Grubb *et al.* 2003). In addition, Groves (1998, 2001, 2005c) provisionally recognizes the monotypic genus *Pseudopotto* and the Martin's False Potto *Pseudopotto martini* (Schwartz 1996). Molecular data indicate that the *Perodicticus*–*Arctocebus* split occurred during the early Miocene, about 20 mya (Perelman *et al.* 2011). Members of the Perodicticinae are characterized within Lorisidae by the absence of an index finger (*Arctocebus*) or by an index finger that is but a stump (*Perodicticus* and *Pseudopotto*).

Tooth formula $I^{2/2}, C^{1/1}, P^{3/3}, M^{3/3} = 36$. Three pairs of nipples (two axial, two pectoral, two abdominal (Hill 1953).

The holotype for the controversial *P. martini* is a partial skull and 'essentially' complete skeleton of an adult ♀ that lived in the Zurich Zoo and which is said to have originated in 'Equatorial Africa'. The only other specimen attributed to *P. martini* (Schwartz 1996) is represented

by a juvenile/subadult skull without a fully erupted dentition from Cameroon (exact locality unknown). The skeletal differences that Schwartz (1996) attributes to *Pseudopotto* are summarized by Groves (1998), Leon (2000) and Sarmiento (1998c). Sarmiento (1998c) examined the non-metric characters for *Pseudopotto* and found them to be prevalent in *Perodicticus* specimens obtained from localities well outside Cameroon. He concluded (p. 45) that, 'Schwartz (1996) does not present convincing data that merit the erection of a new genus or even a new species. All of the data that could be tested indicate that *Pseudopotto* does not differ in any significant manner from *P. potto*.' Grubb *et al.* (2003) also rejected *Pseudopotto* based on current evidence. Despite searches in the forests of Cameroon, no *Pseudopotto* have been located (E. Pimley pers. comm.). This work follows Groves (1993), Oates (1996a, 2011), Kingdon (1997) and Grubb *et al.* (2003) in recognizing but two genera (*Perodicticus* and *Arctocebus*) within Perodicticinae.

Thomas M. Butynski

GENUS *Perodicticus*

Potto

Perodicticus Bennett, 1831. Proc. Zool. Soc. Lond. 1830: 109 [1831].

Genus presumed to be monotypic. Endemic to tropical Africa in moist forest from Guinea (perhaps Guinea-Bissau) eastwards to C Kenya (Hill 1953, Jenkins 1987, Wolfheim 1983, Groves 1993, 2001, 2005c, Oates 1996a, 2011, Kingdon 1997, Butynski & De Jong 2007). There may be more than one species within *Perodicticus* as there is considerable morphological variation among the four to six 'subspecies' (Elliot 1913a, Schwarz 1931b, Hill 1953, Jenkins 1987, Schwartz & Beutel 1995, Groves 2001, Grubb *et al.* 2003, Stump 2005, Butynski & De Jong 2007). Indeed, Oates (2011) recognizes three species. Genus readily distinguished from the one other genus in Perodicticinae (i.e. *Arctocebus*) by a premaxillary that is not elongated, by larger size (HB 290–410 mm vs. <270 mm for *Arctocebus*; T 37–130 mm vs. <15 mm for *Arctocebus*; WT 600–1900 g vs. <325 g for *Arctocebus*), by the presence of a tail and an (intact) third digit, and by long spinous processes ('nuchal' or 'apophyseal' spines) on 3–6 thoracic and cervical vertebrae capped by tubercles that project above the level of the muscles (Elliot 1913a, Schwarz 1931b, Hill 1953, Jenkins 1987, Kingdon 1997). Other characteristics of *Perodicticus* given in the *P. potto* profile.

Thomas M. Butynski

Position of nuchal spines on a Potto *Perodicticus potto* in defensive position.

Perodicticus potto POTTO

Fr. Potto; Ger. Potto

Perodicticus potto (Müller, 1776). In Linnaeus, Vollstrand Natursyst. Suppl., p. 12. Elmina, Gold Coast [Ghana].

Taxonomy Polytypic species. Following Schwarz (1931b), Jenkins (1987), Groves (2001, 2005c) and Grubb *et al.* (2003), one species of Potto is recognized here. Schwarz & Beutel (1995), Groves (2001), Grubb *et al.* (2003) and Stump (2005) suggest that there may be several species here, particularly within *P. p. edwardsi* (Butynski & De Jong 2007). Indeed, recent mitochondrial DNA data indicate that *potto*, *edwardsi* and *ibeanus* might deserve species designation (C. Roos pers. comm.). This is supported by marked differences in body size and skull morphology (Stump 2005, Ravosa 2007). Although Hill (1953), Napier & Napier (1967) and Petter & Petter-Rousseaux (1979) recognize five subspecies, Schwarz (1931b) recognizes four subspecies. More recent taxonomies (Jenkins 1987, Groves 2001, Grubb *et al.* 2003) recognize three subspecies: *potto*, *edwardsi* and *ibeanus*. Oates (2011) treats these as full species. Recently, an additional subspecies has been described, *stockleyi*. Synonyms: *arrhenii*, *batesi*, *bosmannii*, *edwardsi*, *faustus*, *geoffroyi*, *guineensis*, *ibeanus*, *ju-ju*, *nebulosus*, *stockleyi*. Chromosome number: $2n = 62$ (Bender & Chu 1963).

Potto *Perodicticus potto*.

Potto *Perodicticus potto* adult male.

Description Largest loriscid (1.1–1.6 kg). Slow-moving, hunched, quadrupedal climber with thick, woolly pelage. Sexes similar in size and colour. Head round. Muzzle short, robust, overhanging shallow lower jaw. Eyes protuberant, golden-brown. Ears thickened, small, rounded, naked. Nape with thick skin under dense fur (that often has patch of dense, long vibrissae). Body and limbs long and slender, but this not obvious due to the thick fur and typical hunched posture. Pelage of dorsum and outer limbs ranging from blackish to grey to brownish to cinnamon, depending on subspecies. Chin, ventrum and inside of limbs pale grey. Hands and feet with opposable spatulate thumbs and flat nails, except for second digit of hindfoot, which has a grooming claw. Index finger reduced to rudimentary knob. Large scrotum of adult ♂♂ and vulval labia of adult ♀♀ are globular with chequered surface colouring. Long spinal processes on cervical vertebrae 3–9 project above the muscles and are capped by horny tubercles. Pottos born with a white pelage and blue eyes; pelage becomes greyer with age (Cowgill 1969).

Geographic Variation

P. p. edwardsi Central Potto. Western central Africa. Lower Niger R., Nigeria, south-east to Congo R. and Ubangi R., Central African Republic, to south of Congo R., DR Congo, where limit is unknown. Largest subspecies (ca. 1200 g). Dorsum grey or cinnamon-brown to mahogany-brown. Tail relatively short. Skull length: mean 65.8 mm (63.1–68.0, $n = 44$; Schwarz 1931b). Large teeth: upper tooththrow (C–M³): mean 22.9 mm (21.7–24.3, $n = 44$; Schwarz 1931b). P₃ usually higher than P₄ (Groves 2001). A smaller form of *P. p. edwardsi* is found in the Congo Basin (formerly termed *P. p. faustus* (Schwarz 1931b, Jenkins 1987). Synonyms: *batesi*, *faustus*.

P. p. ibeanus Eastern Potto. Central Africa and East Africa. East and south of the Ubangi R., and north and east of Congo R., DR Congo, eastward through Burundi, Rwanda and Uganda to at least the Kakamega-Nandi Forest region, W Kenya. Extent of occurrence estimated at roughly 850,000 km² (Butynski & De Jong 2007). Intermediate in size (ca. 1000 g). Dorsum with tripartite colour pattern; head and forelimbs light brown, shoulders blackish, hindquarters grey to reddish-brown. Dorsum exceptionally thick,

long and woolly. Skull length: mean 63.9 mm (60.0–66.7, $n = 34$; Schwarz 1931b). Small teeth, with upper tooththrow (C–M³): mean 20.8 mm (19.2–22.5, $n = 34$; Schwarz 1931b). P₃ higher than P₄ (Groves 2001). Synonyms: *arrhenii*, *nebulosus*.

P. p. potto Western Potto. West Africa, S Senegal east to Niger R., Nigeria (Grubb *et al.*, Oates 2011). Smallest form (ca. 800 g). Dorsum reddish-brown with dark spinal stripe. Tail relatively long. Skull length: mean 61.4 mm (60.5–63.3, $n = 6$; Schwarz 1931b). Small teeth, with upper tooththrow (C–M³): mean 20.0 mm (18.1–21.3, $n = 6$; Schwarz 1931b). P₃ lower than P₄ (Groves 2001). A larger form (previously termed *P. p. ju-ju*) occurs between Volta R. and Niger R. (Schwarz 1931b, Jenkins 1987, Oates 2011, E. Pimley pers. obs.). Synonyms: *bosmannii*, *geoffroyi*, *guineensis*, *ju-ju*.

P. p. stockleyi Mount Kenya Potto. Known only from one specimen obtained on Mt Kenya, C Kenya. About 210 km from the nearest known other population of *P. potto*. Dorsum cinnamon to dark russet with short (ca. 14 mm) hairs. Vibrissae on dorsum short (ca. 14 mm). Second digit of hand relatively long (6 mm). Tail relatively long (>96 mm; >31% of head+body length; Butynski & De Jong 2007). Synonyms: none.

Similar Species

Arctocebus aureus. Sympatric with *P. p. edwardsi*. South of Sanaga R., Cameroon, south to Congo R., Congo. Much smaller (150–250 g) than Potto. Second digit of hand absent and third digit greatly reduced.

Arctocebus calabarensis. Sympatric with *P. p. potto*. Between Niger R., Nigeria, and Sanaga R., Cameroon. Much smaller (270–325 g) than Potto. Second digit of hand absent and third digit greatly reduced.

Distribution Endemic to Equatorial Africa. Rainforest and Afromontane–Afroalpine BZs. Upper Guinea to about 00°18' N, 37°19' E in C Kenya, south to at least 08° S in DR Congo. There are reports of Pottos for Gambia, Senegal and Guinea-Bissau, but these need confirmation (Hill 1953, Jewell & Oates 1969b; McGrew *et al.* 1978, Petter & Petter-Rousseaux 1979, Wolfheim 1983, Jenkins

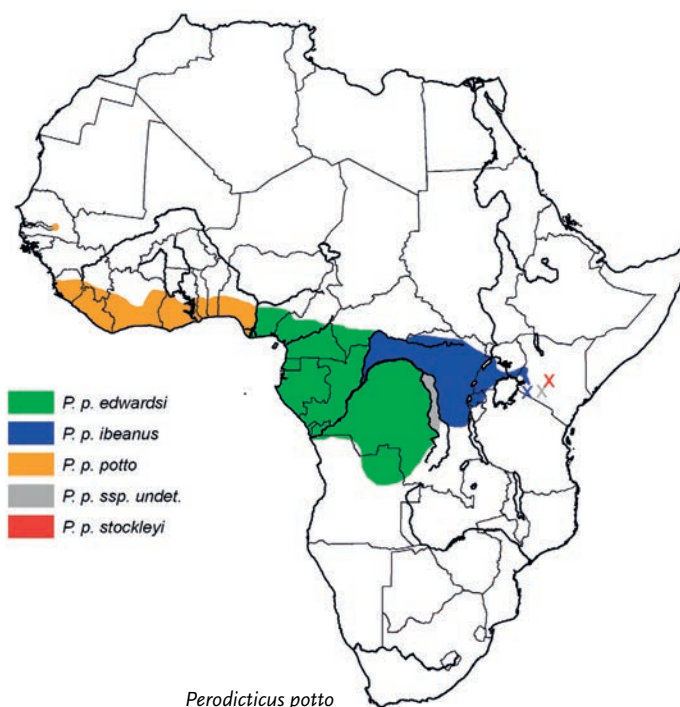

Lateral, palatal and dorsal views of skull of Potto *Perodicticus potto* adult male.

1987, Groves 2001, Grubb *et al.* 2003). See 'Geographic Variation'.

Habitat Swamp, lowland, mid-altitude, montane and riverine forest, coastal scrub, woodland and plantation from 0 to >30 m above ground. Most common in secondary, colonizing forest, flooded primary forest, riverine forest and forest edge (Kingdon 1971, Charles-Dominique 1977, Wolfheim 1983, Oates 1984, Pimley 2002). In Cameroon, most frequently (47% of 8334 observations) at 6–10 m with 32% of observations at 11–15 m (Pimley 2002). Prefers canopy at 5–30 m in C Gabon (Charles-Dominique 1977). *Perodicticus p. edwardsi* occurs from near sea level to at least 1500 m in SW Cameroon (E. Pimley pers. obs.). *Perodicticus p. ibeanus* occurs from 600 to 2300 m (Butynski & De Jong 2007). Mean annual rainfall over the geographic range of *P. p. ibeanus* ranges from ca. 1300 mm to 2000 mm (Butynski & De Jong 2007). For the species as a whole, the approximate limits for rainfall and temperature are 1000–5000 mm and 22–34 °C, respectively (Times Atlas 1975).

Abundance Density averages 8–10 ind/km² (up to 28 in flooded forest) at Makokou, C Gabon (Charles-Dominique 1977). Highest densities occur in flooded primary and riverine forest. Density 4.7 ind/km² in mixed secondary forest and farm bush on Mt Kupé, SW Cameroon (n = 13) (Pimley 2002). In Kibale N. P., SW Uganda, Weisenseel *et al.* (1993) estimate 1.8 ind/km² in selectively logged forest and 17.7 ind/km² in unlogged forest. In contrast, Off (2003), also in Kibale N. P., never encountered Potto in unlogged forest but obtained an estimate of 11.7 ind/km² in logged forest. Encounter rates for several other sites presented in Butynski & De Jong (2007).

Perodicticus potto

Adaptations Nocturnal and arboreal. Reflective tapetum in eye facilitates night vision. Basal metabolic rate (36–40 kcal/day/kg^{0.75}), approximately half that expected for a mammal of this body size (Pollock 1986). Potto has larger brain size than predicted from low metabolic rate. Spines of cervical vertebrae, together with the compact mass of muscle and thick skin of shoulder and neck, form a protective 'scapular shield'. The Potto faces the predator, grips a branch with hands and feet, and tucks the head into the chest to present the scapular shield, accompanied by long touch-sensitive guard hairs. Swinging backwards or sideways from this position, the Potto makes threat 'grunts'. The animal also thrusts forward in attempts to dislodge the predator. A highly agitated Potto will suddenly lunge at a predator by uncoiling the back and striking out with an open mouth or butting with the scapular shield (Charles-Dominique 1977, E. Pimley pers. obs.).

The low vertebral spines of the thorax may increase flexibility, facilitating the Potto's characteristic lateral spinal movement (Kingdon 1971). Such movements enable Pottos to bridge gaps in the canopy and search for fruit clusters while remaining suspended in one spot. Pottos sleep in dense foliage and do not build nests. They use tree-holes in Uganda (Bearder *et al.* 2003). The powerful grip of the Potto, and its ability to remain motionless and silent for long periods, are facilitated by a multi-branched arterial and venous system in the limbs (Suckling *et al.* 1969). Charles-Dominique (1977) found that a 1 kg Potto could support 15 times its body weight suspended underneath it.

Foraging and Food Omnivorous. Pottos forage mainly in the canopy, but also at lower levels and on the ground. Foraging occurs intermittently throughout the night from ca. 1 h after sunset to ca. 1 h before sunrise (E. Pimley pers. obs.). Pottos in C Gabon only became active under full night-time conditions (<20 lux) (Charles-Dominique 1977). In SW Cameroon, Potto ♂♂ travel (i.e. horizontal + vertical travel) an average of 2811 m/night (1330–

OPPOSITE: Potto *Perodicticus potto*.

6440, $n = 6$ animals), while ♀♀ travel an average 707 m/night (951–3290 m, $n = 4$ animals) (Pimley 2002).

Pottos eat ripe fruit and nectaries of banana trees (*Musa* spp.). The Potto peels the flower petals from nectaries to consume nectar and resident insects, while holding the remaining flower in both hands. Pottos frequently move along branches and trunks with their noses and body close to the substrate, sometimes licking up ants or other small invertebrates from the bark (Pimley 2002). This enables effective location of ants, slow-moving invertebrates and gum (Oates 1984). Pottos occasionally forage among Oil Palms *Elaeis guineensis*, presumably for beetles and their larvae (Pimley 2002). Pottos use their teeth and pointed, cornified, tongue, to extract giant West African Land Snails *Achatina achatina* from their shells. For the smaller snails (<8 cm), they hold the shell in one hand, and for the larger shells (>8 cm) both hands are used. Pottos catch moths opportunistically by sitting silently and motionless until a moth flies within arm's reach. The Potto follows the movement of the moth with its eyes, rapidly extends its arm to catch the moth in one hand, and feeds on the moth while it is firmly grasped in one hand (Pimley 2002).

In Uganda, 19 stomachs obtained over seven months held ca. 60% gum and ca. 30% insects. Here it appears gum is the main food during drier periods, and insects and fruit the main foods during wetter periods (Kingdon 1971). In C Gabon, stomach contents yielded 65% fruits, 21% gum and 10% insects (mostly ants) ($n = 41$) (Charles-Dominique 1977). Pottos eat insects that other primates find unpalatable, especially ants, which make up 65% of the invertebrate portion of the diet in C Gabon (Charles-Dominique 1977). Pottos eat the ripe fruits of a large number of plant species, including *Musanga cercopioides*, *Pseudospondias microcarpa*, *Cola longifolia*, *Saphradaceae allophylus*, *Musa* spp., *Peasea americana*, *Psidium guajava*, *Ficus* spp., *Parkia* sp., *Avoun* sp., *Uapaca* sp., *Myrianthus* sp., *Tabernaemontana* sp. and *Parinari* sp. Leaves of *Urera* sp. and gum of *Albizia* sp. and *Sterculia* sp. are eaten. They also eat moss, lichen, fungi, beetles, beetle larvae, caterpillars, locusts, grasshoppers, spiders, millipedes, centipedes, slugs, frogs, birds' eggs, small birds and young bats (Kingdon 1971, Charles-Dominique 1977, Oates 1984, Pimley 2002).

Social and Reproductive Behaviour Non-gregarious. Pottos in C Gabon spend 96% of the time alone and 4% of the time with conspecifics (<20 m apart, $n = 105$; Charles-Dominique 1977). In SW Cameroon, Pottos are within 20 m of conspecifics during 22% of observations ($n = 8334$; Pimley *et al.* 2005b). There is evidence of complex social networks among individuals constituting a dispersed form of social organization. Pottos in C Gabon sleep alone except for mothers with infants (Charles-Dominique 1977). By contrast, in SW Cameroon certain ♂♂ and ♀♀ 'pairs' were together 29% of the time ($n = 8334$ observations) and slept within 20 m of each other 26% of the time ($n = 43$). On one occasion a ♂ and ♀ were observed waking at the same site (Pimley *et al.* 2005b). Members of these 'pairs' were not observed in contact with other Pottos of the opposite sex. They have higher levels of association with each other than with other conspecifics. The only affiliative and sexual behaviour observed between members of the opposite sex was within these 'pairs'. Overlap of home-ranges between 'pairs' is not only spatial, as with neighbouring (unpaired) Pottos, but also temporal, with animals

overlapping each other's ranges at the same time. Interactions within the sexes are lower than between paired ♂♂ and ♀♀. Adult ♂ spend marginally more time within 20 m of a ♂ (1.5% of 8334 observations) than adult ♀♀ spend with other ♀♀ (0% of 8334 observations) (Pimley 2002).

In the montane forests of SW Cameroon, Pottos have a dispersed unimale–unifemale social system, where the ♂ and ♀ of a 'pair' forage alone but show affiliative interactions throughout the year, although not necessarily on a daily basis. This fact, the lack of sexual dimorphism, and the relatively small testes, imply a monogamous mating system in SW Cameroon (Pimley 2002, Pimley *et al.* 2005b). However, in the lowland forest of C Gabon, Pottos have a dispersed unimale–multifemale social system, where the ♂ patrols the home-ranges of one to three ♀♀ (Charles-Dominique 1977). Matriarchies are absent. Charles-Dominique (1977) assumed that Pottos have a polygynous mating system in C Gabon. Differences in the social arrangement of the Potto in C Gabon and SW Cameroon (both *P. p. edwardsi*) are most likely due to ecological differences between the two study sites.

In C Gabon, home-ranges of ♀♀ (mean 7.5 ha, 6–9, $n = 5$) are much smaller than of ♂♂ (mean 17.8 ha, 9–40, $n = 5$) (Charles-Dominique 1977). Home-ranges of ♂♂ and ♀♀ in SW Cameroon are of similar size (mean 31.5 ha, 13.1–44.1, $n = 4$ for ♀♀ and ♂♂ mean 30.6 ha, 19.1–34.2, $n = 6$; Pimley *et al.* 2005a). Home-ranges of one or two ♀♀ and their infant overlapped the territory of one ♂ in C Gabon (Charles-Dominique 1977), while in SW Cameroon the range of one ♂ overlapped extensively the range of one ♀ (mean overlap 68%, $n = 10$ home-ranges; Pimley 2002). Adults are sedentary, except for young ♂♂ at puberty, who have a dispersal stage (Charles-Dominique 1977). These ♂♂ are sexually mature, with testes similar in size to older, sedentary, ♂♂, but their body weight is less. Young adult ♀♀ remain in or near their natal home-ranges.

Much communication is by olfactory cues (urine marking and genital gland secretions) (Kingdon 1971, Charles-Dominique 1977, Pimley 2002). The Potto's method of moving close to branches with the nose down enables scent-marks of conspecifics to be easily located. This also allows for the marking of substrates while moving (Oates 1984). Vocal exchanges are limited (no alarm calls or loud-calls). Screams sometimes given when handled. Pottos in captivity with conspecifics make a high-pitched 'whistle' that seems to serve as a spacing mechanism when other Pottos come too near (E. Pimley pers. obs.). Cowgill *et al.* (1989) frequently observed cooperative behaviour (food-sharing, food-saving, paternal behaviour) among Pottos in captivity. This led them to suggest that such behaviours are part of the natural behavioural repertoire.

Direct scent-marking occurs between same-sex and different-sex pairs during allogrooming (Manley 1974, Charles-Dominique 1977, Pimley 2002). A ♂ scratches his scrotum with his hands, and transfers the secretion to the dorsal pelage of the ♀. Males and ♀♀ pass over the backs of their partner, transferring genital secretions. Scent-marking by the ♂ may inform conspecifics that the ♀ is associated with that ♂, thereby giving him preferential access to her (Gosling 1982). A ♂ updates his scent-marks during regular visits to a ♀. This might inform other ♂♂ of his physical condition and of his 'ownership' of the ♀. Such means of assessment avoid the costs of exerting dominance by threats or overt aggression (Gosling 1982).

Elaborated skin around scrotum of Potto *Perodicticus potto*.

Pimley (2002) observed copulations between Pottos in SW Cameroon. The ♂ and ♀ sit on a branch next to each other for several minutes and then sniff and groom each other's head and neck. The hands are then placed on the shoulder of the other Potto and each side of the face is sniffed and licked alternately for a few minutes. The ♂ then sniffs and licks the female's genitalia, and the ♀ sniffs and licks his genitalia. They then adopt a dorsal-ventral mating position, usually with the ♀ suspended from the underside of a branch and the ♂ suspended under the ♀. One incidence of mating on top of a branch was observed, with the ♂ on the female's back. Copulations last an average of 2.4 min (1–4, $n = 7$). After mating, the pair sit together grooming their own genitalia. The ♂ and ♀ remain within 20 m of each other for an average of 1.9 h (0.8–5.0 h, $n = 7$). Parturition occurs on a branch. Infant carried clinging to mother's ventrum until 3–4 months of age. After 3–8 days the infant is 'parked' among branches and lianas while the mother forages. She retrieves the infant before dawn when both infant and mother utter high-pitched 'tisc' contact calls. By 3–4 months the young Potto is constantly with its mother, either riding on her back or walking just behind (Charles-Dominique 1977).

Interactions between Pottos and other species are rarely observed in the wild (E. Pimley pers. obs.). In C Gabon, Pottos avoid competition with other frugivorous prosimians, such as Cross River Squirrel Galago *Sciurocheirus alleni cameronensis*, by utilizing the canopy to a greater extent (Pimley 2002). Pottos will displace fruit

bats feeding on the ripe fruits of the Umbrella Tree *M. cercopioides* while Two-spotted Palm Civets *Nandinia binotata* have feeding priority over Pottos (E. Pimley pers. obs.).

Reproduction and Population Structure In C Gabon, births ($n = 17$) occur Aug–Jan, inclusive (Charles-Dominique 1977). In contrast, Pottos in SW Cameroon appear not to have a birth season ($n = 4$) (Pimley 2002). Captive Pottos exhibited no seasonal oestrus (Cowgill *et al.* 1989). Oestrous cycle in captivity average 38 days (21–48, $n = 2$; Manley 1966). Gestation averages 197 days (194–205, $n = 5$) in captivity (Cowgill *et al.* 1989) and 193 days in the wild (Charles-Dominique 1977). Postpartum anoestrus of 1 month in SW Cameroon ($n = 1$; Pimley 2002). Inter-birth interval in C Gabon is 12–13 months (Charles-Dominique 1977). Single infant is born in wild populations ($n = 17$; Charles-Dominique 1977), although one case of twins in captivity (Cowgill 1974). Birth-weight for wild Pottos: mean 52 g ($n =$ not specified; Charles-Dominique 1977). Birth-weight for captive Pottos: mean 35 g (30–42, $n = 4$; Cowgill 1969). Weaned at 120–180 days (Charles-Dominique 1977).

In C Gabon offspring independent at 6–8 months ($n = 1$), although still living in the mother's home-range (Charles-Dominique 1977). Males leave mother's home-range at six months. Adult dentition complete by six months, adult body weight attained at 8–14 months, and full sexual maturity reached by 18 months (Charles-Dominique 1977). Sex ratio at birth 1 : 1 in free-ranging juvenile Pottos (Charles-Dominique 1977). Adult sex ratio female-biased in C Gabon, 1 : 1.9 ($n = 23$; Charles-Dominique 1977), but male-biased in SW Cameroon, 1 : 0.6 ($n = 11$; Pimley 2002). Pottos live 26 years in captivity (Bearder & Pitts 1987, Cowgill *et al.* 1989). Wild Pottos in C Gabon live to at least nine years ($n = 2$; Charles-Dominique 1977).

Predators, Parasites and Diseases Poorly known. Predators include Leopard *Panthera pardus* (Hoppe-Dominik 1984), Robust Chimpanzee *Pan troglodytes* (McGrew *et al.* 1978) and Two-spotted Palm Civet *Nandinia binotata* (Nekaris *et al.* 2007). Strong evidence for predation by Black-legged Mongoose *Bdeogale nigripes* (Charles-Dominique 1977). Monkeys (*Cercopithecus* spp., *Mandrillus* spp.), African Golden Cats *Profelis aurata*, Domestic Dogs, large owls *Bubo* spp. and large snakes are among the potential predators. Parasites include trypanosomes *Trypanosoma brucei gambiense* and filarial worms *Loa loa*, but no pathological symptoms observed (Pimley 2002).

Conservation IUCN Category (2012): Least Concern. *P. p. stockleyi* is Data Deficient. CITES (2012): Appendix II.

Widespread in secondary and primary forests, and in severely disturbed forest near human habitation. Main threat is habitat loss due to clear-cutting and intensive agriculture. Eaten by humans in West Africa and central Africa. Extirpated from large parts of its range (Wolfheim 1983). *P. p. stockleyi* only known from one specimen. Preliminary surveys of Mt Kenya and the Aberdares Range have failed to locate additional individuals. Additional surveys are needed in order to determine the distribution and abundance of this subspecies (Butynski & De Jong 2007).

Key References Butynski & De Jong 2007; Charles-Dominique 1977; Jenkins 1987; Kingdon 1971; Oates 1984, 2011; Pimley 2002; Pimley *et al.* 2005a, b.**Elizabeth R. Pimley & Simon K. Bearder****GENUS *Arctocebus*****Angwantibos (Golden Pottos)***Arctocebus* Gray, 1863. Proc. Zool. Soc. Lond. 1863: 150.

The angwantibos, *Arctocebus*, comprise two allopatric species: Calabar Angwantibo *A. calabarensis* and Golden Angwantibo *A. aureus*. Both are confined to forest in the Bight of Biafra, between the Niger R. and Congo R. They are typically confined to areas of dense, liana-rich, undergrowth in primary, secondary and coastal forests that receive high rainfall.

Angwantibos are small, relatively short-limbed and slow-moving, woolly-coated nocturnal primates with short ears, moderately large eyes, narrow pointed muzzles and vestigial (short) tails. The wrists are extremely narrow. Both the third digit and, especially, the second digit of the hand are greatly reduced, specializations in which they resemble *Perodicticus* but even more extreme. There is a grooming claw on the somewhat shortened second digit of the foot. Olfaction appears to be of exceptional importance to both species.

Although bearing some general resemblance with the more robust, longer-tailed Potto *Perodicticus potto*, Angwantibos are much smaller (<325 g to the Potto's >800 g) and have the merest vestiges of a tail (<15 mm vs. >40 mm for Potto). Angwantibos have a more gracile skull with slender zygomatic arches, a more slender rostrum, and a longer, more pointed premaxilla; P⁴ is more molariform, there is a paraconid shelf on P₄, the lower molars have buccal cingulids and M³ is relatively large.

Although De Winton (1902) described *A. aureus* as a new species, Schwarz (1931b) treated this genus as monotypic, despite accurately listing many of the numerous craniodental differences between

them. General recognition of the existence of two species came later (Maier 1980). Following Schwarz (1931b), Jenkins (1987) and C. P. Groves (pers. obs.), the two species may be diagnosed as follows:

Arctocebus calabarensis. Between Niger R., Nigeria, and Sanaga R., Cameroon. Slightly larger, nasals relatively longer, width across orbits less than that across zygomata, premaxillary elongation not extreme, nasal aperture wider than high. Upper incisors relatively robust, with only a narrow gap between them, P² and P₃ crowns somewhat elongated, no buccal cingulum on upper cheekteeth. Dorsum pale tan brown, or buff, often with yellowish or orange tinge. Ventrums whitish or light grey.

Arctocebus aureus. South of Sanaga R., Cameroon, south to Congo R., Congo. Slightly smaller, nasals shorter, orbital rims expanded so that width across orbits is about equal to that across zygomata, greater elongation of premaxilla, nasal aperture higher than wide. Upper incisors tiny, only half the height of canines, with a wide gap between them, P² and P₃ not raised above occlusal plane of other cheekteeth, buccal cingulum present. Dorsum reddish-gold or russet. Ventrums cream, grey or reddish-buff.

The boundary between the two species is probably the Sanaga R., *A. calabarensis* to the north and north-west and *A. aureus* to the south.

Colin P. Groves & Jonathan Kingdon

Arctocebus calabarensis CALABAR ANGWANTIBO (NORTHERN GOLDEN POTTO)

Fr. Potto de Calabar; Ger. Gewöhnlicher Bärenmaki

Arctocebus calabarensis (J. A. Smith, 1860). Proc. Roy. Phys. Soc. Edinburgh 2: 177. Old Calabar, Nigeria.Calabar Angwantibo *Arctocebus calabarensis* adult.*Arctocebus calabarensis*

Taxonomy Monotypic species. Formerly considered one species with two subspecies: Calabar Angwantibo *A. c. calabarensis* and Golden Angwantibo *A. c. aureus*. 'Angwantibo' is the name of this primate in the Ibibio language (Nigeria). Synonyms: none. Chromosome number: $2n = 52$ (Stanyon *et al.* 1992).

Description Small, woolly, slow-moving climber with vestigial tail and pale tan-brown to yellowish-brown dorsal pelage. Sexes alike in size and colour. Muzzle pointed, projecting beyond the lower jaw. Nasal aperture wider than high. Eyes large. Circumocular pattern absent. Ears small, rounded, narrow and naked. Dorsal pelage pale tan-brown, orange-brown, buff or yellowish-brown. Dorsal guard hairs with brown or golden tips. Ventral pelage white, light grey or buff. Tail tip without dark hairs. Second digit of hand absent and third digit greatly reduced. Incisors about two-thirds canine height, with narrow diastema between them. Cheekteeth without buccal cingulum. Biorbital width less than bizygomatic. Nasals ca. 30% of skull length (Schwarz 1931b, Sanderson 1940, Hill 1953, Jenkins 1987, Kingdon 1997, Groves 2001). Infants woollier and more muted in colouring but otherwise resemble adults.

Geographic Variation None recorded.

Similar Species

Arctocebus aureus. Parapatric. South of Sanaga R., Cameroon. Smaller (<270 g). Nasal aperture higher than wide. Dorsal pelage reddish-gold or russet. Tail tip with dark, stiff hairs. Incisors pin-shaped, half canine height, with wide gap between them (Schwarz 1931b, Hill 1953, Jenkins, 1987, Groves 2001).

Perodicticus potto. Sympatric. Appreciably larger (>600 g) with shorter muzzle and longer tail (>40 mm). Third digit present on hands. Neuchal area has long, black vibrissae and spinal processes of cervical vertebrae project above muscles.

Distribution Endemic to West Africa and western central Africa. Rainforest BZ. North to Benue R. and west to Niger R. in S Nigeria, and south to Sanaga R., SW Cameroon. Distribution patchy (Oates & Jewell 1967, Hill & Meester 1977).

Habitat Low to medium-altitude evergreen forest and sub-montane forest. In Nigeria most commonly encountered below 3 m in dense undergrowth of young secondary forest and forest edge where lianas and vines are abundant. Also in forest patches in the derived savanna zone (Jewell & Oates 1969b). In old, closed forest at Korup, Cameroon, below 5 m at forest edge and in tree-fall zones (Bearder & Honess 1992). Known from sea level to 400 m, in a region where mean daily temperature ranges from ca. 25–29 °C, depending on time of year. Across the species' range, mean annual rainfall ranges from 1500 to 4000 mm; in the wettest part of this area, near the coast, there is a Dec–Feb dry season (<50 mm rainfall/month); farther north, however, the dry season may begin in Nov and extend through Mar.

Abundance Can be common in the forest-farm bush-derived savanna mosaic of SE Nigeria, where it was encountered on 27 occasions during 48 night-walks each of 800 m (0.70 encounters/km; Jewell & Oates 1969b). At most other locations, difficult to locate and only infrequently observed.

Lateral, palatal and dorsal views of skull of Calabar Angwantibo *Arctocebus calabarensis* adult.

Adaptations Nocturnal and arboreal. Cryptic, usually moves in a slow, gliding fashion on small branches, twigs and climbers, but can move more rapidly during social interactions or if threatened. Will travel on the ground (Jewell & Oates 1969b, Bearder & Honess 1992). When threatened, can adopt a defence posture in which the back is hunched and head is withdrawn between the arms. Often rocks up and down in this position with its mouth open. If a predator attempts to touch the animal it will be bitten as the *A. calabarensis* lunges with its head beneath the arm-pit (Jewell & Oates 1969b).

Arctocebus calabarensis has poor eyesight and relies mainly on olfaction and hearing for food location and communication. They sleep by day in an upright position in dense vegetation where protected from sun, wind, rain and predators. Although Sanderson (1940) claimed that they sleep suspended from horizontal branches, this was never observed in captive animals in Nigeria.

Foraging and Food Insectivorous. Forages mostly in the undergrowth for invertebrates and fruit. Soft-bodied insects and grubs are preferred (Sanderson 1940). Recently captured *A. calabarensis* in Nigeria ate orthopterans, mantids, beetles and snails (Jewell & Oates 1969b). Based on what is known of the diet of *Arctocebus aureus* (Charles-Dominique 1977), it is likely that caterpillars are also an important part of the diet of *A. calabarensis*.

Social and Reproductive Behaviour Solitary. Not very vocal, relying mainly on scent-marking for communication. Vocal repertoire

Myology of Calabar Angwantibo *Arctocebus calabarensis*.

not studied, but when threatened produces 'hissing' calls (J. Oates pers. obs.). Use a high-pitched 'clicking' call for contact. Adult ♂ ♂ fight if placed together in captivity (Jewell & Oates 1969b). Young carried clinging to the fur or 'parked' while the mother forages. Previous offspring probably rejected on the birth of the next, since ♀ ♀ not observed with more than one young (Jewell & Oates 1969a).

Reproduction and Population Structure Births occur throughout the year in SE Nigeria. Births most common Jan–Apr (mid-dry season to early wet season). The following data on reproduction derive from a study of captives. In two cases, gestation estimated to be 131 and 132 days. Litter-size is one. Birth-weight of one captive was 37 g. Weaned at ca. 3.5 months. Minimum inter-birth interval ca. 4.5 months. Two young can be produced in one year. Sexual maturity at ca. 9–10 months. Oestrous cycle 36–45 days (Jewell & Oates 1969a). Few data available on population sex ratio, but of 13 young brought to Nsukka Zoo, seven were ♂ ♂ and seven were ♀ ♀; of 12 adults brought to the Zoo, two were ♂ ♂ and ten were ♀ ♀ (Jewell & Oates 1969a). Live in captivity to at least 13 years of age (Jones 1982).

Predators, Parasites and Diseases No information, but potential predators include genets *Genetta* spp., Two-spotted Palm Civet *Nandinia binotata*, Central African Linsang *Poiana richardsoni*, cats, monkeys, large owls *Bubo* spp. and large snakes.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II. Occurs in a limited geographical area, but in the 1960s *A. calabarensis* flourished in a mosaic landscape in Nigeria that had a high human population density. Despite their small body size they are captured for human consumption in Nigeria (Jewell & Oates 1969b).

darker. Ears small, rounded and naked. Dorsum reddish-gold or russet. Guard hairs on back, shoulders and haunches fine with light, crinkled tips that give a frosted appearance. Limbs slender and of about equal length. Ventral pelage cream, greyish or reddish-buff. Tail very short with dark, stiff hairs on tip. Second digit of hand absent and third digit greatly reduced. Incisors pin-shaped, half canine height, with wide gap between them. Juvenile darker than adult (Schwarz 1931b, Hill 1953, Jenkins 1987, Schwartz & Beutel 1995, Kingdon 1997).

Taxonomy Monotypic species. Originally considered a subspecies of Calabar Angwantibo *Arctocebus calabarensis*. Sanderson (1940) thought this taxon should be a distinct species and described as such by Maier (1980). Synonym: *ruficeps*. Chromosome number: not known.

Description Small, woolly, slow-moving climber with hunched body, vestigial tail and reddish-gold or russet dorsum. Sexes alike in size and colour. Nose pointed, projecting beyond lower jaw. Nostrils sculpted. Nasal aperture higher than wide. Circumocular pelage

Geographic Variation None recorded.

Similar Species

Arctocebus calabarensis. Parapatric at Sanaga R. SE Nigeria and SW Cameroon north of Sanaga R. Larger (>270 g). Dorsum pale tan-brown, yellowish-brown, buff or fawn. Tail lacks dark hairs. Nasal aperture wider than high. Incisors about two-thirds of canine height, with narrow diastema between them (Schwarz 1931b, Hill 1953, Jenkins 1987, Kingdon 1997, Groves 2001).

Perodicticus potto edwardsi. Sympatric. Much larger (>600 g) with shorter muzzle and longer tail (>40 mm). Third digit of hand present. Neuchal area has long, black vibrissae and spinal processes of cervical vertebrae project above muscles.

Distribution Rainforest BZ. Endemic to western central Africa. Cameroon south of Sanaga R., through Equatorial Guinea (Rio Muni), Gabon and Congo, south to Congo R. Eastwards through Congo to at least Congo R. and Ubangui R. Reported present in W DR Congo to 20° E, but this needs confirmation. Widespread but patchy distribution (Wolfheim 1983).

Habitat Low to medium altitude moist primary and secondary forest. Prefers old tree-fall zones rich in young lianas and where regenerating vegetation is dense (Charles-Dominique 1977).

Abundance Rare to abundant. In C Gabon, 2 ind/km² in forest, but average density about 7 ind/km² in patches of more suitable habitat. Highest density reported is 18 ind/km² (Charles-Dominique 1971, 1974, 1977).

Adaptations Nocturnal and arboreal. Minimizes energy expenditure. *Arctocebus aureus* moves slowly, relying on crypsis, but when disturbed moves quickly to nearest clump of dense vegetation. Adopts a defence posture when threatened. Standing on widely spaced, rigid, fully extended limbs, the head is tucked on the chest with the open mouth beneath an arm-pit. The dark hairs on the tail are raised to form a circle around a pale zone formed by the tail tuft, thus making this the only conspicuous area of the body. A predator touching the tail or hindquarters is bitten by the sharp canines as the animal quickly lunges with its head beneath the arm-pit. If grasped when off the ground, it rolls into a ball and remains attached to a branch. Sometimes drop to the ground when disturbed (Charles-Dominique 1977).

Eyesight is poor but sense of smell good. Relies on scent-marking. Large vertical branches not used since hands and feet adapted only to close around stems <6 cm diameter. Sleeps in dense tangles of vegetation where protected from sun, wind, rain and predators (Charles-Dominique 1977, Kingdon 1997).

Foraging and Food Insectivorous. Usually in the undergrowth at <5 m, but occasionally to 15 m. Often moves to the ground to feed. Hunts in undergrowth, where prey are located primarily by scent. In C Gabon, 85% of diet is insects, 14% is fruit and 1% is wood fibre. Most common prey are caterpillars (65%) and beetles (20%). Also eats crickets, flies and ants (Charles-Dominique 1974, 1977). Smaller prey captured with the hands and transferred directly to the mouth, while larger prey are first held down and killed by biting. Will hold a caterpillar in its mouth by the head while wiping its hands along the caterpillar's body for up to 20 seconds to remove irritating hairs (Charles-Dominique 1977). One captive in S Gabon refused fruit but accepted all insect species offered. These insects were caught with rapid movements of the hands (L. Ambrose pers. obs.).

Social and Reproductive Behaviour Solitary. In C Gabon, *A. aureus* forages alone 98% of the time and in pairs 2% of the time. Animals sleep singly except for mother with infant. Employs 'deferred communication' by means of urine-marking and secretions from

Lateral view of skull of Golden Angwantibo *Arctocebus aureus* adult.

genital glands. This enables the ♂ to detect the approach of oestrus in the ♀. Parturition takes place on a branch. Neonate clings to the fur of the mother's abdomen. From 3 to 8 days after birth, foraging mothers 'park' their infants under a branch. Infants carried dorsally when older. Adult male's range overlaps ranges of several ♀♀ (Charles-Dominique 1977). Rarely vocalizes. Vocalizations are a 'tsic' for mother-infant contact, a deep two-phase 'groan' (inhalation, exhalation) for threat, and a 'wheet' for distress (Charles-Dominique 1977).

Reproduction and Population Structure In C Gabon births occur throughout the year, with the fewest Jun–Aug (dry season). Litter-size is one. Twins not reported. Inter-birth interval is 4–5 months. Mating follows birth without a break (Charles-Dominique 1977). Females can breed more than once a year, allowing a rapid rate of increase suited to exploiting temporary tree-fall zones (Charles-Dominique 1966). In captivity, gestation is 131–136 days (Manley 1967). Birth-weight is 24–30 g. Young are weaned at 100–130 days. Adult weight attained at 8–9 months. Sexual maturity reached at about 9–10 months. Sex ratio at birth, and among adults, is 1 : 1 (Charles-Dominique 1977). Longevity not known.

Predators, Parasites and Diseases No information, but probable predators include genets *Genetta* spp., Two-spotted Palm Civet *Nandinia binotata*, Central African Linsang *Poiana richardsoni*, cats, owls *Bubo* spp. and large snakes.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Has a fairly restricted range with patchy distribution and is not found at high densities. Too cryptic to be at risk from hunting by humans. Main threat is habitat loss.

Southern Lesser Galago *Galago moholi*.

Polygeneric family found throughout sub-Saharan Africa, except for the south-west and extreme south, inhabiting bushlands and woodlands in S and NE Africa as well as tropical and sub-tropical forests. Recently five genera and 24 species have been recognized (Grubb *et al.* 2003, Nekaris & Bearder 2011), five of which had yet to be formally described and named. The taxonomy presented here is more conservative, recognizing 18 species, while acknowledging that several species likely await discovery.

Jenkins (1987) and Kingdon (1997) characterize the galagos (also known as ‘bushbabies’) as long-tailed, woolly, nocturnal and mainly arboreal primates with long hindlegs and elongated bases to the feet (tarsi). The head is rounded, with forward-facing eyes and large, naked ears that retract into compact, folded structures. The moist nose is at the end of a pointed muzzle. The neck is very flexible. The brain case is broader than in Lorisidae and there is no sagittal crest. The orbits are farther apart and less upwardly inclined than in Lorisidae. The bullae are strongly inflated. The mandible has a slender horizontal ramus. The upper incisors are peg-like and subequal in size with a conspicuous central gap; in the upper dentition, the posterior premolar is molariform and the molars have prominent cusps and well-developed talons. Lower incisors and canines are modified to form a comb-like structure. A toothed pseudo-tongue, which serves as a specialized ‘comb’ cleaner, is situated between the tongue and the floor of the mouth.

The limbs are modified for leaping and grasping: the hands are long and prehensile; the thumb is pseudo-opposable; the phalanges are very elongated relative to the metacarpals; the tarsal region is elongated and the first toe (hallux) widely divergent. The palms of

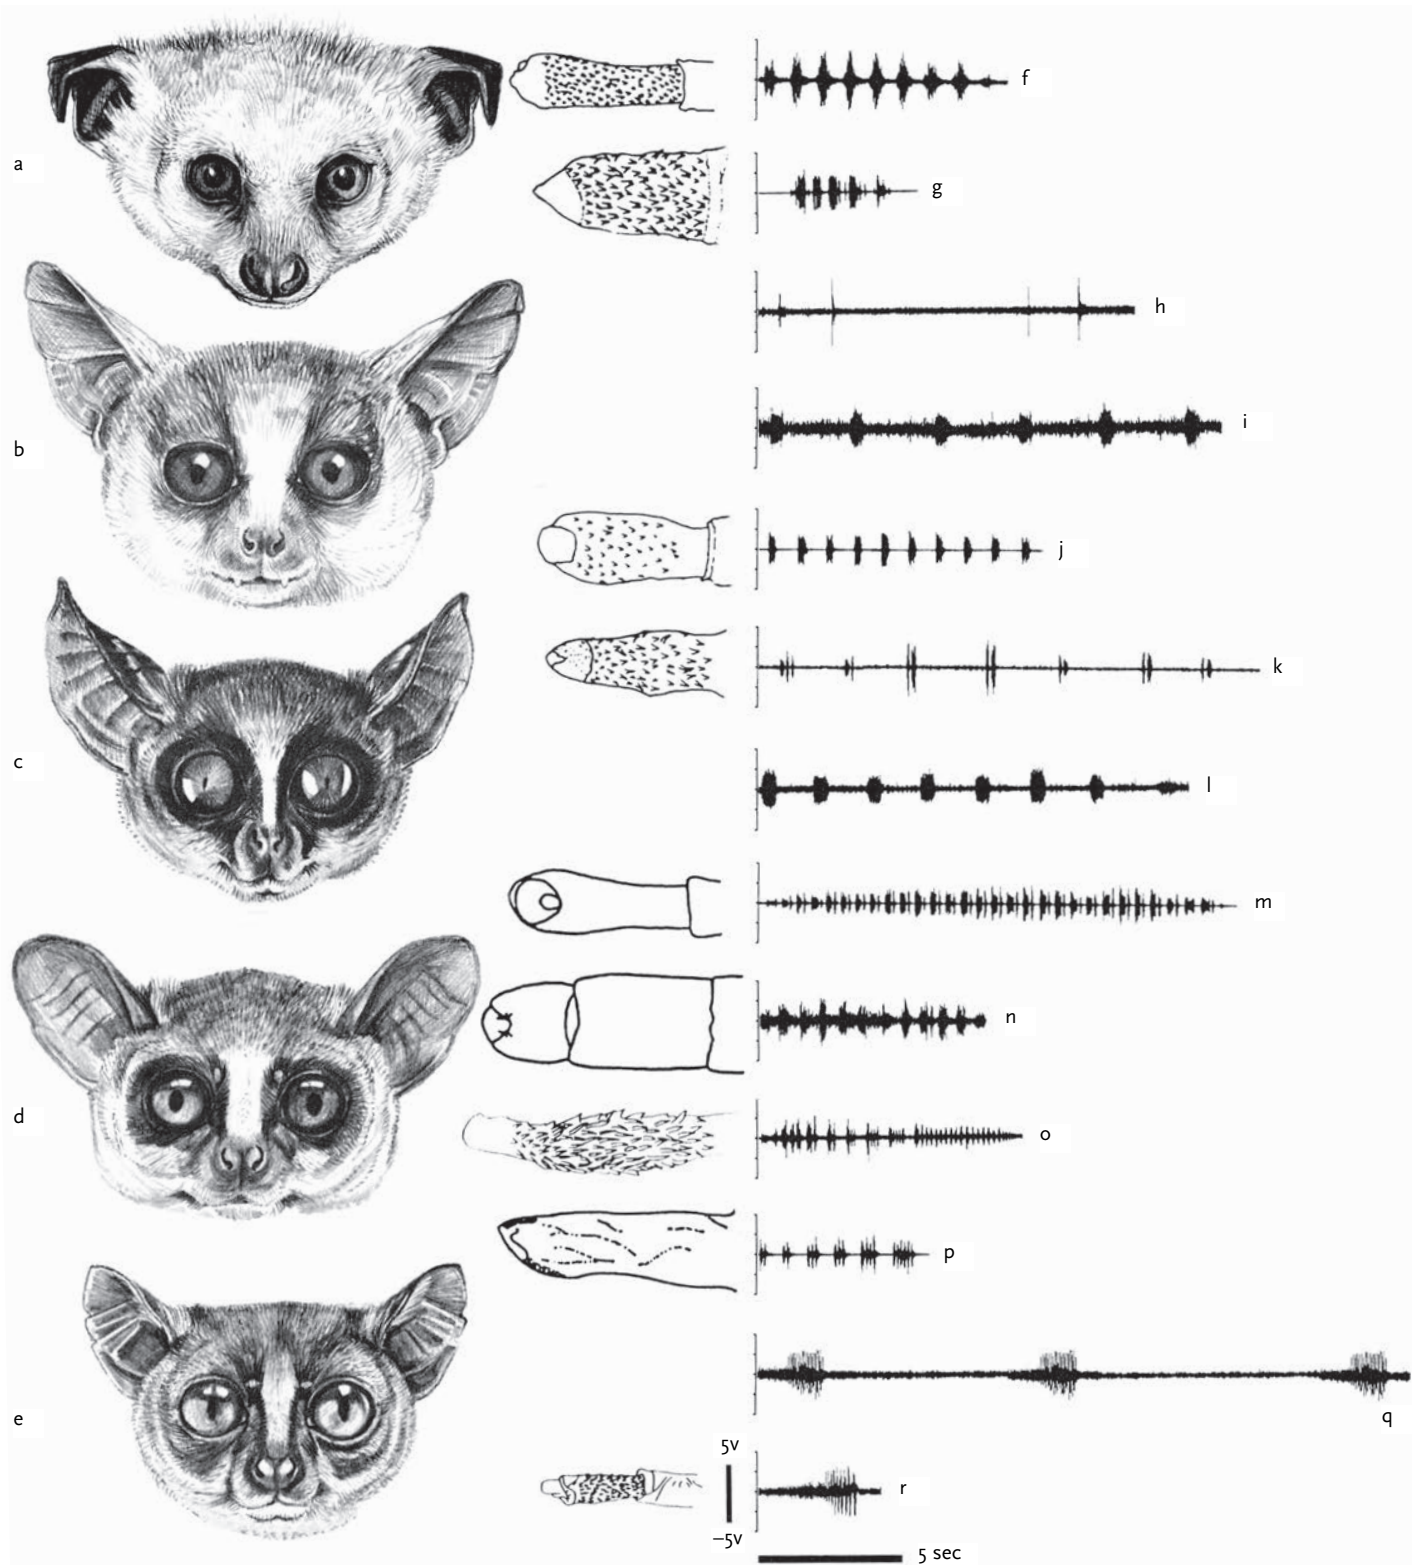

Myology of Small-eared Greater Galago *Otolemur garnettii*.

the hand and soles of the feet have six prominent pads with spatulate, padded tips and conspicuous friction ridges. Inter-ramal (chin) vibrissae are absent but other sets of facial vibrissae are present and carpal vibrissae are found in some species. The nipples are variably arranged in pairs of two or three. The glans penis is elongated and covered with spines; the os penis is simple with the tip often protruding as a knob. The clitoris is long and narrow in the limited sample of species that have been studied. Head + body length range 100–400 mm. Adult body mass ranges 60–2000 g.

The baby-like cries of the largest species, Large-eared Greater Galago *Otolemur crassicaudatus*, have given the galagos their popular name, but each species has a distinctive repertoire of 10 to 25 calls (a ‘vocal profile’) that is species-specific. Many species are best identified by such vocalizations because they play a crucial role in attracting the opposite sex, and they are more noticeably different than relative body sizes or colours.

Galagos eat various combinations of insects, gum and fruit. Up to four species can be found sympatrically, avoiding dietary overlap, or exploiting different areas or heights, within the shared habitat. All species generally forage singly, but some appear to synchronize their movements with companions through calling,

Leaping sequences (from film) for Large-eared Greater Galago *Otolemur crassicaudatus* (top) and Northern Lesser Galago *Galago senegalensis* (from Kingdon 1971).

and in *O. crassicaudatus*, up to three juveniles move as a group with the mother when they feed on fruit, but move alone when only insects and gum are available. Territories are advertised by loud-calls and by laying down scent. Scent rubbing behaviour varies considerably, but all, except the needle-clawed galagos *Euoticus* spp., 'urine-wash'. Urine is voided onto the cupped hand, which is then rubbed onto the sole of one foot. This sequence is generally repeated on the other foot, and ensures that the hands and feet are permanently sticky, improving their grip. Urine-washing onto conspecifics observed in a few cases and direct deposit of urine onto specific areas of substrate ('rhythmic micturition') also occurs. Scent glands are common around the mouth, in the midline of the chest and in the ano-genital region.

Social networks are found in all species studied to date. Social bonds are maintained by regularly meeting others at night, with bouts of mutual sniffing, allogrooming and play, or by huddling together during the day. Adult ♀♀ usually maintain territories that exclude strange ♀♀ but may include adult daughters. The territories of the oldest ♂♂ are generally larger and centred over those of more than one matriarchal group. Males move away from the natal sites at puberty and establish new, large home-ranges. Subordinate ♂♂ avoid conflict with dominant ♂♂ by moving away or hiding when approached.

Galagos usually sleep alone, but sleeping groups of up to eight individuals occur. They sleep by day in a hidden retreat (tree-hole or vegetation tangle) and some species construct leafy nests, particularly when they have infants. Oestrus is usually restricted to a few days and is often synchronized within populations. Tropical species tend to give birth to a single young once a year, while in drier, more seasonal habitats, galagos can give birth to twins twice a year, coinciding with the wettest months. In some species, infants are carried between safe retreats by the mother grasping, in her mouth, a fold of skin on the infant's flanks. In some species of needle-clawed galagos *Euoticus*, greater galagos *Otolemur* and lesser galagos *Galago* the infants may also cling to the mother's fur. In the cold austral winters a dense underfur and the ability to digest gum allows survival even when other food sources are frozen solid. No species are known to exhibit torpor, unlike some lemurs.

Galago locomotion includes vertical clinging and leaping, with the legs brought forward on landing, but this is less common than landing hands first, or quadrupedal running and walking. Gaits employed vary with the demands of the wide range of habitats occupied by the galagos. A similar variety of specializations applies to the special senses. For example, species moving in different heights within forest have eye-shine of different colours (pink, red, yellow or orange) and their ears vary in shape, size and position.

Molecular data indicate that galagos have been a distinctively African lineage for ca. 40 million years (mid-Eocene). Teeth of a putative early galago (*Saharagalago*), dated at >34 mya, were found at a late Eocene site in the Fayum Depression in Egypt (Seiffert *et al.* 2003, 2005b). The phylogenetic relationships among loriforms remain ambiguous despite several attempts to resolve them with molecular, morphological and behavioural evidence. Adaptive radiation within the Galagidae is considerable – even within the same genus. Two genera (*Euoticus* and the squirrel galagos *Sciurocheirus*) are restricted to the moist forests of the Congo Basin and Gulf of Guinea, one (the dwarf galagos *Galagoides*) occurs across tropical Africa from the forests of West Africa and central Africa to the coastal forests along the east coast, and two (*Otolemur* and *Galago*) have representatives in tropical forests as well as in sub-tropical woodlands and bushlands. It remains unclear whether tropical forest forms colonized the sub-tropical regions, or the other way round. Molecular findings place the *Otolemur*–*Galago* split at 15.4 mya (mid-Miocene; Perelman *et al.* 2011).

Taxonomic controversies have been considerable, undoubtedly because of the highly cryptic characteristics of museum specimens and the difficulties of studying galagos in the wild. Hill (1953: 211), for example, notes: ‘The classification of the Galagidae is a vexed question. There is no doubt that 5 main types or groups of galagos at present exist in Africa, but whether each of these is to be regarded as a nominal species or whether they should be treated as genera or sub-genera is difficult to decide.’ The groups in question are:

- 1 the large forms of the *crassicaudatus* type;
- 2 medium-sized forms, long-fingered, *alleni* type;
- 3 small forms typified by *senegalensis* type;

- 4 small forms with specialized, needle-pointed nails typified by *elegantulus* type;
- 5 very small, mouse-like animals typified by *demidovii* type.

The taxonomy of the group has come full circle, largely returning to the treatment proposed by Gray (1863) who was followed, on the basis of cranial and dental peculiarities, by Mivart (1864). The number of species recognized by most authors has risen from six in 1967 to >20 in 2009, mainly on the basis of their species-specific vocal profiles and correlated distinctions in penile morphology. The rate at which new species have been recognized over the past two decades suggests that several more species have yet to be uncovered (Bearder 1999). This volume presents profiles for 18 species of galagos within five genera:

- 1 *Otolemur* for the largest galagos
- 2 *Sciurocheirus* for the long-fingered, forest understorey galagos
- 3 *Galago* for the small leaping, long hind-limbed galagos
- 4 *Euoticus* for the needle-clawed, gum-eating, forest galagos
- 5 *Galagoides* for the dwarf, ‘running’, forest galagos.

No profile is presented here for the recently resurrected, and little known, Malawi Dwarf Galago *Galagoides nyasae* (Grubb *et al.* 2003, Nekaris & Bearder 2011).

The genus *Galagoides* is the least consistent in terms of morphology, ecology and behaviour, representing a ‘wastebasket’ genus for the smallest galagos that may be separated further when more is known about their adaptations and genetics.

Simon K. Bearder & Judith Masters

GENUS *Otolemur* Greater Galagos

Otolemur Coquerel, 1859. Revue Zoologique, Paris 11: 458.

Mwera Greater Galago *Otolemur* sp. nov.? adult male.

Otolemur is a polytypic genus endemic to the woodlands and forests of the southern half of Africa. There are two currently-recognized and named species; Small-eared Greater Galago *O. garnettii* and Large-eared Greater Galago *O. crassicaudatus* (Olson 1979). A third species, Miombo Silver Greater Galago *O. monteiri*, is sometimes recognized

(Groves 2001, 2005c, Grubb *et al.* 2003, Nekaris & Bearder 2011). This volume follows Olson (1979) and Jenkins (1987) in recognizing two species. *Otolemur garnettii* and *O. crassicaudatus* can be distinguished based on a number of characters, including body size and vocal profile.

Distributed throughout most of eastern and south-eastern Africa from coastal S Somalia in the north to KwaZulu–Natal in SE South Africa. From Angola eastwards through Tanzania. Northern distribution limited by the forests of the Congo Basin and deserts of N Kenya and S Somalia. In southern Africa, *Otolemur* does not penetrate the peripheral habitats of the Namib Desert, Kalahari Desert or High Veld of South Africa (Olson 1979, Nash *et al.* 1989, Kingdon 1971, 1997, Groves 2001).

A thorough review of the systematic history of the genus *Otolemur* is provided by Olson (1979). He describes this genus as part of his detailed morphological study of >4000 specimens. His diagnosis (p. 328) for dentally mature individuals is as follows:

‘Head plus body length greater than 23 cm, hind foot greater than 8 cm, body weight over 500 grams, cranial length greater than 5.5 cm, length of upper pre-molar-molar series greater than 1.85 cm

Small-eared Greater Galago *Otolemur garnettii*.

and length of lower pre-molar-molar series greater than 1.65 cm. Cranial features associated with masticatory musculature well developed: marked postorbital constriction, robust zygomatic arches, deep maxillary root of zygomatic bone, relatively long zygomatic arch posterior to postorbital process, large lateral pterygoid plates, coronoid and angular processes of the mandible robust. Foramen magnum directed posteriorly, minimum basicranial flexion, fissure between orbital and temporal fossae large, palatine canals tiny, large triangular area of the horizontal plate of the palatine bones posterior to M3. Lingual margins of maxillary tooth rows parallel or only

slightly divergent posteriorly. Muzzle large and robust, broad not pointed. Molars and P4/4 with low rounded cusps, crowns lacking prominent crests. Diploid number 62. Glans penis clavate, gradually incrassate from base to truncated tip, the tip obliquely inclined from its superior surface downwards. Extraocular recti muscles inserted around equator of eyeball. Pronograde quadruped. Lateral surfaces of limbs more or less the same colour as dorsal body pelage. Dark circumocular rings and light coloured interocular stripe absent. Skin between palmar and plantar pads granular. Caecum unsacculate and rather small'.

Large-eared Greater Galago *Otolemur crassicaudatus*.

Olson (1979) provides a detailed description of the genus and a comprehensive list of features that distinguish *Otolemur* from each of the other genera within the Galagidae, of which the most obvious is their larger body size. Other characteristics that he describes include an intermembral index of 65–70; digital formulae $IV > III > V > II > I$; pedal digit II with toilet-claw; tarsal elongation not as pronounced as in most other galagos; overall colouration of limbs similar to body, lacking bright golden or yellowish colours; tail long and bushy; ventral and dorsal body pelage of different colours except in melanistic individuals; large areas of glandular skin frequently present in scrotal, pectoral and submental regions of mature adults. Male external genitalia with long and slightly curved penis, which gradually thickens towards the tip, glans penis covered with either unidentate or tridentate spines, urethral opening situated in triangular depression below projecting baculum, tip of baculum and urethra surrounded by wrinkled collar; ♀ external genitalia with long thick clitoris, large labia with fine lamellae that converge towards the vagina.

Dentition: $I^{2/2}$, $C^{1/1}$, $P^{3/3}$, $M^{3/3}$; deciduous dentition $i^{3/3}$, $c^{1/1}$, $m^{3/3}$; molariform teeth of both jaws with low rounded cusps and not exhibiting prominent crests between cusps. Postcranial skeleton rather generalized except for elongation of hindlimb, and the calcaneus and navicular elements of the tarsus.

Simon K. Bearder

Otolemur crassicaudatus LARGE-EARED GREATER GALAGO (THICK-TAILED GREATER GALAGO / BUSHBABY)

Fr. Galago à queue touffue; Ger. Großohr-Riesengalago

Otolemur crassicaudatus (É. Geoffroy, 1812). Ann. Mus. Hist. Nat. Paris 19: 166. Quelimane, Mozambique.

Large-eared Greater Galago *Otolemur crassicaudatus* adult male.

Taxonomy Polytypic species. Olson (1979) focused on the genus *Otolemur* and his classification, based on measurements from 4949 galago specimens (including all type specimens) from museums and private collections in Europe, Africa and North America, is used here. This species was referred to as *Galago*

crassicaudatus in most classifications prior to 1979, with *garnettii* as a subspecies (Hill 1953, Napier & Napier 1967, Groves 1974, Petter & Petter Rousseaux 1979). Recognition of two species belonging to the genus *Otolemur* (*O. crassicaudatus* and Small-eared Greater Galago *O. garnettii*) was established by Olson and substantiated by Jenkins (1987), Clark (1988), Zimmermann (1990), Masters (1991) and DelPero *et al.* (2000). Each species has a distinctive vocal profile (Bearder *et al.* 1995) with no obvious vocal differences among the subspecies. Olson (1979) recognizes three subspecies, *O. c. crassicaudatus*, *O. c. monteiroi* and *O. c. argentatus*, whereas Kingdon (1997) recognizes *argentatus* as a species, and Groves (2001, 2005c), Grubb *et al.* (2003) and Nekaris & Bearder (2011) recognize *monteiroi* as a species. This volume follows the taxonomy of Olson (1979).

Honess (1996b), Kingdon (1997), Groves (2001), Grubb *et al.* (2003) and Nekaris & Bearder (2011) recognize a 'dwarf' form of Large-eared Greater Galago (Mwera Greater Galago *Otolemur* sp. nov.?) based on a population of extremely small individuals (<500 g) in SE Tanzania. The calls and appearance of the Mwera Greater Galago could not be distinguished from typical *O. crassicaudatus* (Honess 1996b). These animals are considerably smaller than *O. garnettii*, which share the same fruit trees in the village of Tandangongoro. Dwarfism may be the result of character displacement, since much larger individuals of *O. crassicaudatus* are found a few kilometres away, where *O. garnettii* is absent. Synonyms: *argentatus*, *badius*,

*Otolemur crassicaudatus*

kirkii, *lestradei*, *lonnbergi*, *monteiri*, *umbrosus*, *zuluensis*. Chromosome number: $2n = 62$ (de Boer 1973a, b, Stanyon *et al.* 2002).

Description Large galago with big ears and thickly-furred tail; strongly associated with miombo woodland. The largest galago, but wide variation among adults (550–2000 g). Head dominated by large ears and large robust muzzle. Eyes relatively small. Face markings indistinct or absent. No difference in colour between sexes but adult ♂ significantly heavier than adult ♀, weighing ca. 1500 g vs. 1250 g (Harcourt 1980, 1986b, Masters 1988). Pelage colour highly variable in both sexes, with dorsum ranging from silver-grey to dark brown. Melanistic individuals present in Kenya, Tanzania and E DR Congo, living side by side with individuals that are light silver (almost white). Some individuals are entirely black, or have white on the underside. Outsides of limbs and face typically same colour as body but ventrum is variable in colour and the bushy tail may be lighter or have a black tip. Males have particularly large, light-coloured bare patches of glandular tissue on their chest (Clark 1978a, 1982a, b). Hindlimbs slightly longer than forelimbs but quadrupedalism is the norm; unable to land feet first when leaping (Bearder 1974, Olson 1979, Crompton 1983, 1984, Nash *et al.* 1989). Nails convex and lack lateral points. The newborn is covered with uniform greyish fur. Photographs of *O. crassicaudatus* in Kenya and Tanzania available at: www.wildsolutions.nl

Geographic Variation There is considerable disagreement about subspecies (Hill 1953, Olson 1979, Jenkins 1987, Kingdon 1997, Groves 2001, 2005c Grubb *et al.* 2003, Nekaris & Bearder 2011). Olson's extensive museum studies provide a solid foundation for further research, including studies of genetics, vocalizations and behaviour. In addition to the subspecies noted below, Olson examined 250 individuals that he considered to be hybrids between *O. c. crassicaudatus* and the Miombo Silver Galago *O. c. monteiri* in a wide region from the southern end of L. Malawi, through Zimbabwe and C Mozambique to the confluence of the Bube R. and Limpopo R.

Large-eared Greater Galago *Otolemur crassicaudatus* adult female.

Jenkins (1987) indicates that these animals, together with specimens from S Tanzania, may constitute a separate subspecies for which the earliest name would be *O. c. kirkii*.

O. c. crassicaudatus South African Thick-tailed Galago (99 specimens examined by Olson). In eastern coastal areas south of Limpopo R. South along the KwaZulu–Natal coast, South Africa, to Durban and inland to Pietersberg and Potgeitersrus (Constantino 2001). Only found in riverine or dune forest (Olson 1979). Relatively large HB, tail relatively short (only slightly longer than HB and usually <400 mm). Ears relatively small (60–65 mm). Pelage brown to dark brown, rarely reddish-brown. Tail colour of body but tip sometimes black or dark brown. Melanistic individuals are not known.

O. c. monteiri Miombo Silver Galago (374 specimens examined by Olson). Occurs over a vast area broadly corresponding to *Brachystegia* ('miombo') woodland/savanna between 10 and 15°S. Also in montane and riverine forest. From Angola through Zambia, Zimbabwe, Malawi through Mozambique. Southern limits poorly known. Also in SE DR Congo, Rwanda, Burundi and Tanzania (Olson 1979). In Tanzania, at L. Rukwa, Mahale Mountains N. P. on east shore of L. Tanganyika, Tabora, Dar es Salaam, Mt Kilimanjaro, Mt Meru and Sadaani N. P. In SE Kenya, south of Mombasa (A. Perkin, Y. De Jong & T. Butynski pers. comm.). *Otolemur c. monteiri* similar to *O. c. crassicaudatus* in overall biometrical features but differs significantly in having larger ears (65–70 mm) and a tail (>400 mm) that is notably longer than the body. Dorsum is typically silver or light grey, sometimes with slight brownish wash. Tail almost always lighter in colour than the body and rarely has a blackish tip (Y. de Jong & T. Butynski pers. comm.). Melanistic individuals and populations occur throughout the range. Olson (1979) notes a deviation from the typical pelage pattern in a series of eight specimens from atypical habitat in the Kahemba District, SE DR Congo, which tempted him to designate a new taxon, but he considered that the sample size was too small.

O. c. argentatus Northern Silver Galago (23 specimens examined by Olson). Largest and morphologically most distinctive subspecies. Tanzania and Kenya around the east and south-east shore of L. Victoria, where geographically isolated from other subspecies. In Loita Hills, SC Kenya (Butynski & De Jong 2012). Possibly in NE Rwanda. Characterized by absolutely larger size (HB averages 350 mm and head length 77 mm compared with 320 mm and 70 mm for *O. c. monteiri*) and relatively small ears (55–60 mm). Pelage almost indistinguishable from *O. c. monteiri*, although brownish wash absent except on top of head. Melanistic and silver individuals occur throughout the range and melanism probably more common than in *O. c. monteiri*.

Melanistic Northern Silver Galago *Otolemur crassicaudatus argentatus* adult male.

Similar Species

Otolemur garnettii. Narrowly sympatric or parapatric on coast of East Africa from Mombassa (e.g. Kaya Teleza) to N Mozambique, and from Usambara Mts to Ngorongoro Crater (Nash *et al.* 1989). Sympatric in Loita Hills (Butynski & De Jong 2012). Separated ecologically, preferring wetter parts of shared sites, although they may be seen together in the same tree. About 70% as large as *O. crassicaudatus*. Superficial similarities in appearance mask more subtle contrasts. *Otolemur garnettii* is more agile and able to land feet first when leaping; relatively small ears; nails with concave distal ends and lateral points for gripping branches; single as opposed to multiple births; a longer gestation period; different penile morphology and shape of the baculum (Eaton *et al.* 1973, Olson 1979, Dixson 1995, 1998, Anderson 1998, 2000); a different call repertoire, particularly the loudest calls that are used to attract companions and repel rivals (Bearder *et al.* 1995). Fur carriage of infants not confirmed. Melanistic forms not reported (Nash *et al.* 1989). Confusion between these two species makes the earlier literature difficult to interpret.

Distribution In Somalia-Masai Bushland, Coastal Forest Mosaic, Zambezian Woodland, Southern Rainforest-Savanna Mosaic, Highveld, and Afroalpine BZs. Endemic to Africa south and east of the Congo Basin. Northern distribution in Angola and DR Congo restricted by Congo Basin forest. In NW Tanzania, immediately south of border with Uganda, *O. crassicaudatus* in riverine vegetation bordering moist forest occupied by Thomas's Dwarf Galago *Galagoides thomasi* and Demidoff's Dwarf Galago *Galagoides demidovii*. Distribution restricted by the drier savannas and bushlands of S Kenya and Tanzania. Extends from S Kenya through Tanzania, Malawi, Zambia, E Zimbabwe, E Botswana, E South Africa, and Swaziland to Zululand, south of Durban (Olson 1979, Skinner & Smithers 1990). See Geographic Variation for distributions of subspecies. Kingdon (1971) notes that northern limit of *O. crassicaudatus* corresponds with the southern range of Potto *Perodicticus potto*. Major rivers not a serious barrier to dispersal.

Habitat Found in areas with well-defined seasons. Open woodland and savanna occupied in northern parts of range, especially miombo woodlands. Mainly associated with forests, thickets and well-developed woodland of higher rainfall areas farther south. Over southern part of range, restricted by dry and less densely wooded vegetation of desert margins and savannas. Requires dense shelter to hide during the day but penetrates far into dry regions where there is riverine vegetation (e.g. W Zimbabwe and in Northern Province and Mpumalanga, South Africa). Distribution coincides with availability of tree gum. Eucalyptus *Eucalyptus* spp., pine *Pinus* spp. and Black Wattle *Acacia mearnsii* plantations can be used for sleeping. Occupies urban and peri-urban gardens where there are sufficient fruit trees for food. Occurs from sea level to >1800 m in E Zimbabwe (Skinner & Smithers 1990, Kingdon 1997), and to 2000 m in Udzungwa Mts, SC Tanzania (Rovero *et al.* 2009).

Abundance Locally common. No systematic density estimates exist as detailed studies have been made only in narrow tracts of riverine vegetation as opposed to uniform forest cover. Bearder (1974) studied a ♀ and three infants with a home-range of approximately 7 ha where they were occasionally joined by a ♂. On the east shore of L. Tanganyika, in Mahale Mountains N. P., Tanzania, in old secondary forest (dominated by abandoned Oil Palm *Elaeis guineensis*, Guava *Psidium guajava* and Mango *Mangifera indica*) density of *O. c. monteiri* >50 ind/km² at forest/beach ecotone, but much less than this in the forest interior (T. Butynski & Y. de Jong pers. comm.).

Adaptations Nocturnal and arboreal. Hindlimbs slightly longer than forelimbs but quadrupedalism is the norm; unable to land feet first when leaping (Bearder 1974, Olson 1979, Crompton 1983, 1984, Nash *et al.* 1989). Least agile of the galagos, generally walking or running along the top of broad, horizontal supports, or on the ground (sometimes over 100 m). Able to leap 3 m between trees and hop along the ground bipedally if distressed. Frog-like, quadrupedal hopping on the ground appears unique to *O. crassicaudatus*. Ability to maintain a grip when hanging upside-down beneath a wide horizontal branch to reach gum is remarkable (Bearder & Doyle 1974a, Crompton 1983). Most common sleeping site is dense tangles of creepers and branches at a height of 5–12 m above ground. At one site in Mahale N. P. some sleep among the dense fronds at the top of >10 m high Oil Palms (T. Butynski & Y. de Jong pers. comm.). Adult ♀♀ make nests when they have infants – inaccessible leafy platforms, depressed in the middle with foliage above for shelter (Bearder & Doyle 1974a). Individuals have more than one sleeping site and are not known to move away from a sleeping site during the day (Bearder & Doyle 1974a). Caves and roof spaces in human dwellings also used as shelters. Chest glands produce three major volatile compounds, which are different from those of *O. garnettii* (Katsir & Crewe 1980, Clark 1988).

Foraging and Food Omnivorous. Diet comprised of invertebrates, fruit and gum. Individuals follow regular pathways to reach well-known sources of gum or fruiting trees (Bearder & Doyle 1974a). Usually forages alone when searching for small sources of gum and insects (Clark 1985), but move as a group where large fruit trees are common (Bearder 1974). In South Africa, trees that

Lateral and palatal views of skull of Large-eared Greater Galago *Otolemur crassicaudatus* adult male.

produce abundant gum from established wounds (usually Sweet Thorn *Acacia karoo*) are visited regularly, particularly during the cold, dry winter (Harcourt 1986b, Nash & Weisenseel 2000). In NE South Africa, diet includes 33% fruit, 62% gum and 5% invertebrates where fleshy fruit is readily available (Bearder 1974) but 41% gum and 59% invertebrates where fruit is absent (Clark 1985). Flowers, seeds, nectar and millipedes also consumed (Coe & Isaac 1965, Crompton 1984, Clark 1985, Harcourt 1986b). Feed on hard-shelled and woody, dried fruits in South Africa (Masters *et al.* 1988), and arthropods from the orders Coleoptera, Orthoptera, Hymenoptera, Odonata, Chilopoda and Isoptera. Millipedes (Diplopoda) taken during the summer months (Harcourt 1986b). Termites, *Macrotermes* sp., eaten in Malawi (Happold & Happold 1992). Fish captured from a basin and eaten in captivity (Welker 1976). Many reports of birds being captured in the wild and their brains eaten. This, however, is probably a local tradition as it appears to be absent from some populations (Bearder 1974). Water is obtained from the diet or by licking dew.

Social and Reproductive Behaviour Dispersed groups. Most gregarious of all galagos, probably related to large body size and diet. Where fruit is abundant, the young stay with the mother during the long period of immaturity (15 months) and they frequently move with her as a cohesive group. If an individual becomes separated from the group, it, unlike any other galago, gives a 'buzz' call until reunited (Bearder 2007). Cohesive groups not formed where food sources are scattered in small clumps (Clark 1985, Bearder 1987). Grouping also occurs at sleeping sites during the day when a mother and up to three offspring may be joined by an adult ♂.

Adult ♀♀ occupy separate territories, which they share with their offspring of one or more generations. The sex ratio at birth appears to be biased towards ♂♂. This has been interpreted as an adaptation to reducing competition for food resources (gum) that are shared among related ♀♀. Males on the other hand tend to disperse (Clark 1978b). Male ranges are larger and overlap those of ♀♀. Adult ♀♀ occupy adjacent territories that are visited by up

to six adult ♂♂. Young adult ♂♂ have less frequent access to the ♀♀ but all age/sex classes engage in amicable social interactions, especially grooming, with the exception of territorial ♂♂, which never come together. Juveniles engage in object play, locomotor play and social play, including group play between a mother, two juveniles and an adult ♂ (Bearder 1974).

Females may have mating access to up to six ♂♂ during their oestrus (3–5 days) once each year, indicating a polygynandrous (multimale/multifemale) mating system (Clark 1985). Oestrus periods are synchronized within populations during two weeks during winter (Jun/Jul). Prolonged copulation is common (up to 45 minutes) and has been interpreted as a form of mate-guarding (Dixson 1995). At parturition, ♀♀ may become unusually aggressive to cage-mates (including previous offspring) and mothers cease to join their usual sleeping partners (Bearder & Doyle 1974a, Bearder 1987).

Communication involves a wide range of auditory, visual, tactile and olfactory signals, including 18 structurally distinct calls (Bearder 1974, Clark 1978a, 1988, Petter & Charles-Dominique 1979, Masters 1991, Bearder 2007). The loud child-like cries, audible at 300 m, are the origin of the name 'bushbaby'. Raucous whistles, yaps and cackles of alarm are also given. Conspicuous scent-marking behaviours include cheek-rubbing, chest-gland-rubbing, ano-genital rubbing, rhythmic urination, urine-washing of the hands and feet, and foot-rubbing, which is peculiar to *Otolemur* (Welker 1973, Clark 1982a, b, 1988). An individual will rub the roughened area of the sole of one foot against a branch and then the other, making a distinctive scraping noise (Bearder & Doyle 1974a). Foot-rubbing is done mainly by adult ♂♂ and may accompany urine-washing, rhythmic urination and chest-gland-marking when disturbed in social situations or in the presence of a predator (Bearder 1974, Hager 2001). Chest-gland-marking by adult ♂♂ in captivity is testosterone-dependent (Bullard 1984).

Reproduction and Population Structure Gestation is 132.8 ± 2.6 days ($n = 3$) in the wild (Bearder 1974). Of 20 pregnancies in captivity, six (30%) resulted in singletons and 14 (70%) multiple births, two of which were triplets and 12 twins (Masters *et al.* 1988). In South Africa there is a single birth season during Nov which coincides with the start of the rains (Bearder & Doyle 1974a). In E Zimbabwe (Smithers & Wilson 1979) and Zambia (Ansell 1960) births occur in Aug/Sep. No defined birth season observed in captivity. Infants born in nests, which, at other times, are used as resting places. Just before giving birth the ♀ relines the nest with fresh green leaves and twigs. At birth the neonate weighs ca. 40 g, the eyes are open. Neonate can crawl within 30 min of birth. At first the mother carries each infant, one at a time, in her mouth, holding it by a fold of skin on the flanks or by the back. After about eight days up to three infants may cling to their mother's back. At about three days infants vocalize by giving 'squeaks', and at nine days emit 'clicks' and 'crackles'. In the wild the young travel with the mother after about 25 days of age, either following her or being carried (Bearder 1974). Lactation lasts around ten weeks (Bearder 1974). Mother–infant cannibalism can occur in captivity after the death of an infant (Tartabini 1991). Young move independently after 17 weeks. Maximum longevity in captivity is about 15 years (Doyle 1979).

Predators, Parasites and Diseases Robust Chimpanzee *Pan troglodytes* is a predator of *O. c. monteiroi* (Uehara 1997). Other predators include Leopards *Panthera pardus*, large owls *Bubo* spp., large snakes and genets *Genetta* spp. (Crompton 1984). A wide variety of parasites and pathogens reported for prosimians in captivity although they have few health problems in captivity (Kohn & Haines 1982, Benirschke *et al.* 1985).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

The conservation status of *O. c. argentatus* is of considerable concern as most of the habitat of this isolated subspecies has been destroyed by human activities (N. S. Svoboda & D. Roberts pers. obs.). The population identified by Olson (1979) in the Kahemba District, SE DR Congo (see Geographic Variation), is in particular need of study.

Otolemur garnettii SMALL-EARED GREATER GALAGO (GARNETT'S GALAGO / BUSHBABY)

Fr. Galago de Garnett; Ger. Kleinohr-Risengalago

Otolemur garnettii (Ogilby, 1838). Proc. Zool. Soc. Lond. 1838: 6. Zanzibar I., Tanzania (designated by Thomas 1917).

Small-eared Greater Galago *Otolemur garnettii*.

Taxonomy Polytypic species. Originally called *Otolicnus garnettii* by Ogilby (1838), with no provenance given to the type specimen; the type locality was designated by Thomas (1917: 48) to be Zanzibar I. (now Unguja I.). Since then, numerous synonyms for both the generic and specific name have been used (for details see Olson 1979). Until recently, this taxon considered a subspecies of *Otolemur* (also called *Galago*) *crassicaudatus* (e.g. Hill 1953, Petter & Petter-Rousseaux 1979). This taxon now generally accepted to be a full species (Olson 1979, Harcourt 1984, Jenkins 1987, Masters 1988, Nash *et al.* 1989, Groves 2001, 2005c, Grubb *et al.* 2003, Nekaris & Bearder 2011). Following Groves (2001, 2005c) and Grubb *et al.* (2003), four subspecies are recognized. Chromosome number: 2n = 62 (Masters 1986, Jenkins 1987, Groves 2001). Synonyms: *agisymbanus*, *hindei*, *hindsii*, *kikuyuensis*, *lasiotis*, *panganiensis*.

Description Relatively large galago (size of small domestic cat) with long bushy tail. Second largest galago. Occurs in forests.

Sexes alike, but ♂ slightly heavier than ♀. Head colour varies with colour of dorsum (see below), but may have a whitish face (A. Perkin & T. Butynski pers. obs.) Muzzle blunt and dog-like. Forehead sometimes with darker vertical furrow. Eye-rings not obvious. Ears small relative to size of head and to other galagos. Dorsum varies from reddish-brown to greyish-brown to silvery (Olson 1979, Nash *et al.* 1989), sometimes with a greenish tinge (Groves 2001). Ventrums vary from creamy-white to buff-brown. Tail colour highly variable even within same population (Harcourt 1984). Generally proximal half, or more, of tail is same colour as dorsum, with distal half, or less, varying from black, dark brown to white. Chin, throat and ventrum generally same colour as distal part of tail (Y. de Jong & T. Butynski pers. comm.). Nails are convex. Penile spines usually tridentate, with some bidentate. Baculum elongated, extending beyond glans penis (Dixson 1989, 1995). Photographs of *O. garnettii* from Kenya and Tanzania available at: www.wildsolutions.nl

Geographic Variation

- O. g. garnettii* Zanzibar Small-eared Galago. Zanzibar I., Pemba I. and Mafia I. Dorsum rich reddish-brown. Ventrums yellow, slightly greenish toned. Tail almost black over distal half (Jenkins 1987, Groves 2001).
- O. g. panganiensis* Pangani Small-eared Galago. Loita Hills and at Tavetta, extreme SC Kenya, Tanzania from Tanga, Mt Kilimanjaro, Mt Meru and L. Manyara to south (right) bank of Ruvuma R., extreme N Mozambique (Olson 1979). Dorsum greyish-brown, sometimes with yellow wash. Lacking greenish tones. Ventrums grey-white. Tail usually brown or dark brown over distal quarter (Jenkins 1987, Groves 2001), but sometimes whitish at tip (e.g. Usa R., Mt Meru; Y. de Jong & T. Butynski pers. comm.).
- O. g. lasiotis* White-tailed Small-eared Galago. Juba R., Somalia, south along Kenya and Tanzania coasts to Tanga. Inland to Taita Hills and Kibwezi, Kenya (Jenkins 1987, Groves 2001). Dorsum greyish, greyish-brown or silvery. At Diani, extreme SE Kenya, dorsum varies from dark brown to pale brown. Individuals at Watamu-Gedi, central coast of Kenya, are exceptionally variable in colour (Olson 1979, De Jong & Butynski 2009). Ventrums greyish-white; always paler than dorsum. Distal half or less of tail highly variable, ranging from black, dark brown to white, even at the same locality (Harcourt 1984, De Jong & Butynski 2009).
- O. g. kikuyensis* Kikuyu Small-eared Galago. Kenya Highlands, east of the Eastern Rift Valley; Nairobi, Ngong, Masinga, Aberdares and Mt Kenya. Dorsum grey, often iron grey, with a tinge of green. Muzzle, eye-rings, ears, hands and feet blackish. Ventrums yellow-white. Tail very full, light brown, often nearly black over distal quarter, but sometimes with whitish tip (Groves 2001, De Jong & Butynski 2009).

Similar Species

Otolemur crassicaudatus. Narrowly sympatric or parapatric on the coast of East Africa from Mombasa (e.g. Kaya Teleza; A. Perkin pers. obs.), SE Kenya, to N Mozambique. Sympatric in Loita Hills, SC Kenya (Butynski & De Jong 2012). Also sympatric in Tanzania from Usambara Mts to Ngorongoro Crater (Nash *et al.* 1989). Larger with mean weight of adult ♂ ca. 1250 vs. 900 g for *O. garnettii*. Ears larger, and larger relative to the head (ca. 60

Small-eared Greater Galago *Otolemur garnettii* adult male.

vs. 46 mm). Pelage greyer. Loud 'trailing call' (or 'cry') distinctive (Nash *et al.* 1989, Bearder *et al.* 1995). Confusion between these two species makes the earlier literature difficult to interpret.

Distribution Endemic to eastern Africa. Somalia–Masai Bushland and Coastal Forest Mosaic BZs. In coastal and riverine forests from Jubba R., Somalia, south to N Mozambique. Northernmost record is in the Mathews Range, C Kenya (01° 15' N, 37° 18' E, 1414 m; De Jong & Butynski 2010a). On Manda, Pemba, Zanzibar and Mafia Is. Inland in forests of Kenya Highlands east of Eastern Rift Valley, Tsavo, Taita Hills, Chyulu Hills, Mt Kasigau, Mt Kilimanjaro, Mt Meru, L. Manyara and most Eastern Arc Mts (Olson 1997, De Jong & Butynski 2009, A. Perkin pers. obs.). Only known site in Southern Highlands is Milo Forest (Honess 1996b, A. Perkin & T. Davenport pers. obs.). Although the map in Nash *et al.* (1989) shows *O. garnettii* in the Udzungwa Mts, SC Tanzania, there is not yet evidence of this (Honess 1996b, Butynski *et al.* 1998, Perkin 2001) except for Mbatwa riverine forest in north Udzungwa Mountains N. P. (Rovero *et al.* 2009). Olson (1979) indicates that *O. garnettii panganiensis* occurs just south of the Ruvuma R. in extreme N Mozambique, and that it may occur farther south. See Geographic Variation.

Habitat In forested and forest-agriculture mosaic from sea level to 2000 m, rarely higher; in Tanzania to 2400 m on Mt Kilimanjaro (Grimshaw *et al.* 1995) and in Kenya to 2290 m on Aberdares Range (M. Dodds pers. comm. to Y. de Jong). Mean annual rainfall over geographic range ca. 600–1500 mm (Olson 1979, Y. de Jong & T. Butynski pers. comm.). Gedi and Diani coastal forests, Kenya, are lowland, dry forest on coral rag (Moomaw 1960). These forests are multistratal, often with a thick understorey, a canopy at 15–20 m, mostly of *Combretum schumannii*, and emergents to 25 m (Harcourt & Nash 1986b). In submontane and montane forests of Mt Kenya, Aberdares Range, Mt Meru, Mt Hanang and Eastern Arc Mts, *O. garnettii* is most common at forest edges and in secondary vegetation (A. Perkin, Y. de Jong & T. Butynski pers. obs.).

Otolemur garnettii

Abundance In Diani and Gedi Forests, Kenya, ca. 31–38 ind/km² (Nash & Harcourt 1986). Brief foot and/or vehicle surveys of >20 sites in Kenya and Tanzania yielded encounter rates of 1–5 ind/h, with highest rates in Kenya at Tana River Primate National Reserve, Meru F. R., Ngaia F. R. and Diani (De Jong & Butynski 2009), and in Tanzania at Ngezi-Vumawimbi Nature F. R. (NW Pemba I.), Zanzibar I., Arusha, Zaraningi Forest (in Sadaani N. P.) and L. Manyara (Y. de Jong & T. Butynski pers. comm.).

Adaptations Nocturnal and arboreal. Day spent sleeping in tangled vegetation in tall bushes or trees. Not known to use tree-holes. Loud ‘trailing call’ given by both sexes to announce their presence to conspecifics; most other calls are associated with alarm situations (Harcourt 1984, Bearder *et al.* 1995). Predator and prey detection and localization are associated with well-developed visual and hearing systems. Olfactory communication is important: urine-washing and chest- and foot-rubbing. Glands on chest and abdomen produce an oily, yellowish apocrine secretion (Kingdon 1997). Both sexes have spiky patches on soles of the hindfeet, which are used to rub a substrate and generate sound (Hager 2001).

Locomotion in *O. garnettii* is quadrupedal; when leaping it usually lands hindfeet first, or on all four feet (like *O. crassicaudatus*) (Harcourt 1984); bipedal hopping when on the ground (Harcourt 1984, Harcourt & Nash 1986b). On Mt Kilimanjaro, shows a preference for horizontal supports in mature trees; 51% of 420 observations on horizontal supports and 42% of 527 observations at >10 m in canopy (Svoboda 1999).

Foraging and Food Omnivorous. Forages mostly in trees, rarely on ground. About half of the time spent above 5 m (Harcourt & Nash 1986b). Mostly forages alone, though several animals may congregate in fruiting trees (Nash & Harcourt 1986, A. Perkin pers. obs). Faecal samples indicate that diet at Diani is ca. 50% animal matter and 50% fruit. Fruits eaten include *Ficus* spp., *Grewia* sp.,

Lateral, palatal and dorsal views of skull of Small-eared Greater Galago *Otolemur garnettii* adult male.

Lannea stuhlmanni and *Vitex strickeri* (Harcourt 1984, Harcourt & Nash 1986b). Stomach samples indicate that 50% of diet is of animal matter and 50% is fruits and seeds (Masters *et al.* 1988). Invertebrates make up the majority of animal matter, mostly beetles, orthopterans and centipedes. Spiders, ants, caterpillars, millipedes, heteropterans, snails and termites also eaten. Observed feeding actively on invertebrates disturbed by swarming army ants (= safari ants = driver ants) *Dorylus* sp. (T. Butynski & Y. de Jong pers. comm.). Birds taken on occasion and probably include, at Diani, Kenya Crested Guinea Fowl *Guttera pucherani* (Harcourt & Nash 1986b). Also forages in farmland, taking Bananas *Musa* sp., Breadfruit *Artocarpus altilis*, Mangos *Mangifera indica*, Papaw *Carica papaya* and other fruit crops, plus Coconut Palm *Cocos nucifera* sap, which is tapped by local people for the manufacture of ‘palm wine’ (Masters *et al.* 1988, A. Perkin pers. obs.).

Social and Reproductive Behaviour Solitary. Mean home-range size at Gedi and Diani, calculated from trapping, radio-tracking and sleeping site data is 12.0 ha (10.8–13.0, n = 4) for adult ♀♀ and 17.1 ha (16.6–17.8, n = 3) for adult ♂♂. Home-ranges of resident adult ♂♂ overlap slightly or not at all, though they overlap ranges of younger ♂♂. Transient ♂♂ move through the home-ranges of resident ♂♂ and ♀♀. Same-age ♀♀ also tend to have non-overlapping home-ranges, though they can share home-ranges with others, which are probably relatives. At Gedi both sexes travel, on average, 1.6 km/night; at Diani one radio-collared adult ♂ travelled, on average, farther than the one radio-collared adult ♀, 3 km and 1.8 km, respectively. Adults spend most of the night alone and, usually, sleep alone as well, though grooming and play between individuals occurs. The apparently less social behaviour of this species, compared with *O. crassicaudatus*, may be due to fewer infants

being born (*O. crassicaudatus* frequently has twins or triplets and many of the interactions seen are between adults and youngsters), or to differences in diet (Nash & Harcourt 1986).

Otolemur garnettii has an extensive vocal repertoire, with 12 spectrographically different call types used by adults of both sexes (Harcourt 1984, Zimmermann 1990, Bearder *et al.* 1995, Honess 1996b, Becker *et al.* 2002). The loud 'trailing call' starts with two lower frequency introductory units followed by 5–8 units, which are repeated and trail away. Alarm calls – 'squawks', 'chatters' and 'cackles' – given frequently, are mostly repetitive and are generally not replied to. Low frequency 'growls' given in a state of anxiety. Other calls recorded in captivity are the low frequency 'flutter/hum' and 'short growls', high frequency 'infant clicks', and high frequency adult ♂ 'clicks' and 'spits' (Becker *et al.* 2002).

Little is known about the mating system of *O. garnettii*. Dixon (1998) suggests *O. garnettii* has a 'dispersed' multimale-multifemale mating system inferred from social organization, copulatory patterns and mating activity in captivity, as well as complex penile morphology and large testes. Non-receptive ♀♀ avoid ♂♂. Males initiate copulations with receptive ♀♀. Copulations are lengthy with intromission lasting 13–260 min; this may be related to mate-guarding (Dixon 1998). In the wild it is thought that olfactory cues play an important role in signalling the sexual condition of the ♀ and in attracting mates in the nocturnal non-gregarious society of *O. garnettii* (Dixon 1998).

Reproduction and Population Structure Not well known. It appears that in the Kenyan coastal forests, infants are born Aug–Nov with ♀♀ giving birth once per year (Nash 1983, Harcourt 1984). Of 95 pregnancies in captivity, 91 (96%) yielded singletons, while four (4%) yielded twins (Izard & Simons 1986). Mothers transport infants in their mouths and 'park' them when foraging. In captivity, ovarian cycle is 39–59 days (mean 44), oestrus 7–24 days (mean 12.4), and there is a restrictive phase of receptivity of 2–10 days (mean 5.8) with a peak of 1–2 days (Eaton *et al.* 1973). Eaglen & Simons (1980) give gestation in captivity as 119–138 days.

Predators, Parasites and Diseases Predators probably include large snakes, genets *Genetta* spp., Two-spotted Palm Civets *Nandinia binotata*, large owls *Bubo* spp. and monkeys. When a potential predator is located, *O. garnettii* mobs the predator while emitting a series of loud 'squawks' that can go on for >40 minutes (Honess 1996b, A. Perkin pers. obs.). Other conspecifics generally do not join in this behaviour but may gather round. Prey avoidance strategies enabled by excellent hearing, smell and vision combined with rapid arboreal locomotion skills and cryptic colouration. Will move around during the day when disturbed by humans (A. Perkin pers. obs.).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II. The discontinuous distribution and small size of many of the forests in which *O. garnettii* occurs makes this species vulnerable to clearing for agriculture, logging, settlement and tourism. This is especially the case along the coast and on Zanzibar I. In many areas, killed as a presumed agricultural pest and a symbol of bad luck. Hunted for meat in several localities, such as in the Makonde tribal area, SW Tanzania. There is small-scale collecting for the pet trade (Perkin 1998, A. Perkin pers. obs.).

GENUS *Sciurocheirus*

Squirrel Galagos

Sciurocheirus Gray, 1873. Proc. Zool. Soc. Lond. 1872: 857 [1873].

Lateral, palatal and dorsal views of skull of Bioko Squirrel Galago *Sciurocheirus alleni alleni* adult.

Squirrel galagos or the 'Allen's Galago Group' have generally been treated as *Galago* by most recent authors, although Gray (1873) erected a separate genus, *Sciurocheirus* (squirrel galagos) for *S. alleni*. Masters *et al.* (1994) and Crovella *et al.* (1994) have, on the basis of genetic similarities, allied this species with the greater galagos *Otolemur* spp. Bayes (1998) found considerable genetic differences between *Otolemur* and *Sciurocheirus*, implying an ancient separation. He placed this divergence at ca. 37 mya (mid-Eocene). *Sciurocheirus* spp. differ considerably from *Galago* spp. in skull shape (Hill 1953), anatomy of the foot (Jouffroy & Gunther 1985) and vocal repertoire, including the loud call (Ambrose 2003). Taxonomic placement of the squirrel galagos has been a recurrent problem. Jouffroy & Gunther (1985) showed that, in their locomotor anatomy and in their behaviour, the squirrel galagos stood well apart from all other galagos. Bearder *et al.* (1995) categorized the *alleni* Group within the *Galago senegalensis/moholi* and *matschiei* Group. Groves (1989, 2001) recorded

his misgivings in placing these distinctive animals in *Galago* but could find no clear affinity with any other group of galagos. In their most recent molecular study Masters *et al.* (2007) contend that the closest genetic affinities of these galagos are with *Otolemur*, not *Galago*. This discovery is currently the focus for various re-appraisals of both genera, in the hope of a better diagnosis of their common ancestry and a more refined appreciation of galago evolution.

Groves (2001, 2005c) designated three allopatric forms as full species: Allen's Squirrel Galago *Galago alleni*, Cross River Squirrel Galago *G. cameronensis* and Gabon Squirrel Galago *G. gabonensis*. Ambrose (2003) and Grubb *et al.* (2003) follow Gray (1873) in placing the squirrel galagos in the genus *Sciurocheirus*. Ambrose (2003) considers the loud call repertoires of *alleni* and *cameronensis* to be identical, thereby invalidating the specific distinction for *cameronensis*. There is, however, a significant difference in body weight, with *alleni* being about one-third heavier than *cameronensis*. On this basis, Ambrose (2003) retained *cameronensis* as a subspecies of *S. alleni*. A third species of *Sciurocheirus*, with a distinct vocal repertoire, facial markings and pelage colouration, was discovered in 1993 in the Makandé region, C Gabon, and is formally described and named here for the first time.

Sciurocheirus is a genus of medium-sized forest galagos with a distinct preference for feeding on or close to the floor in forests between the Niger R. and Congo R. These are greyish-brown galagos with russet tinges on the limbs. The pointed muzzle has a pale median stripe and the reddish eyes are set within well-defined mask-patches. Nipples = 2 + 2 + 2 = 6.

Sciurocheirus bound from one vertical support to another, clinging and leaping like a tree-frog. They land hands first, unlike other galagos, which land feet first or with all limbs simultaneously.

Given that their closest genetic relationship appears to be with *Otolemur* (Masters *et al.* 2007), there is the implication that their common ancestor had a wider ecological and geographic range than either descendant lineage. Furthermore, their current occupation of a restricted ecological niche in a restricted geographic region suggests contraction from a wider range of habitats and behaviours. The co-existence and probable competition of five other lorisooids might have influenced just such a contraction and refinement of niche. There are interesting implications for 'use of space' by these galagos, for understanding their preferred foraging zones and the physical structure of their micro-environment.

Colin P. Groves & Jonathan Kingdon

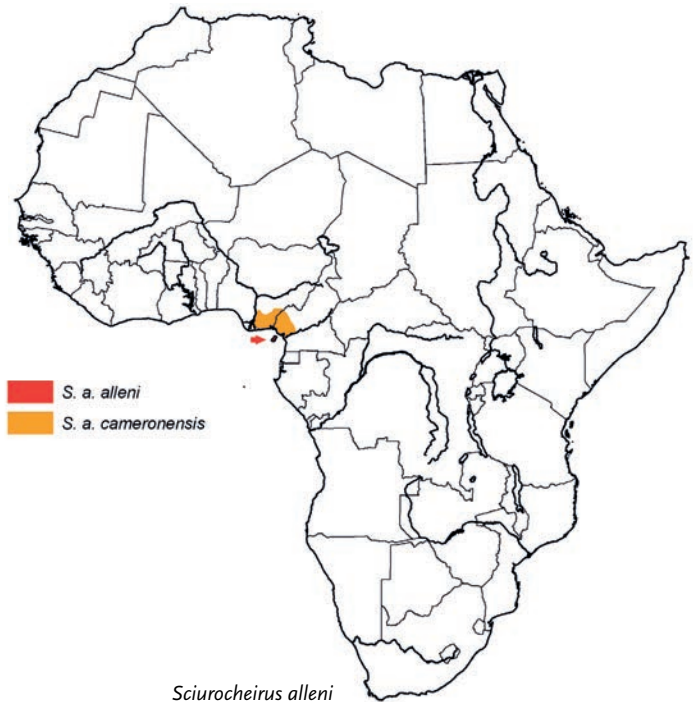

Sciurocheirus alleni ALLEN'S SQUIRREL GALAGO

Fr. Galago d'Allen; Ger. Allen-Buschwaldgalago

Sciurocheirus alleni (Waterhouse, 1838). Proc. Zool. Soc. Lond. 1837: 87 [1838]. Fernando Po (= Bioko I.) Equatorial Guinea.Bioko Squirrel Galago *Sciurocheirus alleni alleni*.

Taxonomy Polytypic species. Gray (1873) placed this species in a new genus, *Sciurocheirus* (squirrel galagos), but most recent authors (Jenkins 1987, Kingdon 1997, Groves 2001, 2005c) have kept *alleni* with the lesser galagos *Galago*. This species is, however, distinct from *Galago* in a number of characters, including the proportions of the skull (Hill 1953) and foot (Jouffroy & Gunther 1985). The vocalizations are also distinct from all other galagos (Ambrose 2003). Recent genetic studies place *alleni* in a clade with the greater galagos *Otolemur* spp. (Crovella *et al.* 1994, Masters *et al.* 1994, 2007). According to Bayes (1998), there is considerable genetic divergence between the squirrel galagos and the greater galagos, emphasizing their taxonomic distinctiveness; based on this evidence, *Sciurocheirus* has now been re-adopted as a full genus (Grubb *et al.* 2003, Nekaris & Bearder 2011). In recent taxonomies three subspecies were recognized, but *S. a. gabonensis* has now been reinstated to full species (Ambrose 1999, 2003) and is now widely recognized (Groves 2001, 2005c, Grubb *et al.* 2003, Nekaris & Bearder 2011). Synonym: *cameronensis*. Chromosome number: $2n = 40$ (Dutrillaux *et al.* 1982b).

Description Medium-sized galago of forests, vocalizing long 'whistles' either as single units, or in phrases of one to six descending units (Ambrose & Perkin 2000, Ambrose 2003). Sexes similar in colouration but ♂♂ probably slightly larger. Snout prominent with pale grey nose-stripe, which forms a broader patch on the forehead.

Cheeks, chin, throat, ventrum and inside of legs whitish to pale grey. Broad black eye-rings make a dark face-mask. Eyes chocolate-brown, large and rounded. Ears bare, black, front and back. Base of ears sometimes ringed with pale grey. Dorsum brown, grizzled dark greyish-brown or grey. Shoulders, flanks, and front and outside of limbs medium to bright rust. Hands and feet greyish-black. Breast-stripe red, about 4 mm wide, in some individuals. Tail evenly bushy, longer than (ca. 120%) HB length, dark grey to black, sometimes with whitish tip (T. Butynski pers. comm.). Old infant/young juvenile/old juvenile all have colour of adult (A. Croce & T. Butynski pers. comm.).

Geographic Variation

S. a. alleni Bioko Squirrel Galago. Bioko I. Larger (WT 300–455 g) than *S. a. cameronensis*. Long 'whistles' nearly always given in descending phrases (Ambrose & Perkin 2000, Ambrose 2003).

S. a. cameronensis Cross River Squirrel Galago. South-east Nigeria and SW Cameroon. Smaller (WT 220–355 g) than *S. a. alleni*. Long 'whistles' most commonly given as single units (Ambrose & Perkin 2000, Ambrose 2003). Variation exists in pelage colour. Some individuals on Mt Kupé, SW Cameroon, have a pale grey tail, which gets progressively paler distally. About 25% of individuals on Mt Cameroon, W Cameroon, have brown dorsum and tail, little or no rust on limbs and flanks, and no obvious eye-rings (Ambrose 1999).

Similar Species

Sciurocheirus gabonensis. Allopatric. South of Sanaga R. S Cameroon south to N Gabon. Colouration similar in Cameroon but redder in Gabon. Tail dark charcoal grey or black, sometimes distal ca.

3 cm is white. Readily distinguished by the contact and alarm call; short, rapid 'whistles' in phrases of 1–10 units (Ambrose 2003).

Distribution Endemic to western central Africa. Rainforest BZ. In forests on Bioko I., Equatorial Guinea, and between Niger R., SE Nigeria and Sanaga R., C Cameroon. *Sciurocheirus a. alleni* widespread on Bioko I. *Sciurocheirus a. cameronensis* in SE Nigeria at Elele and Oban Group Forest Reserves; in S Nigeria at Itu, Tombia, Wilberforce I. and Gbanraun (Bayelsa State); in SW Nigeria in Okomu Forest; in SW Cameroon at Korup Mundemba, Korup Nguti, L. Barombi (Mbo near Kumba), Mt Cameroon and Mt Kupé (Jewell & Oates 1969b, Eisentraut 1973, Bearder & Honess 1992, Butynski & Koster 1994, Ambrose & Perkin 2000, Ambrose 2003, E. Pimley pers. obs.).

Habitat High rainfall lowland, mid-altitude and montane forest. Prefers open understorey in primary forest and old secondary forest. Occurs in plantations and farms on Bioko I. and in Cameroon, but these visited primarily for foraging (Ambrose 2003, T. Butynski pers. comm.). In secondary forest at Elele, Nigeria (Oates & Jewell 1967), and in isolated trees and forest patches in grassland at Moka, Bioko I. (Jewell & Oates 1969b, T. Butynski pers. comm.). In degraded forest fragments around Itu and in Niger Delta swamp forest, S Nigeria (E. Pimley pers. obs.). Occurs from sea level to at least 2250 m on Bioko I. (Butynski & Koster 1994), and up to at least 2000 m in SW Cameroon (Ambrose 1999). Mean annual rainfall over the geographic distribution of *S. alleni* ranges ca. 2000–10,000 mm (T. Butynski pers. comm.). There are two 'dry' seasons on Bioko I.; Dec–Feb when mean monthly rainfall is <100 mm) and Jul–Aug when mean monthly rainfall is <500 mm).

Abundance Common in suitable habitat. At particularly high densities in montane forest; i.e. 14 ind/km² in secondary forest on Mt Kupé (Pimley 2002). During night censuses at Moka, Bioko I., encountered at the rate of 1.8 ind/h (n = 34 encounters; Ambrose & Perkin 2000), and 1.2 ind/h and 1.2 ind/km (n = 59 encounters; Croce 2009). Nocturnal surveys at other sites on Bioko I. typically yield encounter rates of 1–2 ind/h and 1–2 ind/km of night transect (T. Butynski pers. comm.).

Adaptations Nocturnal and arboreal but often comes to the ground to forage. Elongated hindlimbs and long tail for vertical clinging and leaping. Able to move rapidly by leaping several metres between vertical supports (\pm 10 cm diameter). Lands forelimbs first, then 'swivels' around the support and launches off with hindlimbs, often at 1–2 m above the ground. Usually forages close to the ground, but sometimes up to 15 m above ground; in SW Cameroon, 47% of observations at 0–2 m and 81% of observations <5 m (n = 152; Ambrose 1999). On Bioko I., at 0–2 m above ground during 47% of encounters, 2–5 m 29%, 5–10 m 24% (n = 34). Not observed >10 m above the ground (Ambrose & Perkin 2000). Another study on Bioko I. encountered *S. alleni* at mean height of 5.9 m (0–15 m, n = 30, Croce 2009). Hollow trees and lianas are preferred sleeping sites (Bearder *et al.* 2003). Liana tangles favoured for resting and 'parking' young.

The greater part of the range of *S. alleni* is in forests sustained by heavy rainfall deriving from the nearby Atlantic. It is probable

that the ecology, behaviour, reproduction and other physiological adaptations of *S. alleni* are finely attuned to this unusual and localized climate and that, as such, this species differs from its congeners in many subtle respects.

Foraging and Food Frugivorous, insectivorous. Mostly forages on, or close to, the forest floor where it feeds on fallen fruit and hunts for invertebrates. Arthropods grabbed with the hands. Fruit usually bitten first before being held in the hands. Often sits above swarming ants to catch invertebrates disturbed by driver ants *Dorylus* sp. (Ambrose 2003, T. Butynski pers. comm.). Stomachs of specimens in Nigeria contained fruit, insects and molluscs (Jewell & Oates 1969b). One stomach on Bioko I. held beetles and bones of small mammal (T. Butynski pers. comm.). Observed catching and eating a small bird at night on Bioko I. (A. Croce pers. comm.). Frequently observed in banana trees *Musa* sp. where the ripest fruits are selected. Eat ripe fruits of *Rothmannia* sp., False Nutmeg *Pycnanthus angolensis* in Cameroon (Pimley 2002) and Cape Fig *Ficus sur* and *Psychotria* sp. on Bioko I. (T. Butynski & A. Croce pers. comm.). In SW Cameroon, *S. a. cameronensis* ♂♂ travel (i.e. horizontal + vertical travel) an average of 2043 m/night (1825–2261, n = 2 animals), while ♀♀ travel an average 961 m/night (612–1825, n = 6 animals) (Pimley 2002).

Social and Reproductive Behaviour Solitary foragers, but two or three individuals sometimes travel together. In Cameroon, home-ranges are 2.84 ha (2.09–3.58) for two ♂♂ and 1.97 ha (0.60–3.37) for six ♀♀ (Pimley *et al.* 2005a). Groups of between two and seven ♀♀ associated with one central adult ♂. Copulations with outside ♂♂ probably also occur. Some adult ♀♀ sleep together in the same tree-hole on a regular basis. An adult ♂ and adult ♀ recorded sleeping within 10 m of each other. Sleeping partners associate with each other during nocturnal activity and overlap each other's ranges at similar times. Adult ♂ and adult ♀ interactions less frequent. No ♂–♂ interactions observed. Adult ♂ ranges do not overlap. Maturing ♀♀ commonly remain in the home-range area of their mother and can continue to share a sleeping site (Pimley 2002). One mating recorded where copulation was preceded by urine-marking of substrates by both partners. Male mounts ♀ in dorsoventral position and copulatory lock lasts about one hour (Pimley 2002). Mother carries infant by mouth for up to 45 days (S. K. Bearder pers. comm.).

Contact maintained by exchange of 'whistles'. Harsh, low frequency 'croak' used for long-distance contact. Long 'whistles', either as single units, or in phrases of one to six descending units, are characteristic of this species. Variations on this call are used for contact, spacing, cohesion and mild alarm. 'Whistles' that rise and fall in frequency two or three times, and which are interspersed with 'qwocks', are given in the context of high alarm (Ambrose & Perkin 2000, Ambrose 2003).

Reproduction and Population Structure Births probably occur throughout the year. Oestrous and pregnant ♀♀ trapped at various times of the year in Cameroon (Pimley 2002). Infants, juveniles and lactating ♀♀ seen on Mt Kupé in Mar and Apr and parked juveniles in Korup in early Apr. Pregnant and lactating ♀♀ observed on Bioko I. in Mar and Oct (Ambrose 2003, T. Butynski

pers. comm.). Sanderson (1940) recorded pregnant ♀♀ in Cameroon in Dec, Jan, May, Jun and Jul. Adult ♂:adult ♀ ratio in Cameroon is 1 : 2.7 (Pimley 2002).

Predators, Parasites and Diseases Uncertain, but main predators probably include various large owls *Bubo* spp., large snakes, genets *Genetta* spp., Two-spotted Palm Civets *Nandinia binotata*, domestic cats and dogs. Fraser's Eagle-owl *Bubo poensis* occurs throughout the range of *S. a. alleni*. The strong and prolonged alarm calls given by *S. a. alleni* in response to the presence of *B. poensis* suggests that this large forest owl is a major predator (T. Butynski pers. comm.). Analysis of blood samples in Cameroon reveal malaria parasites *Plasmodium falciparum* in *S. a. cameronensis* in Cameroon but no pathological symptoms observed (Pimley 2002). Small numbers sold in the bushmeat market in Malabo, Bioko I.; these are likely caught as a by-catch in traps set for larger species (T. Butynski pers. comm.).

Conservation IUCN Category (2012): Least Concern. Endangered as *S. a. alleni*. CITES (2012): Appendix II.

Locally abundant and more secure in montane forest, although this forest is reduced and fragmented. *Sciurocheirus a. alleni*, endemic to Bioko I. (2017 km²), has a distribution of <1700 km² (T. Butynski pers. comm.). Logging and creation of commercial plantations are responsible for habitat loss in SW Cameroon and SE Nigeria.

Lesley Ambrose & Elizabeth R. Pimley

Sciurocheirus makandensis sp. nov. MAKANDÉ SQUIRREL GALAGO

Fr. Galago écureuil de la Makandé; Ger. Makandé-Buschwaldgalago

Makandé Squirrel Galago *Sciurocheirus makandensis* adult.

Taxonomy Monotypic species. This is a new, previously unnamed, form discovered by L. Ambrose in 1993. Described (but not formally named) as a new species by Ambrose (1999, 2003). Recognized as a full species by Grubb *et al.* (2003) and Nekaris & Bearder (2007, 2011). Compared to other *Sciurocheirus* spp., *Sciurocheirus makandensis* has a distinct vocal repertoire, facial markings and pelage colouration. Synonyms: none. Chromosome number 2n: not known.

Holotype Adult ♂ in photograph in Figure 8b in Ambrose (2003).

An adult ♂ *Sciurocheirus makandensis* is also depicted in Figure 3.1E of Nekaris & Bearder (2007) and in Figure 4.2E of Nekaris & Bearder (2011).

Type locality Makandé, Forêt des Abeilles, SE Gabon, south of Ogooué R. Makandé is at 00° 40' 39" S, 11° 54' 35" E.

Diagnosis Unique loud-call repertoire and loud-call profiles, as detailed in Ambrose (1999, 2003). The alarm unit-whistle is particularly diagnostic; in phrases of 1–5 units with a strong emphasis on the first unit which comprises two audible sub-units. Black eye-rings broader than in other *Sciurocheirus* spp. Black extends from eye-rings down sides of nose and borders a pale grey nose-stripe. Overall a more reddish galago than other *Sciurocheirus* spp.

Sciurocheirus makandensis

Measurements No specimens available for measurement.

Etymology The species name 'makandensis' acknowledges the site of the holotype, Makandé, Forêt des Abeilles, SE Gabon.

Description Medium-sized, forest galago that gives short, fairly rapid 'whistles' in phrases of one to five units with a strong emphasis on the first unit. Sexes similar in colour and pattern of pelage. Eye-rings broad and black with the black extending down the sides of the nose and bordering the pale grey nose-stripe. Crown and facial area russet. Ears exceptionally large, black at base and dark grey distally. Cheeks, chin, throat, chest, belly and insides of the legs greyish-white. Russet colour can suffuse the entire ventrum in mature individuals giving the impression of a reddish rather than greyish galago. Back slate-grey. Pronounced rust colouration on flanks, and on front and outside of limbs. Dorsum of hands and feet russet. Tail typically dark slate-grey proximally and black over distal two-thirds, although this colouration varies with age (Ambrose 1999, 2003).

Geographic Variation Known only from a small area, the Forêt des Abeilles. No systematic variation observed.

Similar Species

Sciurocheirus gabonensis. Allopatric, perhaps parapatric. North of Ogooué R., N Gabon. Contact and alarm call: short, rapid 'whistles' in phrases of 1–10 units. Dorsum mid-grey to reddish-brown in Gabon part of range. Tail dark charcoal-grey or black, sometimes distal ca. 3 cm is white (Ambrose 1999, 2003).

Distribution Endemic to C Gabon. Rainforest BZ. Distribution poorly known. Only identified in Forêt des Abeilles, C Gabon, south of Ogooué R. Might be endemic to this forest or might extend into the adjacent Lopé Reserve, other areas of C Gabon, or even into Congo.

Habitat Forêt des Abeilles is medium altitude (200–700 m) forest of the Guinea-Congolaise type. Mainly primary, closed canopy forest on hilly ground. There are some small, selectively logged areas. Dominant tree families are Caesalpiniaceae (Leguminosae) and Burseraceae (Gesnot 1994). Mean annual rainfall ca. 1750 mm. Two wet seasons (Oct–Dec, Mar–May). Occupies the lower forest strata. Ninety-seven per cent of 37 observations <5 m above ground

Abundance At low densities. More often heard than seen.

Adaptations Nocturnal and arboreal but often forages on the ground. *Sciurocheirus makandensis* has not been studied. Adaptations probably similar to Allen's Squirrel Galago *Sciurocheirus alleni*. It is possible, although perhaps remotely, that the localized occurrence of a strongly erythristic form of *Sciurocheirus* might be influenced by the chemistry of local soils or foods. In this context, it should be noted that a form of Beecroft's Anomalure *Anomalurus beecrofti fulgens* has rufous colouring over much of its body and that this form is also locally distributed in Gabon.

Foraging and Food Omnivorous. Feeds on fruit, including fallen fruit, and invertebrates. Sometimes sits on a horizontal branch just above ants that are carrying invertebrate prey. It seems that the galagos, like many forest-floor birds, benefit both by seizing food items from the ants and by catching invertebrates disturbed by the swarming ants.

Social and Reproductive Behaviour Solitary foragers but up to four individuals sometimes move together through the forest. Animals seen together at dusk suggests that sleeping sites are shared. Use contact vocalizations to maintain regular social contact with familiar animals when dispersed. No information on reproductive behaviour. Harsh, low frequency 'croaks' used for long distance

contact. The characteristic (diagnostic) calls of *S. makandensis*, used in the context of contact and alarm, are short 'whistles' in phrases of one to five units with a strong emphasis on the first unit. These calls are frequently interspersed with 'growls'.

Reproduction and Population Structure Not studied. Immature individuals observed in Aug and Dec.

Predators, Parasites and Diseases No information. Probably predators include large owls *Bubo* spp., large snakes, genets *Genetta* spp., Two-spotted Palm Civet *Nandinia binotata*, Central African Linsang *Poiana richardsoni* and African Golden Cat *Profelis aurata*. One *S. makandensis* became very alarmed at the presence of a *N. binotata*. No information on parasites and diseases.

Conservation IUCN Category (2012): Not assessed. CITES (2012): Appendix II.

If endemic to Forêt des Abeilles, then *S. makandensis* will probably be assessed as Vulnerable; having a low and probably declining population, and a geographic range of <20,000 km². It should be noted that some other species of mammal are known only from the Forêt des Abeilles/Lopé Reserve region, including Duchailu's Rope Squirrel *Funisciurus duchailui* (Brugière *et al.* 2005a) and *A. solatus* (Harrison 1988b). Therefore, the effective protection of these two forests will do much to ensure the long-term conservation of these three species – and many others in this species-rich region. *S. makandensis* is not hunted by humans. Research is needed to determine the conservation status of *S. makandensis* as well as to obtain information on its ecology and behaviour.

Sciurocheirus gabonensis GABON SQUIRREL GALAGO

Fr. Galago écreuil du Gabon; Ger. Gabun-Buschwaldgalago

Sciurocheirus gabonensis (Gray, 1863). Proc. Zool. Soc. Lond. 1863: 146. Gabon.

Taxonomy Monotypic species. Gray (1863) described this galago as a distinct species but most subsequent authors have regarded it as synonymous with *Galago alleni* (Hill 1953, Jenkins 1987). Described as a subspecies of *G. alleni* by Groves (1989) and Kingdon (1997), this taxon has since been re-elevated to full species (Ambrose 1999) and widely accepted (Groves 2001, 2005c, Grubb *et al.* 2003, Nekaris & Bearder 2007, 2011). Synonym: *batesi*. Chromosome number: not known.

Description Medium-sized galago with short, rapid 'whistles' in phrases of 1–10 units (Ambrose 2003). Sexes similar in colouring and size. Pale nose-stripe extends as a broader patch on the forehead. Cheeks, chin, throat and ventrum pale grey. Eye-rings black. Ears

large and rounded, dark brown to black. Dorsum variable among populations, from mid-grey to reddish-brown. Forelimbs, hindlimbs and flanks rust. Pelage redder in Gabon. Tail evenly bushy, charcoal-grey to black, occasionally distal ca. 3 cm is white.

Geographic Variation None recorded.

Similar Species

Sciurocheirus alleni cameronensis Cross River Squirrel Galago. Allopatric at Sanaga R., Cameroon. Distinguished by their calls. Various long, drawn-out 'whistles' given either as single units or in descending phrases of up to six units (Ambrose 1999, 2003, Ambrose & Perkin 2000).

Gabon Squirrel Galago *Sciurocheirus gabonensis* adult.

Sciurocheirus makandensis Makandé Squirrel Galago. Allopatric south of Ogooué R., C Gabon. Holotype from Fôret des Abeilles, C Gabon. Dorsum dark slate-grey. Ventrums and flanks often with extensive russet. Tail slate-grey at base with distal two-thirds black. Calls fairly rapid 'whistles' in phrases of one to five units, with a strong emphasis on first unit (Ambrose 1999, 2003).

Distribution Rainforest BZ. Endemic to western central Africa. In forest between the Sanaga R. and Ogooué R. from S Cameroon, through Rio Muni (Equatorial Guinea), to N Gabon. Distribution into S Gabon uncertain. Eastern extent probably bounded by the Congo R. and Ubangui R., Congo (Nash *et al.* 1989). Likely present in Congo and Central African Republic but no records as yet. In S Cameroon in Lobéké Reserve, Dja Reserve and Ebom (near Kribi) and in C Gabon at Makokou (Ambrose 2003). Also near Evinayong, Rio Muni (Jewell & Oates 1969b).

Habitat Low to medium altitude forest (up to 800 m). Deciduous, semi-deciduous and littoral forest in Cameroon and evergreen forest in Gabon. Prefers the understorey of primary forest but also in secondary forest and cultivated areas.

Mean annual rainfall 1600 mm at Dja Reserve (Laclavère 1980), 1650 mm at Lobéké Reserve (Fimbel & Fimbel 1996) and ca. 1700 mm at Makokou (Charles-Dominique 1977).

Abundance Occurs at low densities in most forests. Present at 15–20 ind/km² at Makokou, C Gabon (Charles-Dominique 1977).

Sciurocheirus gabonensis

Adaptations Nocturnal and arboreal. See Charles-Dominique (1977).

Foraging and Food Omnivorous. Forages on, or close to, the forest floor. In C Gabon an analysis of stomach contents ($n = 12$) revealed a diet of 73% fruit and 25% animal prey. Prey species included: beetles (25%), snails (15%), moths (15%), frogs (8%), ants (8%) and spiders (8%). Termites, centipedes and caterpillars also taken (Charles-Dominique 1977). Contents of one stomach in Rio Muni contained a large number of termites (Jewell & Oates 1969b).

Social and Reproductive Behaviour Solitary foragers but social, maintaining vocal contact with dispersed animals. Females have home-ranges of ca. 10 ha, the size being related to food availability. Males have larger home-ranges (30–50 ha) that overlap those of several ♀♀ and are determined by the locations of the ♀♀. In C Gabon, the range of one ♂ overlapped the ranges of at least eight ♀♀, and he could visit several ♀♀ in a night. Once a ♀ comes into oestrus, the ♂ remains with her exclusively for some days. Females are sedentary; ♂♂ disperse at puberty. Infrequent agonistic behaviour occur between ♂♂. Tree hollows are used as nesting sites. Two to three ♀♀ can sleep together with their offspring. Males always sleep separately. Substrates marked by urine-washing and genital secretions (Charles-Dominique 1977). As for other *Sciurocheirus* spp., a low frequency 'croak' is used for long-distance contact. Short, rapid 'whistles' in phrases of 1–10 units, used in the contexts of contact and alarm, are characteristic of *S. gabonensis* (Ambrose 2003).

Reproduction and Population Structure On the basis of limited data from C Gabon, births occur throughout the year with a slight peak in Jan (dry season). Gestation is 133 days; birth-weight 24 g. Usually a single infant is born, but occasional twin births occur. Infants carried in the mother's mouth from three to seven days after birth and are 'parked' close to the foraging mother. Mothers

and infants spend the day in a tree nest-hole. Adult body-weight is reached at 6–8 months of age and sexual maturity attained at 8–10 months (Charles-Dominique 1977). Birth ♂ : ♀ ratio 1 : 1, but adult ratio 1 : 4. This might be due to intense competition among ♂♂. Males travel greater distances and, therefore, may be at greater risk of predation (Charles-Dominique 1977).

Predators, Parasites and Diseases Uncertain. Large snakes, Two-spotted Palm Civet *Nandinia binotata*, Central African Linsang *Poiana richardsoni* and large owls (perhaps especially Frasher's Eagle-owl *Bubo poensis*) probably prey on *S. gabonensis*. Likely vulnerable to terrestrial carnivores such as Leopard *Panthera pardus*, African Golden Cats *Profelis aurata*, African Civet *Civettictis civetta* and genets *Genetta* spp., as *S. gabonensis* frequently forages in the undergrowth. Potential predators are harassed by following and uttering intense alarm calls. Unless they have been surprised, adult *S. gabonensis* can easily leap away, but infants are vulnerable. Parked infants remain immobile in situations of extreme danger. Only if the branch is shaken will they release their hold and drop to the ground uttering a distress call (Charles-Dominique 1977). No information on parasites and diseases.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Has a broad range over an almost contiguous forest block in S Cameroon, Congo, Rio Muni and N Gabon. Generally occurs at low densities. There is habitat degradation and destruction in some areas. Not hunted by humans.

GENUS *Galago*

Lesser Galagos

Galago É. Geoffroy, 1796. Mag. Encyclop. 1: 49.

The 'lesser galagos', genus *Galago*, as used in this volume, currently comprises four species of short-faced, gum-eating galagos that live mainly outside the main forest block, or, in the case of the Spectacled Lesser Galago *G. matschiei*, in some restricted forest areas in eastern central Africa.

Species within *Galago* are of medium size with a grey or brownish back, round head, large eyes, dark eye-mask, short muzzle, pale nose-stripe, and tails that are not densely furred. They utter short

phrases or single cries that have a regular rhythm repeated many times. Volume depends upon the level of excitement in the caller. All are agile bounders, landing feet first.

Separation of the 'dwarf galagos' *Galagoides* from *Galago* is still controversial; Groves (2001, 2005c) retained all the small species (here provisionally classified as *Galagoides*) within a much enlarged treatment of *Galago*. This approach was supported by cladistic analysis of mainly morphological traits but Groves acknowledged

Southern Lesser Galago *Galago moholi*.

Southern Lesser Galago *Galago moholi*.

the difficulty of separating convergence and parallelism in a group of primates with exacting demands on their specialized anatomy. In the meantime, molecular studies by DelPero *et al.* (2000), Roos *et al.* (2004), Stiner & Turmelle (2003) and Masters *et al.* (2007) reveal complex phylogenetic trees that are consistent in finding *Galago* (in the restricted sense used here) the most recently evolved branch, well separated from the small galagos, which derive from older, more conservative stock (see figure p. 387). Vocal repertoires also support this separation (Bearder *et al.* 1995). We, therefore, join Olson (1979), Nash *et al.* (1989), Bearder *et al.* (1995), Kingdon (1997), Grubb *et al.* (2003), Masters *et al.* (2007) and Nekaris & Bearder (2011) in recognizing both *Galago* and *Galagoides*.

Masters *et al.* (2007) conclude that the non-forest species are the most derived in this group while the genetic profile of *G. matschiei*

puts it in an intermediate position between the dry-country *Galago* spp. and the forest-dwelling Needle-clawed Galagos *Euoticus* spp. *Galago matschiei* might, therefore, represent an approximation of the common ancestry of both genera and its inclusion in *Galago* could be semi-arbitrary because it also shares traits, such as enlarged orbits and pointed nails, with *Euoticus*.

The three non-forest species in *Galago* inhabit the entire woodland, treed savanna and dense bushland zones of tropical Africa; Northern Lesser Galago *G. senegalensis* and Somali Lesser Galago *G. gallarum* mainly north of the Equator on a centre–west axis, and South Lesser Galago *G. moholi* south of the Equator on a longitudinal south–east axis. They are commonest in woodlands dominated by *Acacia*, *Brachystegia*, *Isoberrlinia* and *Commiphora*, at lower densities, *Mopane* and *Colophospermum*. Gum and insects are the main foods. Other animal foods and fruits are more marginal but can be important locally and seasonally. Where tree hollows are present they are used for shelter but tree forks and branch tangles are more generally available. Where neither hollows nor trunks are available, *Galago* spp. may make a leaf shelter or take over an old bird's nest as a day-time retreat. Fires represent a major hazard, mainly because they expose the galagos to hawks and other predators as they flee.

Recruitment rates are high, with ♀♀ commonly bearing one or two young twice a year. Home-ranges in ♀♀ and ♂♂ overlap. Scent-marking with urine, genital rubbing and saliva-dribbling is most intense around sleeping sites but is maintained at favourite posts scattered around the home-range. Gestation is about 130 days and the young develop fast, moving out of the nest at two weeks and becoming independent at about two months.

The most striking adaptation of the lesser galagos is the extraordinary speed when jumping or running during escape or while hunting active prey. They have the physiological ability to extract nutrients and energy from the gums, which buffer them over seasonal droughts.

Jonathan Kingdon

Galago senegalensis NORTHERN LESSER GALAGO (SENEGAL LESSER GALAGO, SENEGAL LESSER BUSHBABY)

Fr. Galago du Sénégal; Ger. Senegal-Galago

Galago senegalensis É. Geoffroy, 1796. *Mag. Encyclop.* 1: 38. Senegal.

Taxonomy Polytypic species. Originally, only the species *Galago senegalensis* was recognized (Schwarz 1931a). Seven species have since been split from this taxon: Southern Lesser Galago *Galago moholi*, Somali Lesser Galago *Galago gallarum*, Spectacled Lesser Galago *Galago matschiei*, Zanzibar Dwarf Galago *Galagoides zanzibaricus*, Mozambique Dwarf Galago *Galagoides granti*, Malawi Dwarf Galago *Galagoides nyasae* and Kenya Coast Dwarf Galago *Galagoides cocos*, based on differences in vocalizations, genetics and morphology of the body, cranium, penis and hand pads (e.g. Zimmermann *et al.* 1988, Nash *et al.* 1989, Zimmermann 1990, Bearder 1999, Anderson *et al.* 2000, DelPero *et al.* 2000, Masters & Bragg 2000, Groves 2001, 2005c, Anderson, M. J. 1999, 2001, Grubb *et al.* 2003, Nekaris & Bearder 2011). All species can be distinguished by their

species-specific advertisement call. It may well be that additional cryptic species will be recognized from within *G. senegalensis* as this remains a widespread taxon with considerable variation (Masters & Bragg 2000). Here we follow Groves (2001, 2005c) in recognizing four subspecies. Synonyms: *acaciarum*, *albipes*, *braccatus*, *calago*, *camerounensis*, *dunni*, *galago*, *geoffroyi*, *pupulus*, *sennariensis*, *sotikae*, *teng*. Chromosome number: 2n = 36, 37, or 38 (Ying & Butler 1971, De Boer 1973a, b, Romagno 2001).

Description Medium-sized, long-limbed galago with long, short-haired tail. Low pitched 'woo' (or 'honk') advertisement (loud) call distinctive. Sexes similar in colour. In the wild, adult ♀♀ weigh ca. 89% as much as adult ♂♂ (Nash *et al.* 1989). Dorsum

Northern Lesser Galago *Galago senegalensis* adult.

of head, neck, forelimbs and forefeet grey or brownish-grey. Eye-rings dark, complete. Inter-ocular stripe white. Ears greyish or flesh-coloured. Ventrums pale yellowish-white. Outer surface of hindlimbs and hindfeet pale to bright yellow. Tail grey to brown. Penile spines (Anderson 2000) and hand (volar) pads (Anderson 1999) diagnostic. Young similar to adult in colour. *Galago senegalensis* 'woo' call is distinctive as it is the lowest-pitched of all lesser galago advertisement calls. Photographs of *G. senegalensis* from many sites in Kenya and Tanzania available at: www.wildsolutions.nl

Geographic Variation Subspecies difficult to distinguish based on published data (Schwarz 1931a, Hill 1953, Kingdon 1997, Groves 2001, Grubb *et al.* 2003). Clear diagnosis requires sophisticated phylogeographic study taking into account vocalizations, behaviour, morphology and genetics. Ranges and sample sizes for the data on means presented in this section are given under Measurements.

G. s. senegalensis Senegal Lesser Galago. Senegal and Gambia, east across the White Nile to Karamoja, Uganda, to Mt Elgon, Kenya. Limited in south by forest belt and in north by Sahara. HB short

Lateral and palatal views of skull of Northern Lesser Galago *Galago senegalensis* adult.

(mean 164 mm). Ears medium (mean 40 mm). Lower parts of hindlimbs pale yellow. Tail grey, brown distally.

G. s. braccatus Kenya Lesser Galago. Highlands of C and S Kenya and N Tanzania east of Eastern Rift Valley to Indian Ocean. South through the Tsavo region to the Pangani R and Mt Meru. Northern limit undetermined. HB short (mean 164 mm). Ears medium (mean 38 mm). Front of limbs bright yellow or russet. Tail brown.

G. s. dunni Ethiopia Lesser Galago. Ethiopian Plateau, Ogaden and Somalia. Limits of range unknown. Limit coincident in east and south with that of *G. gallarum*, and in west with *G. s. senegalensis*. HB longest (mean 188 mm). Ears shortest (mean 35 mm). Hindlimbs pale yellow. Tail grey, brown distally.

G. s. sotikae Uganda Lesser Galago. Ankole, Uganda, to south of L. Victoria (Mwanza), Tanzania, to Telek R., Kenya. Recently observed in Grumeti G. R. (in western Serengeti), in L. Manyara N. P., near Dodoma, and in Mikumi N. P., Tanzania. As such, T. Butynski & Y. de Jong (pers. obs.) suspect that the southern limit is to at least Rufiji R., SC Tanzania. HB medium-long (mean 180 mm). Ears longest (mean 43 mm). Dorsum more brownish-grey than other subspecies. Hindlimbs without yellow wash. Tail grey-brown, browner distally.

Similar Species

Galago gallarum. L. Turkana, NW Kenya, east to Shebeyli R. of Ethiopia and Somalia, south-east to Tana R., Kenya. Back brownish-buff with pinkish tinge. Narrow dark brown eye-rings often incomplete laterally. Face and throat whitish. Tail mostly black. Ears black, short (mean 35 mm). Hindfoot short (mean 62 mm). Distinctive 'quack' loud-call (Butynski & De Jong 2004).

Galago matschiei. Lualaba R., DR Congo, east to E Uganda. Forest species. Dark brown. Eye-rings black and large. Nails keeled and pointed. Distinctive 'churr' call (= 'woo' = 'honk') higher-pitched and of longer duration.

Galago moholi. Northern limit is south end L. Victoria and C Tanzania. Very similar to *G. senegalensis*. Averages slightly smaller but much overlap in body measurements: HB mean 150 mm (n = 826) vs. 165 mm (n = 508) for *G. senegalensis*; T mean 228 mm (n = 824) vs. 255 mm (n = 498) for *G. senegalensis*;

HF mean 59 mm ($n = 812$) vs. 67 mm ($n = 498$) for *G. senegalensis*; WT mean 158 g ($n = 477$) vs. 206 g ($n = 388$) for *G. senegalensis* (Olson & Nash 2002). Thus, body size alone cannot be used to distinguish *G. moholi* from *G. senegalensis*. Inter-ocular stripe off-white. Hindlimbs less yellow or without yellow. Distinctive 'bark' loud-call mostly of 2–4 units, higher-pitched and shorter-duration than 'woo'.

Distribution Endemic to tropical Africa. Guinea Savanna, Sudan Savanna, Somalia–Masai, Afromontane–Afroalpine, and Zambezan BZs. Over most of its range *G. senegalensis* is the only small galago in savanna, thorn scrub and woodland. Limits of distribution poorly known. See Geographic Variation. Broad distribution across Africa from Senegal (ca. 16° N) to Gulf of Aden (ca. 15° N) in area between Sahara and coastal forest in west, and Congo Basin forests on the south. Present in suitable habitat over much of East Africa (Nash *et al.* 1989) south to at least L. Rukwa and Udzungwa Mts (Rovero *et al.* 2009).

Habitat Savanna, thorn scrub, open woodland and riverine woodland over most of its range, but also in closed forest east of L. Victoria (the most densely forested part of its range) (Nash *et al.* 1989, Svensson & Bearder 2012). Altitude and rainfall limits poorly documented; ca. 350–1200 mm annual rainfall. In Kenya known from near sea level to at least 2400 m (Mau F. R.) (T. Butynski pers. obs.). Closely associated with various *Acacia* spp. In *Terminalia* and *Combretum* bushland, and *Isoberlina* and *Julbernardia* woodland (Kingdon 1971, 1997). Not found in areas of long grass, perhaps due to fire (Haddow & Ellice 1964).

Abundance Locally common. Densities in moist Whistling Thorn *Acacia drepanolobium* and Fever Tree *Acacia xanthophloea* woodland in Laikipia, C Kenya, can be >20 ind/ha. Densities are usually much lower than this, however, with far fewer than 1 ind/ha in the drier, more scrubby habitats, and at the highest altitudes in closed canopy montane forest (T. Butynski pers. obs.). For example, surveys in riverine woodland and bush habitats in Laikipia yielded densities of 0.4–2.4 ind/ha, with highest density in *A. xanthophloea* woodland and lowest density in *Acacia etbaica* bushland (Off *et al.* 2008). At Mutara Ranch, Laikipia, another site dominated by *A. xanthophloea* and *A. drepanolobium*, present at ca. 1.5 ind/ha (Nash & Whitten 1989).

Adaptations Nocturnal and arboreal. Locomotor pattern involves leaps between supports and resting, usually with the body in a relatively vertical position (similar to *G. moholi* [Crompton 1984] and *G. gallarum* [Butynski & De Jong 2004]). Bipedal hopping when on the ground. In Laikipia, found at a mean height of 7.4 m (S.D. 6.6, $n = 185$ encounters); on ground 1% of time and <10 m high 59% (Off *et al.* 2008). Based on gut transit time and other indicators, gut adaptations for digestion of acacia gums has been suggested (Nash 1989). Predator and prey detection, and localization in a three-dimensional dark world, associated with well-developed visual and hearing systems. As determined by conditioned responses, the smallest determinable difference in visual depth corresponds to an angle of 42° , and visual acuity is $04^{\circ}28'$ of arc. This is greater than in rats, cats or Megachiroptera, but less than in diurnal anthropoid primates (Treff 1967). Ears highly mobile and

can move independently of each other. Hearing, as determined by the classically conditioned suppression of licking, 250–64,000 Hz. This is much broader than in anthropoid primates, which have high frequency limits falling between 17,600 and 49,500 Hz (Heffner *et al.* 1969, Heffner 2004).

In Karamoja, Uganda, *G. senegalensis* inhabits tree-holes, often 1–2 m above ground, especially in hollow rotten branches leading upwards from a hole. Also inhabits unoccupied man-made beehives (hollowed out sections of trees hung 5–10 m above the ground). Leaf nests rarely constructed in N Karamoja, but common on Tanzania coast where thicket habitat contains few large trees (Haddow & Ellice 1964). In *A. drepanolobium* scrubland in Laikipia, leaf nests 3–4 m above ground in trees with the densest foliage (e.g. *Scutia myrtina*, *Maerua triphylla*). Leaves for nest construction carried in the mouth. Nest a loose bundle of leaves among dense foliage of thin branches. Construction takes about 30 min. Also, nests in hollow boles and branches of short, stout trees (e.g. *M. triphylla*). One entrance hole only 35 cm above ground (T. Butynski & J. Kalina pers. obs.). Also in Laikipia, found sleeping in dense *Grewia* spp. shrubs (Nash & Whitten 1989) and in dense *Acacia mellifera* shrubs (Off *et al.* 2008). Uses wooden nest boxes placed for birds. One ♀ with young used abandoned nest, 7 m above ground, of White-bellied Go-away-birds *Corythaixoides leucogaster* (J. K. Waithaka, J. Kalina & T. Butynski pers. obs.). Nest at Naivasha in dead hollow limb (73 cm circumference) 5 m above ground. Diameter of entrance hole 5 cm (T. Butynski & Y de Jong pers. obs.). See Svensson & Bearder (2012) for data from The Gambia.

Foraging and Food Omnivorous. Active all night on the Equator in Laikipia, from dusk (ca. 18:45h) to just prior to dawn (ca. 05:30h). Moves at least 600 m/night (J. K. Waithaka pers. comm.), suggesting a home-range of at least 4 ha, probably much larger at some sites (T. Butynski & J. Kalina pers. obs.). In a brief study, animals foraged in trees and on the ground, and covered open

spaces of up to 50 m (by bipedal hopping) to move between foraging sites (Nash & Whitten 1989). No detailed study of the diet, but diet appears similar to that of *G. moholi* (Bearder & Doyle 1974a, Bearder & Martin 1980). Stomach contents of wild animals in Kenya held a variety of insects and some vegetable matter (Haddow & Ellice 1964). Coleoptera and Lepidoptera (caterpillars) made up the bulk of stomach contents ($n = 103$). Spiders and scorpions also found. Captures winged termites (alates) on the ground. Fruits of Desert Date *Balanites aegyptiaca*, Tamarind *Tamarindus* sp. and *Sclerocarya* sp. eaten (Kingdon 1971). *Acacia drepanolobium* and *A. xanthophloea* gum eaten in Kenya, probably extensively, at least during the dry season (Nash & Whitten 1989, J. K. Waithaka, J. Kalina & T. Butynski pers. obs.). Other acacia gums are probably used in other localities. Eats nectar from Baobab *Adansonia digitata* and other flowers, and may be a pollinator (Root 1973). See Svensson & Bearder (2012) for data from The Gambia.

Social and Reproductive Behaviour Solitary or in small groups. In Laikipia, of 123 encounters, 81% solitary, 16% pairs, 3% groups of three (Off *et al.* 2008). In Uganda, nesting groups of 1–6 animals (including immatures) usually found with either one or no ♂ (Haddow & Ellice 1964). One bird nest box in Laikipia was occupied by three animals (T. Magor & T. Elliot pers. comm.). Usually forage alone but sometimes in groups of up to three. In captivity courting ♂♂ chase ♀♀. Copulation durations range from a few seconds to ten minutes. A pair may mate repeatedly for the 24–48 h the ♀ is receptive (L. T. Nash & E. Zimmermann pers. obs.). Partner preferences during the juvenile period suggest, as in other galagos, that ♂♂ disperse from the natal range more often than ♀♀ (Nash 1993).

Most secondary references to the behaviour of *G. senegalensis* refer to studies of *G. moholi* in South Africa (e.g. Bearder & Doyle 1974a, Bearder 1987, Pullen *et al.* 2000). *Galago moholi* ♂♂ and ♀♀ form overlapping territories. Females may be intolerant of other adult ♀♀ in their ranges. Males appear more tolerant of other ♂♂, provided one ♂ is smaller and/or submissive. Although it is possible to place unrelated, same-sex adults of *G. senegalensis* in the same captive social group, aggression is most likely between same-sexed adults, and the most stable captive groups are formed from the descendants of a single pair (Nash 1993, E. Zimmermann pers. obs.). In an experiment that examined the effects of subject sex, intruder sex and mate presence/absence on behaviour, ♀♀ were more interested in ♀ intruders and did not alter their behaviour toward an intruder in the presence of their mate (Glick 1993). In contrast, ♂♂ were more interested in ♀ intruders when the mate was absent, but in ♂ intruders when the mate was present (possible mate-guarding). Females seemed more concerned with a resource competitor, whether or not the ♂ they lived with was present during the test. In captivity aggressive behaviours consist of chasing, grappling and biting that can lead to severe wounding. Such behaviour can be persistent once initiated. Submissive animals flee, often to the floor, and will vocalize when grappling or bitten. Multiharmonic screams, with variable frequency and temporal patterns, are given under such circumstances (L. T. Nash & E. Zimmermann pers. obs.).

In Laikipia, ♀♀ with young nest away from conspecifics (J. K. Waithaka pers. comm.). In captivity, reproduction often improves by separating the mother and neonate from other animals (L. T.

Nash pers. obs.). Successful reproduction in captive animals also occurred in a family group consisting of a breeding ♂, two breeding ♀♀ (mother and daughter) and four offspring ♂♂, of which two were sexually mature (E. Zimmermann pers. obs.). Sometimes in a group where mother and adult daughter have infants at the same time, the grandmother may nurse the grandchild, suggesting that cooperative breeding may occur (Kessler & Nash 2010). In contrast, at parturition ♀♀ may become unusually aggressive to cage mates (including previous offspring). This may correspond to the habit in the Large-eared Greater Galago *Otolemur crassicaudatus* and *G. moholi* of the mother ceasing to join her usual sleeping partners around the time of parturition (Sauer & Sauer 1963, Bearder & Doyle 1974a, Bearder 1987).

Galago senegalensis has an extensive vocal repertoire, with 18 spectrographically different call types used by adults of both sexes. This indicates the importance of the acoustic domain for social communication (Zimmermann 1985, 1989, Zimmermann *et al.* 1988). Short, high frequency ‘zek’ and ultrasonic calls by infants separated from their mothers alert the mother and lead to her sudden vocal and phonotactic responses (Zimmermann 1981). High frequency and ultrasonic calls might have evolved as an anti-predator strategy, since raptors are insensitive to this frequency range. During ontogeny these calls develop gradually into the low frequency species-specific contact or loud-calls. Loud-calls used in contact and alarm situations are the most prominent calls of the species’ repertoire (Zimmermann 1985, Bearder *et al.* 1995, Anderson *et al.* 2000, Svensson & Bearder 2012). Inter-specific differences in fundamental frequency and phonological syntax are important for distinguishing *G. senegalensis* and *G. moholi*. *Galago senegalensis* also uses urine-marking extensively, which may both enhance grip and leave chemical signals for conspecifics. Captive ♂♂ react differently to the urine of ♂♂, non-oestrous ♀♀ and oestrous ♀♀ (R. Carpetis pers. comm., L. T. Nash pers. obs.).

Infants carried in mother’s mouth, not clinging to her body. Mother ‘parks’ infant on a limb for the night and collects infant prior to dawn (Bearder *et al.* 2003). The same ‘parking places’ used repeatedly (J. K. Waithaka pers. comm.).

Reproduction and Population Structure Based on embryos of collected animals, two birth seasons/year in Sudan (10–12°N) ($n = 36$) and in N Karamoja, N Uganda (04°N) ($n = 66$) (Haddow & Ellice 1964, Butler 1967). In Karamoja this corresponds with births in Feb–Mar (late dry season) and Jun–Jul (peak wet season), while in Sudan birth peaks are probably in Mar (end dry season) and Dec (mid-dry season). As in *G. moholi* (Izard & Simons 1987), birth seasonality is lost under constant photoperiod in captivity (L. T. Nash pers. obs.). Also, no birth seasonality observed in captivity under the changing photoperiod of the northern hemisphere (in S Germany) with unrestricted food (E. Zimmermann pers. obs.). This suggests that seasonal reproduction is induced either by changing temperatures, or by a combination of changing temperatures and food availability.

Singletons are usual and twinning uncommon in *G. s. braccatus* and *G. s. senegalensis* (Haddow & Ellice 1964, Butler 1967, Izard & Nash 1988, Zimmermann 1989). Captive *G. senegalensis* may undergo long periods of anoestrous, during which the vagina remains sealed. Gestation averages 141 days \pm 2 days in both of two samples, one

from a captive colony of *G. s. braccatus* (n = 12) and one from a captive colony of *G. s. senegalensis* (n = 23) (Izard & Nash 1988, Zimmermann 1989). Compared to *G. moholi*, *G. senegalensis* has a longer gestation period (ca. 114%) and only occasional twinning (8% of litters vs. 41%) (n = 62 for *G. senegalensis*, n = 103 for *G. moholi*). These are major criteria separating the two taxa at the species level (Izard & Nash 1988).

Mean birth-weight of singletons is 19 ± 2.6 g (n = 40). A fertile postpartum oestrus can occur in both the wild and in captivity, leading to the co-occurrence of pregnancy and lactation (Haddow & Ellice 1964, L. T. Nash & E. Zimmermann pers. obs.). Captive ♀♀ reach sexual maturity (first vaginal opening) at 372 days (S.D. = 112, n = 12). This might be altered by birth seasonality in the wild. Males in captivity reach sexual maturity at about 455–540 days (n = 12). Inter-birth intervals in captivity are highly variable, ranging from one gestation period (ca. 141 days) to several years (due to periods of anoestrus). Weaning occurred at 10–14 weeks across two colonies (n = 33) (Zimmermann 1989, Nash 2003).

It is unclear whether the birth sex ratio is skewed toward ♂♂ as strongly as in some other galagos. About 58% of the *G. s. braccatus* born in a captive colony were ♂♂ (n = 46) (L. T. Nash pers. obs.), whereas in another captive colony there was no sex bias (n = 23) (E. Zimmermann pers. obs.). Limited field data suggest the adult sex ratio is not skewed toward ♂♂ (Masters *et al.* 1993). Longevity in captivity is >13 years (L. T. Nash & E. Zimmermann pers. obs.).

Predators, Parasites and Diseases Robust Chimpanzees *Pan troglodytes* preyed on galagos that were likely *G. senegalensis* (McGrew *et al.* 1978, O'Malley 2010) and capture *G. senegalensis* using spear-like tools (Pruetz & Bertolani 2007). In Kenya, L. T. Nash (pers. obs.) saw a *G. senegalensis* give a 'startle' response when foraging on the ground, possibly in response to a nearby, low-perched owl. As with other species of galagos, large raptors, large snakes, genets *Genetta* spp. and diurnal primates are likely predators.

Diseases poorly known. *Galago senegalensis* implicated as a reservoir of Yellow Fever virus as it can circulate the virus and develop antibodies without showing clinical signs of the disease (Haddow & Ellice 1964).

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

All four subspecies are widespread and able to survive in woodlands and bushlands that have been somewhat degraded by human activities.

Measurements

Galago senegalensis

HB: 165 (132–210) mm, n = 508
T: 255 (195–303) mm, n = 498
HF: 67 (52–78) mm, n = 498
E: 40 (21–57) mm, n = 483
WT: 206 (112–300) g, n = 388

Northern Lesser Galago *Galago senegalensis*.

GLS: 43 (S.D. ± 1.5) mm, n = 212

From many sites represented in many museum collections (Nash *et al.* 1989, Olson & Nash 2002), except GLS from Masters & Bragg (2000). Sexes combined. Captive adult *G. s. braccatus*, but not neonates, are sexually dimorphic in weight. Captive adults considerably heavier than wild adults. Captive ♂♂ = $360 \text{ g} \pm 72$ S.D. (n = 9); captive ♀♀ = $266 \text{ g} \pm 47$ S.D. (n = 10) (Izard & Nash 1988). Wild ♂♂ mean ca. 225 g and wild ♀♀ mean ca. 200 g (ranges and sample sizes not available; Nash *et al.* 1989).

Galago moholi SOUTHERN LESSER GALAGO (SOUTH AFRICAN LESSER GALAGO)

Fr. Galago Moholi; Ger. Moholi-Galago

Galago moholi A. Smith, 1836. Rept. Exped. Exploring Central Africa, 1834: 42 [1836]. Marico R.—Limpopo R. confluence, Limpopo, West Transvaal, South Africa.

Southern Lesser Galago *Galago moholi* adult.

Taxonomy Polytypic species. Formerly regarded as a subspecies of the Northern Lesser Galago *Galago senegalensis* (Groves 1974, Olson 1979). Although remarkably similar in appearance to *G. senegalensis*, there are marked differences in their biology. Despite being housed together, no *moholi* × *senegalensis* hybrids reported. Separated from *G. senegalensis* by Zimmermann *et al.* (1988), Jenkins (1987), Groves (1989) and Nash *et al.* (1989). Two subspecies recognized by Smithers (1971), Ansell (1978), Olson (1979), Meester *et al.* (1986), Skinner & Smithers 1990 and Grubb *et al.* (2003); Moholi Lesser Galago *G. m. moholi* and Namibia Lesser Galago *G. m. bradfieldi*. Synonyms: *australis*, *bradfieldi*, *conspicillatus*, *intontoi*, *mossambicus*, *tumbolensis*. Chromosome number: $2n = 38$ (Ying & Butler 1971).

Description Medium-sized galago with greyish-brown dorsum. Flanks, feet, hands and inner limbs yellowish. Advertisement call a distinctive sharp, tonal, 'bark'. Adult ♀♀ like adult ♂♂ but slightly smaller, weighing ca. 90% as much. Head broad. Muzzle short. Eyes large, orange. Eye-rings black, diamond-shaped. Nose-stripe pale off-white. Ears grey, large. Dorsum buffy or greyish-brown. Ventrums white, sometimes suffused with yellow. Hands have long spatulate fingers but nails not pointed. Tail long, darker than rest of pelage, but not very bushy. Differences in hand pad shape and size, and penile morphology between *G. moholi* and *G. senegalensis* distinguishes these two species (Anderson 1999, 2000, Anderson *et al.* 2000). Young are of similar colouration to adults.

Geographic Variation Subspecies occupy two sub-regions but geographic limits of both are poorly known. The two subspecies do not appear to differ noticeably in their body measurements

(Smithers 1971, Jenkins 1987, Groves 2001). As such, at this time, subspecific designation is based on pelage colouration. A review of the information available on body size and colouration of these two debated taxa suggest an extensive hybrid zone or cline between them (T. Butynski pers. comm.). Adjacent populations in NE South Africa diverge considerably in average body weights (♂♂ 210 g and 195 g, ♀♀ 185 g and 165 g, respectively), suggesting the importance of highly local influences (Nash *et al.* 1989).

G. m. moholi Moholi Lesser Galago. Occupies eastern part of species' range. From S Tanzania southward through E Zambia, Mozambique, Zimbabwe, E Botswana to Limpopo Province, NE South Africa. Outer limbs, feet and hands greyish-brown or light brown with yellow tinge. Sides of ventrum suffused with yellow.

G. m. bradfieldi Namibia Lesser Galago. Occupies western part of species' range. From N Namibia and SC Angola eastward through S DR Congo to W Zambia and Magadigadi Pans, N Botswana. Outer limbs, feet and hands pale grey with little or no yellow tinge. Sides of ventrum white with faint yellow wash (Sauer & Sauer 1963, Smithers 1971).

Similar Species

Galago senegalensis. In same habitat as *G. moholi* in Tanzania but not known to be sympatric. Probably parapatric in Tanzania from L. Victoria south to Rufiji R. Very similar to *G. moholi*. Slightly larger but much overlap in body measurements: HB mean 165 mm ($n = 508$) vs. 150 mm ($n = 826$) for *G. moholi*; T mean 255 mm ($n = 498$) vs. 228 mm ($n = 824$) for *G. moholi*; HF mean 67 mm ($n = 498$) vs. 59 mm ($n = 812$) for *G. moholi*; WT mean 206 g ($n = 388$) vs. 158 g ($n = 477$) for *G. moholi* (Olson & Nash 2002).

Thus, body size alone cannot be used to distinguish *G. senegalensis* from *G. moholi*. Inter-ocular stripe broader, shorter, much whiter. Eye-rings always round. Hindlimbs bright yellow. Distinctive low pitched, single-unit 'woo' (or 'honk') loud-call monotonously repeated many times (Zimmermann *et al.* 1988). Hand pad and penile morphology diagnostic (Anderson 1999, 2000, Anderson *et al.* 2000).

Galagoides granti. Eastern Africa coastline from Rufiji R. south to Limpopo R. and westward inland to S Malawi, extreme E Zimbabwe and W Tanzania (Butynski *et al.* 2006). Parapatric in Mozambique and Zimbabwe (Masters & Bragg 2000). In denser, more moist, vegetation types. Similar in size. Ears broad, black behind. Dorsum buffy-brown with pinkish tinge. Tail bushy, wider over distal ca. 80%, darker than dorsum with distal ca. 10–60% blackish-brown. Distinctive 'incremental' loud-call (Butynski *et al.* 2006).

Galagoides zanzibaricus udzungwensis. NE Tanzania along coastal plain south to Rufiji R. and inland to Udzungwa Mts of SC Tanzania. Similar in size but ears average shorter; seldom longer than 33 mm. Dorsum buffy-brown. Tail sparsely furred (tail bone visible), hairs relatively coarse/wiry, and distal ca. 25% slightly darker brown or dusky. Distinctive 'single-unit rolling' loud call (Butynski *et al.* 2006).

Distribution Endemic to Africa south of S Tanzania. Zambezan Woodland, Kalahari Desert and Coastal Forest Mosaic BZs. From NW Namibia and SC Angola eastward through S DR Congo to SE Tanzania, Mozambique and NE South Africa (Smithers 1971, Skinner & Smithers 1990). Presence in Rwanda and Burundi needs confirmation (Oates 1996, De Jong & Butynski 2012). See Geographic Variation.

Habitat Semi-arid habitats; open woodland, open savanna, bush, forest fringe. Present in association with *Acacia* spp., from which gum, the primary component of the diet, is obtained. Less common in *Baikiaea* and miombo *Brachystegia* associations, as well as mopane *Colophospermum* and mixed associations of *Burkea*–*Terminalia*, *Terminalia*–*Acacia*, and *Terminalia*–*Combretum* (Skinner & Smithers 1990). Able to live in close association with humans, occupying gardens and using buildings as sleeping places. Found from sea level to 1500 m (Soutpansberg, South Africa; Bearder 1974). Habitat is drought-prone with very unpredictable rainfall (mean annual rainfall 599–1463 mm; Bearder & Doyle 1974a).

Abundance Common in prime habitat. Density in NE South Africa 13.5 ind/km² (Pullen 2000) in uniform and contiguous vegetation where animals are distributed fairly evenly. At Balovale, Zambia, >50 ind/km² (Lumsden & Masters 2001). Abundance highest where vegetation is more contiguous since *G. moholi* is restricted to woody vegetation for food and nests. Land clearing is a major factor affecting distribution since *G. moholi* are unable to move across large gaps that lack woody vegetation.

Adaptations Nocturnal and arboreal. A robust galago able to withstand a wide range of temperature variation from 4 °C to 38 °C (Pullen 2000). Onset and cessation of activity usually triggered by critical levels of light at dusk and dawn. *Galago moholi* have a number

Galago moholi

of behavioural and physical characteristics that are highly specialized and suited to their nocturnal life-style. The limbs are long and powerful, particularly the hindlegs, and the spatulate hands and feet allow the animal to leap securely up to 5 m from tree to tree, even on dark nights. The long tail acts as a rudder to balance the jump. The longest leaps are accompanied by raising the arms sharply on either side of the head. Walking and climbing used to negotiate highly thorny trees. Frequently crosses between trees on the ground using rapid bipedal hopping.

The fur is cryptically coloured to blend in with the vegetation and thick enough to provide both insulation and scent dispersal. A thick under-fur develops before winter and is moulted in spring. No evidence of torpor despite freezing mid-winter temperatures (Mzilikazi *et al.* 2006). Glands on the chest and scrotum are often rubbed on the substrate to mark a location. 'Urine-washing' of the hands and feet serves both to mark the substrate and improve grip (see below). Indirect chemical signals allow conspecifics to assess each other at a distance. The solitary nature of *G. moholi* is thought to be a strategy to reduce predation and competition for food.

Eyesight is particularly well adapted to a nocturnal life with the benefit of a reflective tapetum in the eye to re-reflect available ambient light. The pupils narrow to a vertical slit during the day and the animals can move around without difficulty, even in bright sunlight, if disturbed or hungry. They sleep alone or in small groups during the day in nests, tree holes, or on branches and forks in trees. Nests are usually in particularly thorny and dense acacia trees and are made by using fresh leaves and small twigs from broad-leaved trees (e.g. *Rhus*, *Grewia*). These are shaped into a platform, which can support up to eight animals (Bearder 1969). At Balovale, nest holes found at heights of 1–13 m above ground with most between 3 and 8 m. About 20% of nests found were occupied. Of the inhabitants of 122 nest holes, 34% were single ♂♂, 29% single ♀♀, 15% ♂/♀ pairs. Nest had from 1–3 ♂♂ and 1–3 ♀♀. Mean group size in nests was 1.6 animals (Lumsden & Masters 2001). In particularly

Lateral view of skull of Southern Lesser Galago *Galago moholi* adult.

cold weather, *G. moholi* nest in more sunny positions and are more likely to share nests.

Gut specialized for digestion of gum (Caton *et al.* 2000). Free water not required. Procumbent lower incisors and canines form a well-developed tooth-comb or scraper, which is used to prise gum from the surface of trees, and during lengthy mutual or self-grooming sessions. Tooth comb kept clean by a serrated sub-lingula. Like all species of galago, *G. moholi* has a unique loud-call and penile morphology.

Foraging and Food Omnivorous/gummivorous. No fruit is consumed in the wild; invertebrates 52%, gums 48% (Bearder & Martin 1979, 1980). Gums, produced by trees (mostly *Acacia* spp.) in response to wood-boring insects and other damage, are composed of long-chain polysaccharides that can be digested by microorganisms in the specialized caecum, providing both energy and essential minerals (Bearder & Martin 1980). The most productive gum-producing trees are Sweet Thorn *Acacia karoo* and Umbrella Thorn *Acacia tortilis*. Feeding on gums increases during the cold, dry winter (May–Aug) when insect availability declines, or ceases (Charles-Dominique & Bearder 1979, Crompton 1984). In winter they move more directly from one gum tree to another, often along the ground. In the warm, wet summer (Nov–Feb), when they tend to feed more on insects, they travel mostly through the trees (Harcourt 1986b).

Feeding activity is at a maximum just after sunset, after which they rest and feed sporadically until sunrise. In the wet season *G. moholi* spends up to 2 h 15 min each night catching insects (Bearder 1969). The large eyes and highly mobile ears are used to pinpoint insects, and the excellent sense of smell helps to locate sources of gum. On the coldest nights the gum becomes frozen solid. On these occasions the animals cease their activity and return to their sleeping up to 4 h before dawn (Bearder & Martin 1980). Moths, grasshoppers and beetle larvae are favoured when plentiful in NE South Africa during the summer months (Nov–Feb), but the staple food is acacia gum, which is licked or eaten in small pieces. *Galago moholi* is able to live in a wide range of habitats, probably due in large part to the ability to use gum as a refuge food. *Galago moholi* always forages alone and when feeding will always include certain favourite trees. In winter (May–Aug) in NE South Africa, when the grass is dry and short, this species forages in grass for short periods (Pullen 2000). *Galago moholi* tends to use familiar pathways and to rigorously mark routes. The average nightly distance travelled is 2.0 km, moving through an average of 500 trees each night ($n = 57$, Bearder & Martin 1979).

Social and Reproductive Behaviour Though primarily non-gregarious, *G. moholi* shows much social association both during the

night and during the day (Bearder 1987). They spend up to 30% of the night within 50 m of conspecifics. In NE South Africa, home-ranges of adult ♂♂ (mean 7.2 ha, 3.8–13.2, $n = 9$) are larger than those of adult ♀♀ (mean 4.6 ha, 0.14–10.2, $n = 4$; Pullen 2000). Male home-ranges have considerable overlap both with ♂♂ (50%) and ♀♀ (38%), but ♀♀ do not share any of their home-range with ♀♀ other than their related offspring. Adult ♂♂ are not territorial. This reflects the social system, where adult ♀♀ are ‘dispersed’ in the environment, with adult ♂♂ being unable to defend an area containing sufficient ♀♀. Adult ♂♂ home-ranges may double in size in the mating season (Bearder & Doyle 1974a, Pullen 2000), as they search over wider areas for oestrous ♀♀. *Galago moholi* has a dispersed mating system where ♀♀ mate with more than one ♂ (Pullen 2000). The penile morphology of *G. moholi* fits well with the hypothesis that adaptation of complex penile morphologies are positively correlated with complexity of the mating system (Dixson 1989).

When individuals meet they may avoid each other or social interactions follow a predictable pattern depending on age, sex and familiarity. Interactions are generally brief (but can last several hours) and involve chasing, grooming and naso-nasal and naso-genital sniffing. Subordinates invariably retreat, usually descending to the ground, and give various anxiety and alarm calls. Dominant individuals remain silent. Friendly contact includes play, grappling, chasing and vigorous alternate grooming. Same sex adult strangers are highly aggressive and serious fights can occur (Bearder & Doyle 1974b). Adult ♀♀ rarely come into contact with one another unless related, while adult ♂♂ often interact with both sexes. During the day, adult ♂♂ sleep alone ca. 70% of the time, while adult ♀♀ sleep alone ca. 44% of the time (Pullen 2000). Adult ♂♂ often sleep with adult ♀♀ except during the birth season in Oct. During the mating season, dominant ♂♂ show a three-fold increase in nest-sharing with adult ♀♀. Infants share a nest with their mothers but are regularly carried one at a time in the mouth between nest sites or ‘parked’. Two ♀♀ and their infants may share the same nest but they only carry their own infants. Mothers spend only ca. 33% of the night with their infants, grooming and nursing. Infants make ‘click’ and ‘crackle’ vocalizations when distressed. At four weeks old they sometimes follow their mother and make independent forays but remain alone for most of the night until joined at dawn by their mother (Bearder 1969).

Adult ♀♀ are philopatric. Subadult ♂♂ disperse into new areas to avoid intrasexual competition and inbreeding. Originally the mating system was thought to be polygynous (Bearder & Martin 1979), however, ♀♀ can mate with up to four ♂♂ (Pullen 2000). The mating season in NE South Africa peaks in the middle of May (cold, dry season). During the short oestrus (up to three days), ♂♂ will mate with as many ♀♀ as possible. Just prior to the mating season ♂♂ show significant growth in body weight and testicular size (Pullen *et al.* 2000), a feature common in multimale mating systems that involve sperm competition. Due to intense competition for mates, copulation can be prolonged (up to 50 min). This is probably a mate-guarding tactic by ♂♂ (Dixson 1998). Genetic studies of paternity indicate twins may be fathered by two different ♂♂ (Pullen 2000).

Chemical communication is well developed. Glands on chin, chest and ano-genital region are often rubbed on the substrate

to mark a location, with bouts of mutual sniffing during social encounters (Bearder & Doyle 1974b). Oestrus is signalled by vaginal secretions (Lipschitz 1997). Marking is also carried out by urine washing using hands and feet to deposit urine, enhancing communication at a distance and moistening the hands and feet to promote grip (Harcourt 1981). Loud calls are made by both sexes, irrespective of the mating season. The vocal repertoire is sophisticated, including 19 calls, both continuous and discrete, that can be mixed into complex sequences, as well as two infant-specific calls (Bearder 2007). Most calls are associated with various levels of anxiety or alarm when disturbed; for example by conspecifics or potential predators. Calling may continue for >1 h, such as when mobbing a potential predator, and this sometimes attracts other galagos, which join in with calling. The mixture of different calls, and their loudness and speed of repetition, varies in relation to the intensity of the threat. Other calls are used to attract companions and maintain contact with infants. Companions and rivals are also recognized visually, probably by means of distinctive facial markings (Bearder *et al.* 2006). Apart from acacia rats *Thallomys* spp., there are no non-predator arboreal nocturnal animals with which *G. moholi* are known to interact.

Reproduction and Population Structure *Galago moholi* has two birth seasons. The primary one occurs in late Sep during the hot, wet season, when food is plentiful. Females sometimes enter a postpartum oestrus resulting in a second birth season in early Feb. So restricted is the primary birth season that in NE South Africa, during two consecutive years, three ♀♀ entered oestrus only one day later than the year before (Pullen 2000). Gestation in captivity is 121–124 days (Doyle *et al.* 1971), but wild ♀♀ appear to have a longer gestation of 125–130 days (n = 6; Pullen 2000). Females usually give birth to twins (85%, n = 6) though it is common for primiparous ♀♀ to give birth to singletons (Doyle *et al.* 1967). In the wild, five-day-old infants weigh ca. 12 g (n = 4) but weight gain is rapid and at ten days infants can weigh 33 g (n = 6; Pullen 2000). During the birth season ♀♀ nest alone and preferably use tree-holes as these offer greater protection than platform nests to their growing infants. Infants leave the nest for the first time at ten days and are weaned at 11 weeks (Doyle 1979). Females reach maturity at 200 days and ♂♂ at 326 days (Doyle 1979). Juvenile mortality rates are high. In captivity, Izard & Simons (1987) record a juvenile mortality rate of 51% while in the wild a rate of 55% was recorded (Pullen 2000). In NE South Africa, adult ♂♂ outnumber adult ♀♀ (1.8 : 1; n = 11; Pullen 2000; 2.6 : 1; n = 24; Bearder & Martin 1979). Male-biased sex ratio appears to be common in prosimians and is thought to occur due to a male-biased sex ratio at birth (Clark 1985, Debyser 1995, Watson *et al.* 1996). A high replacement rate of adult ♂♂ is found in the wild. This is common in most non-gregarious prosimians with ♀ philopatry. Live to at least 14 years in captivity (S. K. Bearder pers. obs.).

Predators, Parasites and Diseases Small carnivores, large owls and large snakes are probably the major predators (Charles-Dominique & Bearder 1979). Spotted Eagle-owls *Bubo africanus* observed feeding on *G. moholi*. White-throated Monitor Lizards *Varanus albigularis albigularis* also implicated in predation (Pullen 2000). Common Genets *Genetta genetta* often observed stalking *G.*

moholi and, judging by the intense alarm calls given by *G. moholi*, this is a predator to be taken seriously. Nightly travel distance and size of the area traversed are inversely related to the level of ambient light. *Galago moholi* generally retreat to a dense patch of trees when there is no moon, probably in relation to the risk of predation (Bearder *et al.* 2002). Parasites and diseases not studied but ear ticks and body lice are common.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Still common at many sites but widespread destruction, degradation and fragmentation of habitats means declining distribution and abundance. They are frequently taken from the wild and sold as pets, but their nocturnal activity and habit of urinating on their hands and feet do not make them ideal pets.

Galago gallarum SOMALI LESSER GALAGO (SOMALI BUSHBABY)

Fr. Galago de Somalie; Ger. Somali-Galago

Galago gallarum Thomas, 1901. Ann. Mag. Nat. Hist., ser. 7, 8: 27. Webi Dau (Dawa R.), Boran County, Ethiopia.

Somali Lesser Galago *Galago gallarum*.

Taxonomy Monotypic species. Named and first recognized as a species by Thomas (1901) but then subsumed as a subspecies of the Northern Lesser Galago *Galago senegalensis*. Elevated back to full species status by Olson, T.R. (1979, 1986). This taxonomy now widely supported (Nash *et al.* 1989, Bearder *et al.* 1995, Kingdon 1997, Masters & Bragg 2000, Groves 2001, 2005c, Grubb *et al.* 2003, Nekaris & Bearder 2011). Synonyms: none. Chromosome number: not known.

Description Medium-sized galago with whitish face and throat, and contrasting dark brown eye-rings, and black ears and tail. Loud advertisement 'quack' call distinctive. Sexes alike in colour and pattern of pelage. No data available on sexual dimorphism, but ♂♂ probably

slightly (10–20%) heavier than ♀♀ as in other *Galago* spp. (Izard & Nash 1988, Harcourt & Bearder 1989). Head broad. Muzzle short, blackish over distal half. Nose black, slightly up-turned at tip. Chin with light pink skin. Face, throat, chest and belly off-white, with greyish tint on belly. Inter-ocular stripe off-white, broad. Eye-rings dark brown, narrow, sometimes incomplete laterally. Black 'tear line' from inner corner of eyes down sides of muzzle. Eyelids greyish. Eyes large, orange-brown. Reflected eye-shine is bright orange. Ears bare, shiny black skin on front and dull black skin on back. Dorsal pelage short (not woolly), variable, from light sandy brown to buff to fulvous, lighter on head. Dorsal hairs dark grey over basal half, buff near middle followed by whitish subterminal band and blackish tip. Shoulders buff or light rufous. Outer forelimbs and hands buff to sandy-brown. Hips, outer hindlimbs and feet yellowish-buff. Digits blackish. Tail mostly black but dark brown or reddish towards base. Hand (volar) pads distinctive (Anderson 1999). Young similar to adult in colour. Photographs of *G. gallarum* in Kenya available at: www.wildsolutions.nl

Geographic Variation None recorded. In the field, animals in N Kenya appear more rufous on shoulders and flanks than those on the southern fringe of the range in Kenya.

Similar Species

Galago senegalensis. Sympatric with *G. gallarum* on northern and southern fringes of *G. gallarum* range (Olson, T.R. 1986, Nash *et al.* 1989, Butynski & De Jong 2004, D. Olson pers. comm.) and probably also along much of the western and north-eastern fringe. Loud 'woo' (or 'honk') advertisement call distinctive. Dorsum grey or brownish-grey. Ears brown or greyish on back and pinkish or flesh-coloured inside. Tail grey to brown. Generally in wetter habitats than *G. gallarum* (e.g. woodland, forest).

Galagoides cocos. Probably slightly sympatric or parapatric along the south-eastern (coastal) fringe of range of *G. gallarum* in Kenya and

Galago gallarum

Somalia. Smaller. Loud incremental advertisement call distinctive. Dorsum and outer limbs dark brown. Ears dusky behind and pinkish inside (Butynski *et al.* 2006). In wetter habitats than *G. gallarum* (e.g. coastal and riverine forest).

In the field under lamplight, *G. senegalensis* and *G. cocos* do not have a dark brown or black muzzle, eye-rings, ears, or tail that contrast sharply against a whitish face and pale (sandy and buff) body as for *G. gallarum*. Best single phenotypic museum character is the colour of the ears; black in *G. gallarum* and not black in *G. senegalensis* or *G. cocos*.

Distribution Somalia-Masai Bushland BZ. Endemic to the semi-arid thorn scrub and thorn scrub/woodland of E Kenya, Somalia and S Ethiopia where, in most places, it is the only small galago present. Distribution limits poorly known. Western limits uncertain, but may be present to at least east shore of L. Turkana, Kenya (Groves 2001, 2005c). Not known west of Eastern Rift Valley. From Eastern Rift Valley and southern base of Abyssinian Plateau, Ethiopia, east to NE Somalia, south-west to coastal strip of Somalia and NE Kenya, to lower Tana R. (Butynski & De Jong 2004, Butynski *et al.* 2006, De Jong & Butynski 2011). Known southern limit is 01° 34' 24" S; 40° 07' 07" E, 180 m asl (Perkin & Butynski 2003).

Habitat In drier habitats than other galagos. Prefers relatively dense *Acacia*–*Commiphora* deciduous bushland and thicket, and small trees (2–15 m). Here, most of the bushes and trees have thorns or spines, and many produce gum. The ground vegetation (grass and herbs) varies from dense to absent. Soils well drained, rocky or sandy – not loamy. Absent from open woodland and open bushland where the mean distance between bushes or trees is greater than ca. 3 m, and where fewer than about four woody species are present. At pristine sites in Meru N. P. (425–600 m), Kenya, where *G. gallarum* is present, the following woody species are common: Hook-thorn

Acacia mellifera, Umbrella Thorn *Acacia tortilis*, *Commiphora holtziana*, *Commiphora samharensis*, *Terminalia orbicularis*, *Terminalia spinosa*, *Boscia Boscia coriacea*, *Dobera glabra*, Doum Palm *Hyphaene compressa* and *Euphorbia bussei*. The area is especially rich in *Commiphora* spp., but *A. tortilis* is the dominant and tallest tree (ca. 15 m) in many places. Present at low density in 'bushy woodland' at some sites (e.g. Drake-Brockman 1910, De Jong & Butynski 2010a) but use of this habitat type seems uncommon. The one bushy woodland site found to date in Kenya (base of Mathews Range, C Kenya) borders a small swamp and *Acacia*–*Commiphora* bushland. This site is dominated by large *Newtonia Newtonia hildebrandtii*, *Melia volkensii* and *Acacia* spp.

Galago gallarum present (and sometimes common) in severely degraded habitats that are used intensively by people and livestock. For example, common in *A. mellifera*-dominant bushland and thicket where the following other woody species are present: Egyptian Thorn *Acacia nilotica*, False Umbrella Thorn *Acacia reficiens*, *B. coriacea* and Sickie Bush *Dichrostachys cinerea*. The tallest trees in such habitats are often <7 m.

Rainfall and altitude limits poorly documented: ca. 200–750 mm annual rainfall. Altitude in Kenya, from ca. 4 m (Kiunga, extreme north coast) to 1250 m (base of Mathews Range), and in Somalia from 5 m (at Jamaame) to 1200 m (at Odweina) (Butynski & De Jong 2004, De Jong & T. Butynski 2010a, 2011).

Abundance Locally common, but absent from large areas of unsuitable habitat within the species' geographic range. Over much of the range the density is probably less than 1 ind/ha but densities are much higher than this at some sites. For example, in Meru N. P. some sites hold > 4 ind/ha, while in N Kenya one site (near Moyale) supported an estimated >5 ind/ha (Butynski & De Jong 2004).

Adaptations Nocturnal and arboreal. In drier, 'thornier' habitats than any other galago, or any other African primate. Does not require 'free-water'. Can move rapidly through the thorniest of vegetation (e.g. *Acacia* spp., *D. cinerea*, *T. spinosa*). The ears and hindfeet of *G. gallarum* are shorter than those of the similar-sized *G. senegalensis*. These may be adaptations for moving through very thorny/spiny vegetation. When on bushes and trees, moves quadrupedally, head first much like a tree squirrel – even when moving vertically downwards. Adults make horizontal leaps of >2.5 m between branches. Because bushes and trees are often more than a few metres apart, adults frequently come to the ground to hop bipedally to the next bush or tree. Adults jump from >1.3 m to the ground, make a series of 2 m long hops, and then leap >1 m up into a bush or tree. Vision, sense of smell and hearing appear to be well developed. Ears highly mobile and often moved independently of each other.

Most habitats in which *G. gallarum* occurs have few or no trees large enough to provide holes big enough for *G. gallarum* to enter. Probably most often sleeps in the open on branches within a barrier of dense thorns or spines. No nest building observed but sometimes sleeps in bird or rodent 'grass ball' nests amongst dense thorns. Only one case of use of tree-holes observed to date; two individuals observed at dusk in a large, old, *N. hildebrandtii* in which there were numerous holes.

Probably receives a high level of protection against predators both by the camouflage afforded by its pelage and by the extremely dense, thorny/spiny, vegetation. This species is particularly cautious prior

to coming to the ground, suggesting that it is most vulnerable to predators while on the ground.

Foraging and Food Omnivorous. Diet little known. When active, *G. gallarum* spends most of the time foraging in bushes and trees. Forages at all heights from ground to near the top of the tallest trees (ca. 20 m), but mostly at 1–5 m. Also forages for invertebrates on the ground under cover of dense bushes or herbs. Will pounce on large (>4 cm long) invertebrates on the ground from height of >1 m. Gum frequently eaten, but most of the time foraging is spent intensively searching for invertebrates. Some fruit probably eaten when (seasonally) available. Expected to eat the eggs and nestlings of small birds, as well as the neonates of small arboreal mammals. This might prove be the galago with the highest portion of animal matter in the diet.

Social and Reproductive Behaviour Non-gregarious, usually alone or in pairs. Social behaviour poorly known but probably similar to other *Galago* spp. Largest number seen together (i.e. within 5 m) is three. Species-specific loud (advertisement) call is a ‘quack’ that is probably used in the context of long-distance spacing and territoriality. The human ear can hear the ‘quack’ at >300 m. Where densities are relatively high (>4 ind/ha) there may be a ‘dawn chorus’ of ‘quack’ calls with 4–5 animals calling over an area of 2 ha for ca. 10 min. ‘Dusk chorus’ not heard but ‘quacks’ often given during first five hours after dusk. Incidence of ‘quack’ calls appears to be directly related to population density. Other calls include ‘yaps’, ‘chitters’, ‘pings’ and ‘woos’ (Butynski & De Jong 2004, De Jong & Butynski 2004).

Scent-marks by rubbing chin and hands against branches. Mutual grooming between mother and large juvenile occurs. Large juvenile seen clinging to fur of ventrum of mother and carried. Carrying young on the fur is not known for any other *Galago* spp., and is only known for four other species of galagos (Bearder 1999, Bearder *et al.* 2003). Young ‘parked’ at night for long periods in a single clump of several trees while mother forages to at least 50 m away.

Reproduction and Population Structure Poorly known. Rate of reproduction unknown but probably two pregnancies per year as for other *Galago* spp. (Izard & Nash 1988, Zimmermann 1989). Since *G. senegalensis* and *G. gallarum* have similar body weights, it is likely that these two species are similar in terms of gestation length (139–146 days), litter-size (one), birth-weight (15–23 g), age at weaning (10–14 weeks), age at sexual maturity (15 months) and oestrus length (1–3 days) (data for *G. senegalensis*; Zimmermann 1989). Given the considerable seasonality of the region over which *G. gallarum* lives, reproductive activities are expected to be highly seasonal, with lactation and weaning coinciding with periods of maximum food availability (Nash 1983, Butynski 1988). In the region occupied by

G. gallarum, the periods of maximum food availability are likely to be during the Apr–Jun and Nov–Dec wet seasons. If so, births might peak in Feb–Mar and Sep–Oct. Twice in Sep 2003, Butynski & De Jong (2004) observed adult ♀♀ with single large juveniles that were probably weaned. This suggests both that a single infant is (usually) born and that at least some births occur around Mar.

Predators, Parasites and Diseases Unknown. There are many potential predators, including large snakes, large owls *Bubo* spp., Golden Jackals *Canis aureus*, Black-backed Jackals *Canis mesomelas*, mongooses *Herpestes* spp., genetids *Genetta* spp., Wildcats *Felis sylvestris*, Servals *Felis serval* and Caracals *Felis caracal*.

Conservation IUCN Category (2012): Least Concern. CITES (2012): Appendix II.

Common at some sites and widespread. Occurs in semi-arid areas that are of little value for crop production. Persists over large areas where the habitat has been severely degraded through human use and overgrazing by domestic livestock. Present in some protected areas in Kenya, including Meru N. P. and Shaba National Reserve. The long-term survival of this species appears secure.

Measurements

Galago gallarum

HB: 167 (130–200) mm, n = 25

T: 252 (205–293) mm, n = 25

HF: 62 (57–75) mm, n = 25

E: 35 (30–40) mm, n = 27

WT: n. d.

GLS: 42.5 (40.2–45.5) mm, n = 12

Body measurements: numerous museums (Olson & Nash 2002).

Skull measurements: BMNH (Schwarz 1931a). Sexes combined.

HB (♂♂): 178 (154–196) mm, n = 8

HB (♀♀): 168 (145–181) mm, n = 9

T (♂♂): 259 (245–274) mm, n = 8

T (♀♀): 246 (227–271) mm, n = 9

HF (♂♂): 67 (64–70) mm, n = 6

HF (♀♀): 63 (60–71) mm, n = 9

E (♂♂): 35 (28–38) mm, n = 7

E (♀♀): 34 (32–37) mm, n = 4

WT: n. d.

GLS: 42.8 ± 2.2 (40.2–45.5) mm, n = 5

Body measurements (J. Masters pers. comm. in Butynski & De Jong 2004). GLS is for ♂♂ and ♀♀ combined (Masters & Bragg 2000).

Galago matschiei SPECTACLED LESSER GALAGO (EASTERN NEEDLE-CLAWED GALAGO)

Fr. Galago mignon sombre; Ger. Brillengalago

Galago matschiei Lorenz, 1917. Ann. K. K. Naturhist. Hofmus, Wien 31: 237. Moera, Ituri R., DR Congo.Spectacled Lesser Galago *Galago matschiei* adult.

Taxonomy Monotypic species. Schwarz (1931a), unaware that Lorenz (1917) had already named this taxon, described it as a subspecies of the Senegal Galago *Galago senegalensis inustus*. Hayman (1937) noticed the unique keeled nails of *inustus* and raised this taxon to specific rank as *Galago inustus*. Hill (1953) included *inustus* in *Euoticus* and this was followed by most authors. Walker (1974) and Groves (1974) concluded that *inustus* was likely a forest derivative of *G. senegalensis* but, none the less, deserving of specific status. As pointed out by Olson (1979), the senior name is '*matschiei*'. Thus, current authorities use the name '*Galago matschiei*' (e.g. Bearder *et al.* 1995, Kingdon 1997, Groves 2001, 2005c, Grubb *et al.* 2003, Masters *et al.* 2007). Prior to Olson (1979), the type specimen for *matschiei* had been considered a junior synonym of Thomas's Dwarf Galago *Galagoides thomasi* (Jenkins 1987, Nash *et al.* 1989).

Those morphological (Olson 1979, Masters & Brothers 2002), vocal (Zimmermann 1990) and molecular (Masters *et al.* 2007) phylogenetic analyses that consider *G. matschiei*, all firmly place *G. matschiei* within the genus *Galago*. The most current morphological-molecular analysis (Masters *et al.* 2007) suggests that *G. matschiei* may be the most unique of the species within *Galago*, even more so than the Southern Needle-clawed Galago *Euoticus elegantulus*. This suggests that *G. matschiei* is a relict species within the *Galago* *Euoticus* clade. Synonym: *inustus*. Chromosome number: not known.

Description Medium-sized (ca. 210 g), dark-brown, forest-living galago with black ears and large eyes surrounded by brownish-black eye-rings. Adult ♀ like adult ♂ in pattern and colouration of pelage. Eyes and orbits large, surrounded by broad, well-demarcated, orbital rings ('face-mask') and bordered by a well-defined ridge, especially at the brows. Iris amber. Nose-stripe broad, white, extending onto forehead. Ears variable, either all black or black-tipped (Ambrose 2006). Sides of face, sides of neck, throat, ventrum and insides of legs pale grey. In the pattern of the face and the colour of the ears, *G. matschiei* most resembles the Somali Lesser Galago *Galago gallarum*. Dorsum and upper limbs dark 'burnt' brown or dark grey-brown. Shoulders brown with yellow tinge. Tail dark grey, sometimes grey-brown, darker distally. Tail evenly furred, not bushy or only moderately bushy, often held coiled when sitting and sometimes also when running (Ambrose 2006). Nails of hands and feet (except on pollex, hallux and second pedal digit), over the distal two-thirds of their length, have a slightly raised, central, longitudinal ridge or keel, and end in a sharp, projecting, point. Thus, the nails are similar to those of the needle-clawed galagos *Euoticus* spp., but not so strongly keeled (Hayman 1937, Hill 1953). Infants have full adult colouration (Ambrose 2006). The penile structure for *G. matschiei* is species-specific, being very different from that of all other species of galagos (Anderson 1998, 2000). Eye-shine is orange, but a much stronger orange in the west (e.g. Bwindi Impenetrable N. P. and Kibale N. P., SW Uganda) than in the east (e.g. Mabira, Mpanga and Zika Forest Reserves). At Bwindi Impenetrable N. P. the eye-shine is so bright that it leaves orange traces when the animals move their heads (Ambrose 2006, T. Butynski pers. obs.).

Geographic Variation None recorded except for the following one adult ♂ specimen captured (but not collected) on 20 April 1996 in bamboo at 2330 m on the Itombwe Massif, E DR Congo (03° 52' S, 28° 52' E) by T. Butynski. This site represents about a 130 km range extension to the south for *G. matschiei*. This specimen was identified as a *G. matschiei* based on its body measurements and keeled, pointed, nails. The specimen (photograph in Omari *et al.* 1999: 311) differs from typical *G. matschiei* as follows: face-mask pattern distinct (Bearder *et al.* 2003), with blackish-brown stripe from the inner corner of each eye down along the side of the muzzle to the mouth. Crown and dorsum light rusty-brown becoming lighter and more buff on the sides. Forelimbs and hindlimbs buff-brown. Tops of hands and feet lightly furred buffy-grey. Tail dark dusky brown all over, fuller towards tip. Chest buff, greyer towards midline. Ventrum greyish becoming buff towards the sides.

Similar Species

Galago senegalensis. Probably narrowly sympatric, especially in SC Uganda (e.g. Mpanga F. R.; Nash *et al.* 1989, Ambrose 2006). Dorsum greyer. In woodlands and on edge of dense, moist forest. Flanks distinctly yellow or yellowish-buff. Nails not keeled or pointed. Gives 'woo' (or 'honk' loud call).

Spectacled Lesser Galago *Galago matschiei*.

Galagoides demidovii. Sympatric. Much smaller (Jenkins 1987, Olson & Nash 2002). HB: mean 129 mm (73–155, $n = 200$). Tail: mean 179 mm (110–215, $n = 199$). WT: mean 70 g (44–97, $n = 49$). GLS: mean 37 mm (35–41, $n = 59$). Nails not keeled or pointed. Face-mask not obvious or well-demarcated. Gives 'crescendo' and 'buzz' calls.

Galagoides thomasi. Sympatric. Much smaller (Olson & Nash 2002). HB: mean 146 mm (123–166, $n = 47$). Tail: mean 195 mm (150–233, $n = 46$). WT: mean 99 g (55–149, $n = 29$). GLS: <40 mm (Groves 2001). Nails not keeled or pointed. Face-mask not obvious or well-demarcated. Gives 'crescendo' and 'buzz' calls.

Distribution Endemic to the Albertine Rift region and S Uganda. Rainforest and Afromontane–Afroalpine BZs. Northern limit Djugu Hills, DR Congo (ca. 01.92°N, 30.50°E; Schwarz 1931a), west side of L. Albert. Southwards down western flank of Albertine Rift to south end of Itombwe Massif (03° 52' S, 28° 52' E; Omari *et al.* 1999). Western range lies along the western flank of Albertine Rift (to ca. 90 km west of L. Kivu and 130 km west of L. Edward). Farthest locality west is ca. 28° 06' E (Rahm 1965). Eastern limit is Mabira F. R. (00° 29' N, 33° 00' E; Ambrose 2006) on left bank of Nile R. and north shore of L. Victoria, Uganda. On east flank of Albertine Rift from Bwamba (at the north end of the Rwenzori Mts) and Kibale

*Galago matschiei*

N. P., SW Uganda (not Budongo F. R.; Ambrose 2006) southwards to Kibira N. P., NW Burundi (02° 44' S, 29° 12' E; Masters *et al.* 2007). There may be a ca. 200 km gap in distribution between Albertine Rift population at Kibale N. P. and Mpanga F. R./Mabira F. R. population to east as there are no records from this region and suitable habitat may be lacking. Ambrose surveyed South Busoga F. R. and Mt Elgon, Uganda, east of the Nile R., but did not find *G. matschiei* at either site. Specimens reported to be *G. matschiei* from Mt Moroto (02° 32' N, 34° 46' E) on the Uganda/Kenya border ca. 300 km north-east of Mabira F. R. and on the right bank of the Nile R. (Nash *et al.* 1989). Otherwise, there are no specimen or site records for *G. matschiei* east of the Nile R. The extent of occurrence for *G. matschiei* is roughly 79,000 km². The area of occupancy remains unknown but is certainly very much less than this.

Interestingly, *G. matschiei*, Demidoff's Dwarf Galago *Galagoides demidovii* and Thomas's Dwarf Galago *Galagoides thomasi* are not confirmed to occur to the east of the Nile R. in the moist forests of eastern Uganda, Kenya or Ethiopia. In Kenya and Ethiopia, at least, *G. senegalensis* is the smallest galago of moist forest – occurring at low densities at least on the edges of montane forest (e.g. Mau F. R., Kenya, and Herenna Forest, Ethiopia; T. Butynski pers. obs.). In Uganda and DR Congo, *G. senegalensis* is not known to be a member of the moist forest community of galagos (T. Butynski pers. obs.) except on the north-west side of L. Victoria where *G. senegalensis* is parapatric, if not sympatric, with *G. matschiei*, *G. demidovii* and *G. thomasi* (Ambrose 2002).

Habitat Restricted to primary and secondary mid-altitude, montane and bamboo forest. Uses vegetation at all heights, moving freely between the canopy and thick tangles at lower levels (Kingdon 1997, Ambrose 2006, T. Butynski pers. obs.). Altitudinal limits ca. 670–2500 m (Vincent 1972, Dowsett & Dowsett-Lemaire 1990). The lowest known altitude is on the Kirimia R., Bwamba (00° 52' N, 30° 05' E; R. Dowsett & F. Dowsett-Lemaire pers. comm.). Mean annual rainfall over geographic range ca. 1500–2500 mm.

Spectacled Lesser Galago *Galago matschiei* showing details of hands and feet.

Abundance Ambrose (2002, 2006) recorded the following encounter and loud-call rates for *G. matschiei* for seven sites across Uganda from the left bank of the Nile R. to near the border with DR Congo (range 0.08–1.71 ind/h; 0.00–0.57 calls/h):

Mabira F. R., SC Uganda: 0.33 ind/h (n = 15) and 0.02 calls/h (n = 2).

Zika Forest, SC Uganda: 1.14 ind/h (n = 4). No calls heard.

Mpanga F. R., SC Uganda: 0.36 ind/h (n = 11). No calls heard.

Buhoma, Bwindi N. P., SW Uganda: 0.37 ind/h (n = 19) and 0.02 calls/h (n = 1).

Kanyanchu, Kibale N. P., SW Uganda: 1.71 ind/h (n = 39) and 0.57 calls/h (n = 14). At highest density on forest edge in gum-producing *Albizia* sp. trees.

Echuya F. R., SW Uganda: 0.10 ind/h (n = 2). No calls heard.

Maramagambo F. R., SW Uganda: 0.08 ind/h (n = 1). No calls heard.

Adaptations Nocturnal and arboreal. The pointed, keeled nails of *G. matschiei* are thought to be an adaptation for more effective use of vertical supports (Cartmill 1974, Off & Gebo 2005). The exceptionally well developed face-mask probably aids in species recognition as well as in contact and spacing among conspecifics. Kingdon (1971), comparing the skull of *G. matschiei* with that of *G. moholi*, illustrated the enlarged, strongly ridged orbits of the former and noted that the mandibular ramus is shallow and splayed so that it intrudes less into the orbital cavity, a development that he judged an accommodation to the enlarged, forward-looking eyes of this species. Sleeps and seeks refuge predominantly in holes in trees

Lateral view of skull of Spectacled Lesser Galago *Galago matschiei* adult.

(Ambrose 2006, Bearder *et al.* 2003). Building of nests out of leaves and twigs not reported, but as for all other *Galago* spp., it is likely that *G. matschiei* does, at least occasionally, engage in nest-building.

Foraging and Food Omnivorous. Frequency of locomotor and postural behaviours studied in Kibale N. P. (Off & Gebo 2005). The most frequent locomotor behaviours for *G. matschiei* are leaps (31%) and bipedal hops (25%). Arboreal quadrupedalism (13%) is relatively infrequent. Leaping, bipedal hopping, and vertical clinging and leaping, comprise 75% of the locomotor behaviours ($n = 368$). The most common postures are vertical clinging (57%) and standing (32%) ($n = 44$).
